ISCRAM 2019: Towards individual-centric emergency management systems ... xiii

Scientific Committee xv

Organization Committee xvi

Sponsors xvii

Invited Talks xviii

Professional day xxii

Workshops xxiii

Track Chairs xxv

Reviewers xxviii

ISCRAM 2019 Best Paper Awards Nominees xxx

Tracks

Track 1. Analytical Modeling and Simulation..... 1

CoRe papers

Reliability of expert estimates of cascading failures in Critical Infrastructure; Ahmed Abdeltawab Abdelgawad, Jose J. Gonzalez; Centre for Integrated Emergency Management (CIEM), University of Agder, Norway (ID 113) 2

Simulation Analysis of Fire Hydrant Usability Levels after Large Earthquake; Toshihiro Osaragi, Noriaki Hirokawa; Tokyo Institute of Technology (ID 122) 22

Simulation Platform for Unmanned Aerial Systems in Emergency Ad Hoc Networks; Patrick Lieser, Julian Zobel, Björn Richerzhagen, Ralf Steinmetz; Technical University Darmstadt, Germany (ID 137) 36

Understanding the Main Themes Towards a Visual Analytics Based Model for Crisis Management Decision-Making; Flavio Dusse[1], Renato Novais[2], Manoel Mendonça[1] ; [1]UFBA, Brazil; [2]IFBA, Brazil (ID 139).. 51

The Dynamics of Cyber Resilience Management; Juan Francisco Carías[1], Leire Labaka[1], Jose Maria Sarriegi[1], Andrea Tapia[2], Josune Hernantes[1] ; [1]University of Navarra, TECNUN, Spain; [2]Pennsylvania State University, USA (ID 140) 64

ESCAPE: Exploring by Simulation Cities Awareness on Population Evacuation; Eric Daudé[1], Kevin Chapuis[2], Clément Caron[1], Alexis Drogoul[2], Benoit Gaudou[2,5], Sebastien Rey-Coyrehourq[1], Arnaud Saval[3], Patrick Taillandier[4], Pierrick Tranouez[3], Jean-Daniel Zucker[2] ; [1]Université de Normandie, UMR 6266, IDEES, Rouen, France; [2]Sorbonne University, IRD, UMMISCO; [3]University of Rouen Normandie, EA LITIS; [4]University of Toulouse, INRA, MIAT; [5]University of Toulouse Capitole, IRIT (ID 145) 76

WiPe papers

Assessing Flood Recovery of Small Businesses using Agent-Based Modelling and Simulation; Meshal Alharbi[1], Graham Coates[2]; [1]Durham University, United Kingdom; [2]Newcastle University, United Kingdom (ID 184) 94

Location-allocation model for earthquake shelter solved using MPSO algorithm; Xiujuan Zhao[1], Jianguo Chen[1], Peng Du[2], Wei Xu[3], Ran Liu[2], Hongyong Yuan[1] ; [1]Tsinghua University, China, People's Republic of; [2]Beijing Global Safety Technology Co., Ltd, China, People's Republic of; [3]Beijng Normal University, China, People's Republic of (ID 191) 105

Improving Emergency Response through Business Process, Case Management, and Decision Models; Marco Polo Ruiz Herrera, Juan Sánchez Díaz; Universitat Politècnica de València, Spain (ID 210) 116

Simulation of Crowd Response During Emergency Considering People's Rational and Irrational Thinking; Anying Chen, Guofeng Su, Manchun Liang; Tsinghua University, People's Republic of China (ID 217) 126

A Preliminary Optimisation-based Approach to Coordinate the Response of Ambulances in Mass Casualty Incidents; Haya Aldossary, Graham Coates; Newcastle University, United Kingdom (ID 218) ... 139

A New Data-Driven Approach to Measuring Hurricane Risk; Duygu Pamukçu[1], Christopher William Zobel[1], Andrew Arnette[2]; [1]Virginia Tech, United States of America; [2]University of Wyoming, United States of America (ID 240) 151

Track 2. Command and Control Studies 158

CoRe papers

Cause and Effect: A Qualitative Analysis of Obstacles to Information Sharing During a Regional Disaster Exercise; Abbas Ganji, Tom Wilson, Sonia Saveli, Dharma Dailey, Mark Haselkorn; University of Washington, United States of America (ID 103) 159

Supporting Inter-Organizational Learning – A Review of Post-Excercise Knowledge Sharing; Johan Nordström, Björn Johan Erik Johansson; Swedish Defence Research Agency (ID 116) 173

Opportunistic Affiliation in Spontaneous Volunteer Management; Daniel Auferbauer[1], Roman Ganhör[2], Hilda Tellioğlu[2]; [1]AIT Austrian Institute of Technology; [2]TU Wien (ID 126) 186

WiPe papers

Analysis of Common Operational Picture and Situational Awareness during Multiple Emergency Response Scenarios; Kristine Steen-Tveit, Jaziar Radianti; University of Agder, Norway (ID 196) 199

Who Learns from Crisis Management Exercises: An Explorative Study; Mari Olsén, Niklas Hallberg, Kristoffer Darin Mattsson; Swedish Defence Research Agency, Sweden (ID 202) 209

Evaluating the observation protocol of the Team Resilience Assessment Method for Simulation (TRAMS); Amanda Jaber[1], Björn Johan Erik Johansson[1], Linnea Bergsten[1], Joeri Laere van[2], Peter Berggren[1]; [1]Linköping University, Sweden; [2]Skövde University, Sweden (ID 206) 218

Design to Fit – Morphological Analysis as a Tool for Exercise Design; Pär Hans Tuve Eriksson, Niklas Hallberg; FOI, Sweden (ID 219) 230

Do's and Don'ts in Inter-Organizational Crisis Management Exercises; Kristoffer Karl Darin-Mattsson, Niklas Hallberg; Swedish Defence Research Agency (FOI), Sweden (ID 223) 242

Testing the implementation of a flying localization system into emergency response using a tabletop exercise; Sebastian Schmitz, Konrad Barth, Tim Brüstle, Tobias Gleibs, Ompe Aimé Mudimu; TH Köln – University of Applied Sciences (ID 230) 252

Track 3. Ethical, Legal and Social Issues 262

WiPe papers

Efficiently allocating safety tips after an earthquake – lessons learned from the smartphone application LastQuake; Laure Fallou[1], Laura Petersen[2], Rémy Bossu[1,3], Frédéric Roussel[1] ; [1]Euro-Mediterranean Seismological Centre (EMSC), France; [2]Centre National de Recherche Scientifique (CNRS), France; [3]CEA, DAM, DIF, F-91297 Arpajon, France (ID 209) 263

What can we learn from a crisis management exercise? Trusting social media in a french firefighters' department; Florent Castagnino; Telecom ParisTech, France (ID 233) 276

On Liquid Ground: Contesting the facts around Shouguang Flood on Weibo; Lixiong Chen, Monika Buscher, Yang Hu; Lancaster University, United Kingdom (ID 245) 288

Managing Risk Across Borders: ethical implications of engaging information technology for transboundary disaster collaboration; Katrina Petersen; Trilateral Research Ltd., United Kingdom (ID 248) 298

Track 4. Logistics and Supply-Chain Management in Crisis Response..... 306

WiPe paper

Towards Social Media Decision Support for Joined EMS and Crisis Logistics; Kathrin Eismann[1], Melanie Reuter-Oppermann[2], Kai Fischbach[1]; [1]University of Bamberg, Germany; [2]Karlsruhe Institute of Technology, Germany (ID 201) 307

Track 5. Intelligent and Semantic Web Systems..... 317

WiPe papers

Sharing Gut Feelings to Support Collaborative Decision Making; Frâncila Weidt Neiva[1], Marcos Roberto da Silva Borges[1]; [1]Universidade Federal do Rio de Janeiro (UFRJ), Brasil (ID 155) 318

How to build an innovative C2 system supporting individual-centric emergency needs?; Guillaume Lambert[1], Bruno Fontaine[2], Michel Monneret[1], Mourad Madani[1]; [1]French Ministry of Interior, France; [2]ToMCo, digital strategy advisor (ID 171) 327

Vigi Flood: a serious game for understanding the challenges of crisis communication; Carole Adam[1], Eric Andonoff[2]; [1]University Grenoble-Alpes, France; [2]University Toulouse-Capitole, France (ID 181) 338

Multi-agent geospatial simulation of human interactions and behaviour in bushfires; Mancheva Lyuba, Adam Carole, Dugdale Julie; Univ. Grenoble Alpes, LIG, F-38000 Grenoble, France (ID 186) 352

Data Acquisition for ad-hoc Evacuation Simulations of Public Buildings; Ingo J. Timm, Bernhard Hess, Fabian Lorig; Trier University, Germany (ID 215) 367

Communication in Emergency Management through Data Integration and Trust: an introduction to the CEM-DIT system; Fiona Jennet McNeill[1], Diana Bental[1], Jeremy Bryan[2], Paolo Missier[3], Jannetta S. Steyn[3], Tom Kumar[3]; [1]Heriot-Watt University, Scotland; [2]Coventry University, United Kingdom; [3]Newcastle University, United Kingdom (ID 227) 376

Real-time Emergency Response through Performant IoT Architectures; Claudio Arbib[1], Davide Arcelli[1], Julie Dugdale[2], Mahyar Tourchi Moghaddam[1], Henry Muccini[1]; [1]University of L'Aquila, Italy; [2]University of Grenoble (ID 252) 388

Track 6. Geospatial Technologies and Geographic Information Science for Crisis Management 402

CoRe paper
Exploring multiplexing tools for co-visualization in crisis unitsd; Christelle Pierkot[1], Sidonie Christophe[2], Jean François Girres[1] ; [1]Univ. Paul-Valéry Montpellier 3, IRD, UMR GRED 220, F34000 Montpellier, France; [2]Univ. Paris-Est, LASTIG GEOVIS, IGN, ENSG, F-94160 Saint-Mande, France (ID 131) 403

WiPe papers
Semantic Understanding of Human Mobility Lifestyle to support Crisis Management; Humasak Tommy Argo Simanjuntak, Fabio Ciravegna; The University of Sheffield, United Kingdom (ID 134) 421

Sorting the good from the bad smartphone application to alert residents in case of disasters - Experiments in France; Esteban Bopp[1], Johnny Douvinet[1], Damien Serre[2] ; [1]UMR ESPACE 7300 CNRS, Département de Géographie, Université d'Avignon; [2]Ecosystèmes Insulaires Océaniens, UMR 241, Université de la Polynésie Française (ID 141) 435

Identifying potential landslide location using Unmanned Aerial Vehicles (UAVs); Jorge Vargas-Florez[1], Grovher Palomino[2], Andres Flores[1], Gloria Valdivia[2], Carlos Saito[1], Daniel Arteaga[2], Mario Balcazar[1], Miguel Fernandez[1], José Oliden[2], Daniel Díaz[2] ; [1]Pontifical Catholic University of Peru, Peru; [2]National University of Engineering (ID 148) 450

Evaluating the effects of consecutive hurricane hits on evacuation patterns in Dominica; Martin Hilljegerdes[1], Ellen-Wien Augustijn-Beckers[2] ; [1]GIScience Research Group, Institute of Geography, Heidelberg University, Germany; [2]Department of Geo-Information Processing, Faculty of Geo-Information Science and Earth Observation,University of Twente, The Netherlands (ID 220) 462

Instagrammers report about the deadly wildfires of East Attica, 2018, Greece: An introductory analytic assessment for disaster management purposes; Stathis G. Arapostathis; Harokopio Univesrsity, Greece (ID 244) 473

Track 7. Planning, Foresight and Risk Analysis 482

CoRe papers
Challenges in Community Resilience Planning and Opportunities with Simulation Modeling; Abbas Ganji, Negin Alimohammadi, Scott Miles; University of Washington, USA (ID 133) 483

Combining a social science approach and GIS-based simulation to analyse evacuation in natural disasters: A case study in the Chilean community of Talcahuano; Susanne Kubisch[1], Johanna Stötzer[1], Sina Keller[1], María Bull[2], Andreas Braun[1]; [1]Karlsruhe Institute of Technology, Germany; [2]Universidad Católica de la Santísima Concepción, Chile (ID 138) 497

Simulating Spontaneous Volunteers: A System Entity Structure for Defining Disaster Scenarios; Sebastian Lindner, Stefan Sackmann, Hans Betke; Martin Luther University Halle-Wittenberg, Germany (ID 146)..... 516

WiPe papers
Applying Generic AcciMap to a DDOS Attack on a Western-European Telecom Operator; Hans C.A. Wienen[1], Faiza A. Bukhsh[1], Eelco Vriezekolk[2], Roel J. Wieringa[1]; [1]University of Twente, Netherlands, The; [2]Agentschap Telecom, The Netherlands *(ID 189)* 528

Medical Resources assignments for Disaster Medical relief Forces Using an Injury-Driven Ontology Model; Min Zhu[1,2], Ruxue Chen[1], Shaobo Zhong[3], Quanyi Huang[2], Jing Ouyang[1], Guang Tian[1]; [1]6th Medical Center of General Hospital of PLA, China; [2]Tsinghua University, China; Beijing Research Center of Urban Systems Engineering, Beijing, China (ID 190) 536

A Delphi approach for the establishment of the fundamental principles of an Organizational Security System in Public Administration; Victor Amadeo Bañuls Silvera[1], Rafael Cantueso Burguillos[2], Fernando Tejedor Panchón[3], Miguel ignacio Ramírez de la Huerga[3], Murray Turoff[4], [1]Universidad Pablo de Olavide,

Spain; [2]Junta de Andalucía, Spain; [3]MSIG Smart Management, Spain; [4]New Jersey Institute of Technology, USA (ID 204) 549

Towards an organization certified in emergency plans management; Ana Gabriela Núñez Avila, Mª Carmen Penadés Gramage; Universitat Politècnica de València, Spain (ID 207) 559

Towards a Capability Model for Emergency Training Improvement; Patricia Quiroz-Palma[1,2], Ma Carmen Penadés[1], Ana-Gabriela Núñez[1]; [1]Universitat Politècnica de Valencia, Spain; [2]Universidad Laica Eloy Alfaro de Manabi, Manta-Ecuador (ID 211) 566

Towards an Automatic Assistance in Crisis Resolution with Process Mining; Hoang Nam Ho[2], Mourad Rabah[1], Ronan Champagnat[1], Frédéric Bretrand[1]; [1]Université de La Rochelle / L3i, France; [2]Kereon intelligence, France (ID 213) 574

From Hindsight to Foresight: using collaborative methodologies to tackle the wicked problems and improve the Emergency System; Marian Zulean[1], Gabriela Prelipcean[2], Florin Druga[3]; [1]University of Bucharest, ICUB, Romania; [2]University "Stefan cel Mare" Suceava; [3]University of Bucharest, Romania (ID 229) 586

Information collection using process visualisation in the risk management concept for emergency response; Christoph Amelunxen, Janina Isabella Sander; Paderborn University, Germany (ID 243) 593

The Design of a Mobile Application for Crowdsourcing in Disaster Risk Reduction; Quynh Nhu Nguyen, Claudio Rossi, Antonella Frisiello, Links Foundation, Italy (ID 256) 607

Track 8. Social Media in Crisis and Conflicts 619

CoRe papers

Social Media Use in Emergencies of Citizens in the United Kingdom; Thomas Spielhofer[2], Anna Sophie Hahne[2], Christian Reuter[1], Marc-André Kaufhold[1], Stefka Schmid[1] ; [1]Technische Universität Darmstadt, Science and Technology for Peace and Security (PEASEC), Germany; [2]The Tavistock Institute of Human Relations (TIHR) (ID 104) 620

Identifying Disaster Damage Images Using a Domain Adaptation Approach; Xukun Li[1], Doina Caragea[1], Cornelia Caragea[2], Muhammad Imran[3], Ferda Ofli[3] ; [1]Department of Computer Science, Kansas State University, United States of America; [2]Department of Computer Science, University of Illinois at Chicago, United States of America; [3]Qatar Computing Research Institute, Hamad Bin Khalifa University, Qatar (ID 109) 633

Integrating Social Media into a Pan-European Flood Awareness System: A Multilingual Approach; Valerio Lorini[1,2], Carlos Castillo[2], Francesco Dottori[1], Milan Kalas[3], Domenico Nappo[1], Peter Salamon[1]; [1]European Commission, Joint Research Centre (JRC), Ispra, Italy; [2]Universitat Pompeu Fabra, Barcelona, Spain; [3]KAJO, Slovakia (ID 111) 646

Rumour Detection on Social Media for Crisis Management; Sooji Han, Fabio Ciravegna; The University of Sheffield, United Kingdom (ID 118) 660

Information Uses and Gratifications Related to Crisis: Student Perceptions since the Egyptian Uprising; Steven Sheetz[1], Andrea Kavanaugh[1], Edward Fox[1], Riham Hassan[2], Seungwon Yang[3], Mohamed Magdy[4], Shoemaker Donald[1] ; [1]Virginia Tech, United States of America; [2]Microsoft; [3]Louisiana State University; [4]Arab Academy of Science and Technology (ID 120) 674

TREC Incident Streams: Finding Actionable Information on Social Media; Richard McCreadie[1], Cody Buntain[2], Ian Soboroff[3] ; [1]University of Glasgow, United Kingdom; [2]New York University, USA; [3]National Institute of Standards and Technology, USA (ID 127) 691

Detecting Disaster Recovery Activities via Social Media Communication Topics; Yuya Shibuya, Hideyuki Tanaka; The University of Tokyo, Japan (ID 150) 706

CrisisDPS: Crisis Data Processing Services; Firoj Alam, Ferda Ofli, Muhammad Imran; Qatar Computing Research Institute, Qatar (ID 152) 719

Integrating Social Media in Emergency Dispatch via Distributed Sensemaking; Rob Grace[1], Shane Halse[1], Jess Kropczynski[2], Andrea Tapia[1]; [1]Pennsylvania State University, United States of America; [2]University of Cincinnati, United States of America (ID 159) 734

WiPe papers

Counter Narratives in Social Media: An Empirical Study on Combat and Prevention of Terrorism; Amanda Langer[1], Marc-André Kaufhold[1,2], Elena Maria Runft[1], Christian Reuter[2], Margarita Grinko[1], Volkmar Pipek[1] ;[1]University of Siegen, Institute for Information Systems, Germany; [2]Technische Universität Darmstadt, Science and Technology for Peace and Security (PEASEC), Germany (ID 119) 746

Understanding patterns and mood changes through tweets about disasters; Liuqing Li, Edward A. Fox; Virginia Tech, United States of America (ID 121) 756

Filtering images extracted from social media in the response phase of emergency events; Sara Barozzi[1], Jose Luis Fernandez Marquez[2], Amudha Ravi Shankar[2], Barbara Pernici[1] ; [1]Politecnico di Milano; [2]University of Geneva (ID 142) 768

Simulating real-time Twitter data from historical datasets; Shane Errol Halse[1], Rob Grace[1], Jess Kropczynski[2], Andrea Tapia[1] ; [1]PSU, United States of America; [2]University of Cincinnati (ID 160)..... 780

Sympathy Detection in Disaster Twitter Data; Yingjie Li[1], Seoyeon Park[1], Cornelia Caragea[1], Doina Caragea[2], Andrea Tapia[3]; [1]University of Illinois at Chicago, United States of America; [2]Kansas State University, United States of America; [3]Pennsylvania State University, United States of America (ID 161).... 788

Requirements for Software to Support the use of Social Media in Emergency Management: A Delphi Study; Starr Roxanne Hiltz[1], Amanda Hughes[2], Muhammad Imran[3], Linda Plotnick[1], Robert Power[4], Murray Turoff[1] ; [1]NJIT, United States of America; [2]Brigham Young U.; [3]Qatar Computing Research Inst.; [4]Commonwealth Scientific and Industrial Research Organisation, Australia (ID 169) 799

Robust filtering of crisis-related tweets; Jens Kersten[1], Anna Kruspe[1], Matti Wiegmann[2], Friederike Klan[1] ; [1]German Aerospace Center (DLR), Germany; [2]Bauhaus-Universität Weimar (ID 173) 814

Detecting event-related tweets by example using few-shot models; Anna Kruspe, Jens Kersten, Friederike Klan; German Aerospace Center (DLR), Germany (ID 175) 825

Facebook Disaster Maps: Aggregate Insights for Crisis Response & Recovery; Paige Maas, Shankar Iyer, Andreas Gros, Wonhee Park, Laura McGorman, Chaya Nayak, P. Alex Dow; Facebook, United States of America (ID 176) 836

#CampFireMissing: An Analysis of Tweets About Missing and Found People From California Wildfires; Humaira Waqas, Muhammad Imran; Qatar Computing Research Institute, Qatar (ID 179) 848

Comparison of Social Media in English and Russian During Emergencies and Mass Convergence Events; Fedor Vitiugin[1], Carlos Castillo[2]; [1]Independent; [2]Universitat Pompeu Fabra (ID 180) 857

When Official Systems Overload: A Framework for Finding Social Media Calls for Help during Evacuations; Steve Peterson[1], Keri Stephens[2], Hemant Purohit[3], Amanda Hughes[4] ; [1]National Institutes of Health, United States of America; [2]The University of Texas at Austin; [3]George Mason University; [4]Brigham Young University (ID 192) 867

Enhancing the usability of a disaster app: exploring the perspective of the public as users; Marion Lara Tan[1], Raj Prasanna[1], Kristin Stock[1], Emma Hudson-Doyle[1], Graham Leonard[2], David Johnston[1]; [1]Massey University, New Zealand; [2]GNS Science, New Zealand (ID 212) 876

Predicting Hurricane Damage Using Social Media Posts Coupled with Physical and Socio-Economic Variables; Guoqin Ma, Chittayong Surakitbanharn; Stanford University, United States of America (ID 221) 887

Towards Automated Individual Communication for Coordination of Spontaneous Volunteers; Sophie Gerstmann, Hans Betke, Stefan Sackmann; Martin-Luther University Halle-Wittenberg, Germany (ID 231). 897

Evaluation of Digital Volunteers using a Design Approach: Motivations and Contributions in Disaster Response; Gabriela C Barrera, Maria C Yang; MIT, Cambridge, MA, United States of America (ID 236) 906

Refining a Coding Scheme to Identify Actionable Information on Social Media; Jess Kropczynski[1], Rob Grace[2], Shane Halse[2], Doina Caragea[3], Cornelia Caragea[4], Andrea Tapia[2] ; [1]Uiniversity of Cincinnati, United States of America; [2]The Pennsylvania State University; [3]Kansas State University; [4]University of Illinois at Chicago (ID 247) 916

Real-time Adaptive Crawler for Tracking Unfolding Events on Twitter; Asmelash Teka Hadgu[1], Sallam Abualhaija[2], Claudia Niederée[1] ; [1]L3S Research Center, Leibniz universität Hannover, Germany; [2]Interdisciplinary Centre for Security, Reliability and Trust (ID 251) 923

Track 9. Universal Design of ICT in Emergency Management..... 932

WiPe papers

Life-Area Broadcasting System (LABS) for Usual and Emergency Cases by Using Easy Contents Management System and New Speaker Devices; Jun Sasaki[1], Taeko Maejima[1], Shuang Li[1], Yusuke Sato[2], Minoru Hiyama[3]; [1]Iwate Preefctural University, Japan; [2]Sato Watch Ltc.; [3]Holonic Systems Ltc. (ID 177)... 933

Understanding Situational Disabilities and Situational Awareness in Disasters; Terje Gjøsæter[1], Jaziar Radianti[2], Weiqin Chen[1] ; [1]Oslo Metropolitan University; [2]Centre for Integrated Emergency Management, University of Agder (ID 188) 940

Track 10. Knowledge, Semantics and AI for Risk and Crisis Management..... 950

CoRe papers

An Automatic Approach to Qualitative Risk Assessment in Metropolitan Areas; Denis Barcaroli[1], Alex Coletti[2], Antonio De Nicola[1], Antonio Di Pietro[1], Luigi La Porta[1], Maurizio Pollino[1], Vittorio Rosato[1], Giordano Vicoli[1], Maria Luisa Villani[1], Enrico Zavagnini[1]; [1]ENEA, Italy; [2]Booz Hallen Hamilton, United States (ID 147) 951

SEMIoTICS: Semantic Model-Driven Development for IoT Interoperability of Emergency Services; Joao Moreira, Luis Ferreira Pires, Marten Sinderen; U.Twente, The Netherlands (ID 149) 961

WiPe papers

Generating Crisis Situation by Using Ontology and Fuzzy Theory; Sammy Abdelghani Teffali, Nada Matta, Eric Chatelet; University of technology of Troyes, France (ID 108) 974

Situation Representation and Awareness for Rescue Operations; Samer CHEHADE[1,2], Nada MATTA[1], Jean-Baptiste POTHIN[2], Remi COGRANNE[1]; [1]University of Technology of Troyes, France; [2]DataHertz, France (ID 114) 980

Video Summarization And Video Highlight Selection Tools To Facilitate Fire Incident Management; Florian Vandecasteele, Krishna Kumar, Kenzo Milleville, Steven Verstockt; Ghent University - IDLAB, Belgium (ID 115) 992

Casualty Information Extraction and Analysis from News; Basanta Chaulagain, Aman Shakya, Bhuwan Bhatt, Dip Kiran Pradhan Newar, Sanjeeb; Prasad Panday, Rom Kant Pandey; Dept. of Electronics and Computer Engineering, Pulchowk Campus, Institute of Engineering, Tribhuvan University, Nepal (ID 187) 1002

A Unified Approach Integrating Human Shared Mental Models with Intelligent Autonomous Team Formation for Crisis Management; Prithviraj Dasgupta[1], Deepak Khazanchi[1,2] ; [1]University of Nebraska Omaha, United States of America; [2]Center for Integrated Emergency management (CIEM), University of Agder, Norway (ID 193) 1012

A Modular Ontology for Semantically Enhanced Interoperability in Operational Disaster Response; Linda Elmhadhbi, Mohamed-Hedi Karray, Bernard Archimède; University of Toulouse, France (ID 226) 1021

Track 11. Community Engagement & Healthcare Systems..... 1030

CoRe papers

Taxonomy of Community Interaction in Crises and Disasters; Daniel Auferbauer[1], Christoph Ruggenthaler[1], Gerald Czech[2], Ivan Gojmerac[1] ; [1]AIT Austrian Institute of Technology; [2]Austrian Red Cross (ID 130) 1031

Identifying functions for smartphone based applications in volunteer emergency response; Elina Ramsell, Tobias Andersson Granberg, Sofie Pilemalm; Linköping University, Sweden (ID 136) 1044

WiPe papers

Trends in Humanitarian Health Information during 2010 Haiti Earthquake: Motivation for Curating Domain Knowledge Base; Jennifer Lisa Chan[1], Gabriel Nam[2], Allison G. Marshall[3], Hemant Purohit[4] ; [1]Northwestern University, United States of America; [2]University of Pennsylvania,United States of America; [3]Temple University, United States of America; [4]George Mason University, United States of America (ID 195) 1057

Community resilience towards disruptions in the payment system; Peter Berggren[1], Molly Lundberg[1], Joeri van Laere[2], Björn J E Johansson[1]; [1]Linköping University, Sweden; [2]Skövde University (ID 203) 1070

Visualizing Early Warning Signs of Behavioral Crisis in Military Veterans: Empowering Peer Decision Support; Olawunmi George[1], Rizwana Rizia[1], MD Fitrat Hossain[1], Nadiyah Johnson[1], Carla Echeveste[2], Jose Lizarraga Mazaba[2], Katinka Hooyer[2], Zeno Franco[2], Mark Flower[3], Sheikh Iqbal Ahamed[1], Praveen Madiraju[1], Lisa Rein[2]; [1]Marquette University; [2]Medical College of Wisconsin; [3]Dryhootch of America (ID 214) 1077

Designing Disaster Information Management Systems 2.0: Connecting communities and responders; Kenny Meesters, Vittorio Nespeca, Tina Comes; Delft University of Technology, The Netherlands (ID 216) 1089

The reciprocity of data integration in disaster risk analysis; David Paulus, Kenny Meesters, Gerdien de Vries, Bartel Van de Walle; TU Delft, The Netherlands (ID 222) 1103

Review-based taxonomy of post-impact volunteerism types to improve citizen integration into crisis response; Robin Batard[1,2], Caroline Rizza[1], Aurélie Montarnal[2], Frédérick Bénaben[2], Christophe Prieur[1];[1]Telecom ParisTech; [2]IMT Mines Albi (ID 234) 1114

Track 12. Tool Talks..... 1125

CoRe papers

Management of Sensor Data with Open Standards; Philipp Hertweck, Tobias Hellmund, Hylke van der Schaaf, Jürgen Moßgraber, Jan-Wilhelm Blume; Fraunhofer IOSB, Germany (ID 117) 1126

Robust Private Web Maps with Open Tools and Open Data; Bas Lijnse; Netherlands Defence Academy / Radboud University Nijmegen, The Netherlands (ID 135) 1140

EMAssistant: A Learning Analytics System for Social and Web Data Filtering to Assist Trainees and Volunteers of Emergency Services; Rahul Pandey, Gaurav Bahl, Hemant Purohit; George Mason University, United States of America (ID 163) 1151

WiPe papers
Evaluation Framework for the iTRACK Integrated System, Ahmed Abdeltawab Abdelgawad, Tina Comes; Centre for Integrated Emergency Management (CIEM), University of Agder, Norway (ID 129) 1160

Supporting firefighter training through visualising indoor positioning, motion and time use data; [1]Jo Dugstad [2]Wake, Barbara Wasson, [2]Edvard Pires Bjørgen, [2]Fredrik Vonheim Heimsæter; [1]NORCE, [2]SLATE-University of Bergen (ID) 1173

Track 13. Privacy Risk Management in Critical Infrastructures..... 1183

CoRe paper
Renouncing Privacy in Crisis Management? People's View on Social Media Monitoring and Surveillance; Larissa Aldehoff, Meri Dankenbring, Christian Reuter; Technische Universität Darmstadt, Science and Technology for Peace and Security (PEASEC) (ID 106) 1184

WiPe paper
Anonymizing Cybersecurity Data in Critical Infrastructures: The CIPSEC Approach; Ana Rodríguez-Hoyos[1,2], José Estrada-Jiménez[1,2], David Rebollo-Monedero[1], Jordi Forné[1], Rubén Trapero Burgos[3], Antonio Álvarez Romero[3], Rodrigo Diaz Rodríguez[3] ; [1]Universitat Politécnica de Catalunya (UPC), Barcelona, España; [2]Escuela Politécnica Nacional (EPN), Quito, Ecuador; [3]ATOS, Madrid, España (ID 199).. 1198

Track 14. Protecting Critical Infrastructures in Crisis Situations 1209

CoRe papers
Evaluating Critical Infrastructure Resilience via Tolerance Triangles: Hungarian Highway pilot case study; Laura Petersen[1,2], Eva Horvath[3], Johan Sjöström[4]; [1]Euro-Mediterranean Seismological Centre (EMSC); [2]French National Center for Scientific Research (CNRS); [3]Magyar Közút Nonprofit Zrt; [4]RISE Research Institutes of Sweden (ID 128) 1210

Enhanced Crisis-Preparation of Critical Infrastructures through a Participatory Qualitative-Quantitative Interdependency Analysis Approachd; Axel Dierich[1], Katerina Tzavella[2], Neysa Jacqueline Setiadi[2], Alexander Fekete[2] ; [1]inter 3 Institute for Resource Management, Germany· 2Technische Hochschule Köln, Germany (ID 144) 1226

WiPe papers
Choosing Ways to Increase Resilience in Critical Infrastructures; Sandra König; Austrian Institute of Technology, Austria (ID 178) 1245

Cascading Threats in Critical Infrastructures with Control Systems; Sandra König, Stefan Schauer; Austrian Institute of Technology, Austria (ID 197) 1252

On the usage of Virtual Reality for Crisis Management exercises in Critical Industrial Sites; Aurélie Congès[1], Frédérick Bénaben[1], Olivier Pierre[2], Francis Savic[3], Olivier Chabiron[2], Matthieu Lauras[1] ; [1]IMT Mines Albi, France; [2]Immersive Factory; [3]Report One (ID 258) 1260

Track 15. Open Track..... 1269

CoRe papers

Understanding Aggregate Human Behaviour Changes in Response to a Natural Disaster in Vanuatu via Mobile Network Data Analysis; Rajius Idzalika, Yulistina Riyadi, Imaduddin Amin, George Hodge, Jong Gun Lee; Pulse Lab Jakarta, Indonesia (ID 123) 1270

*First In, Left Out : Current Technological Limitations from the Perspective of Fire Engine Compa*nies; Katelynn Amaris Kapalo, Pamela Wisniewski, Joseph J. LaViola Jr.; University of Central Florida, United States of America (ID 156) 1286

WiPe papers

Design and development methods for improving acceptance of IT among emergency responders; Erion Elmasllari; Fraunhofer FIT, Germany (ID 107) 1300

Structured crisis training with mixed reality simulations; Jo Erskine Hannay, Yelte Kikke; Univeristy of Oslo, Norway (ID 157) 1310

Challenges and Trends of Data Management for Firefighting in Germany and the Netherlands; Kevin Wesendrup, Nicola Rupp, Adam Widera, Bernd Hellingrath; University of Münster, Germany (ID 165) .. 1320

The Influence of Swift Trust on Virtual Team's Sensemaking in Crisis: A Research Model; Xiaodan Yu[3], Deepak Khazanchi[1,2] ; [1]University of Nebraska Omaha, USA; [2]Center for Integrated Emergency management (CIEM), University of Agder, Norway; [3]University of International Business & Economics, Beijing, China (ID 166) 1330

Dark Web, Black Markets: The Utility of Dark in Disaster Recovery Research; Kathleen Ann Moore; James Madison University, United States of America (ID 182) 1337

Integrating citizen initiatives in a technological platform for collaborative crisis management; Robin Batard[1,2], Aurélie Montarnal[2], Frédérick Benaben[2], Caroline Rizza[1], Christophe Prieur[1], Andrea Tapia[3]; [1]Telecom ParisTech; [2]IMT Mines Albi; [3]The Pennsylvania State University (ID 259) 1346

Sharing Incident and Threat Information for Common Situational Understanding; Bjørn Erik Munkvold[1], Jaziar Radianti[1], Jan Ketil Rød[2], Tomasz Opach[2], Mikael Snaprud[3], Sofie Pilemalm[4], Deborah Bunker[5] ; [1]CIEM, University of Agder; [2]Norwegian University of Science and Technology; [3]Tingtun AS; [4]CARER Linköping University; [5]University of Sydney (ID 260) 1357

Posters & Demos 1364

Towards proactive agility of crisis response; Anne-Marie Barthe-Delanoë[1], Audrey Fertier[2]; [1]Laboratoire de Génie Chimique, Université de Toulouse, CNRS, INPF, UPS, Toulouse, France; [2]Centre de Génie Industriel, IMT Mines Albi, Albi, France (ID p238) 1365

The Search for Embeddedness: Leveraging Scientific Modeling in Disaster Response; Theresa Jefferson[1], John R. Harrald[2] ;[1]Loyola University Maryland, USA;[2]Virginia Tech, USA (ID p342) 1367

LETSCROWD: Dynamic Risk Assessment for Mass Gatherings; Carlo Dambra[1], Alex Gralewski[2], Jordi Arias[3] *;* [1]ZenaByte s.r.l.,Italy, [2]PROPRS Ltd., United Kingdom [3]ETRA I+D S.A., Spain (ID p308) 1369

Comparative Study of Feature Representations for Disaster Tweet Classification; Pallavi Jain[1], Bianca Schoen-Phelan[1], Robert Ross[1] ; [1]Technological University Dublin, Ireland (ID p310) 1371

Collaboration in Emergency Response Drills: an Experience with Firefighters; Paulo Victor R. de Carvalho[1], Angela W. Righi[2], Gilbert J. Huber[3], Jose Orlando Gomes[3] ; [1]Instituto de Engenharia Nuclear Brasil; [2]Universidade de Santa Maria, Brasil; [3]Universidade Federal do Rio de Janeiro, Brasil (ID p301)... 1373

Evaluating the Performance of Deep Learning Methods for Hurricane-Related Image Classification; Matthew Johnson[1], Dhiraj Murthy[1], Brett W. Robertson[1], William Roth Smith[1], Keri K. Stephens[1] ; [1] The University of Texas at Austin (ID p305) 1375

Multi-agent planning and execution with risk analysis and multi-criteria optimization: the case of rescue plans to environmental and humanitarian crisis; Cendrella CHAHINE[1,2], Thierry VIDAL[2], François PERES[2], Mohamad El FALOU[1] ; [1]ULF Tripoli (Université de Technologie et de Sciences Appliquées Libano-Française), Lebanon; [2]LGP-ENIT (Le Laboratoire Génie de Production de l'École Nationale d'Ingénieurs de Tarbes), France (ID p311) 1377

CroMa – Crowd Management in Trans-portation Infrastructures; Alexander Gabriel[1], Andreas Lotter[1], Frank Fiedrich[1] ; [1]University of Wuppertal (ID p306) 1379

Towards Bridging the Gap between Demand and Supply in Humanitarian Geodata Use; Melanie Eckle[1], Sven Lautenbach[1], Alexander Zipf[1] ; [1]GIScience Research Group, Institute of Geography, Heidelberg University, Germany (ID p331) 1381

Geographic and Content-Based Prioritization of Tweets for Emergency Response: The Cases of Weather-Related Disaster Events; A. Marcela Suarez, Keith C. Clarke; University of California, Santa Barbara; USA (ID p340) 1383

Serious gaming for training non-technical skills in crisis management and emergency response; Isabelle Turcotte[1], Gabrielle Teyssier-Roberge[1], Rego Granlund[2], Sébastien Tremblay[1] ; [1]Laval University, France, [2]RISE Research Institutes of Sweden (ID p303a) 1385

A comparison of two methodologies to assess shallow landslide risk; Erica Akemi Goto[1], Keith Clarke[1] ; [1]University of California, Santa Barbara (ID p316) 1387

Analysis of Japanese Tweets about 2018 Typhoon Jebi by Creating Co-occurrence Networks; Sanetoshi Yamada; Keisuke Utsu , Osamu Uchida; Tokai University (ID p225) 1391

Standardization for an enhanced crisis management; René Lindner; DIN, Germany (ID p309) 1393

Constructing Trust in Disaster Communications; Yuko Murayama; Tsuda University, Japan (ID p154) ... 1395

Gathering Local Knowledge for Disaster Risk Reduction: The Use of Sketch Maps in Group Discussions; Carolin Klonner, Luca Blessing; Institute of Geography, Heidelberg, Germany (ID p348) 1397

Towards a comprehensive architecture to extract situational models from Twitter data; Julien COCHE[1], Aurelie MONTARNAL[1], Andrea TAPIA[2], Frederick BENABEN[1]; [1]IMT Mines Albi, France; [2]PennState University, USA (ID p315) 1399

A Filtering and Visualization Workbench for Messages in Crisis Management; Jan Blume, Philipp Hertweck, Tobias Hellmund, Jürgen Moßgraber; Fraunhofer IOSB, Germany (ID p303) 1401

Distributed Learning Automata-based Intelligence for Propagation-based Fake News Detection on Social Media During Crisis; Ahmed Abouzeid[1,2], Ole-Christoffer Granmo[1,2], Christian Webersik[1,2], Morten Goodwin[1,2]; [1]University of Agder, Norway; [2]Center of Integrated Emergency Management (CIEM), Norway (ID p312) 1403

Analysis of Tweets with Rescue Request Hashtags in The 2018 Japan Floods; Shuji Nishikawa, Osamu Uchida, Keisuke Utsu; Tokai University, Japan (ID p102) 1405

Social Media in Disaster Management: Exploring the Information Exchange Behavior in the Underserved Communities; Thiagarajan Ramakrishnan, Louis Ngamassi, Shahedur Rahman; Prairie View A&M University, USA (ID p314) 1407

AIOSAT - Autonomous Indoor & Outdoor Safety Tracking System; Iñigo Adin[1], Bart Scheers[2], Jose Manuel Sanchez[3], Javier Ferreira[4], Berend Jan van der Zwag[5], Didier de Wulf[6], Ymko Attema[7] ; [1]CEIT, Spain, [2]RMA, Belgium, [3]INTEGRASYS, Spain, [4]SAXION, Netherlands, [5]INERTIA, Netherlands, [6]Hulpverleningszone Centrum, Belgium, [7]Twente Safety Campus, Netherlands (ID p304) 1409

Towards a privacy aware information system for emergency response; Alba Morales, Enrico Daga, Enrico Motta; The Open University, United Kingdon (ID p309) 1411

Mission Track: Plans into Actions; Víctor A. Bañuls[1], Jaime E. del Palacio[2], Eduardo del Palacio[2], Fernando Tejedor[2]; [1]Universidad Pablo de Olavide, Spain; [2]Mission Track, Spain (ID d001) 1414

ISCRAM 2019: Towards individual-centric emergency management systems

The theme of ISCRAM 2019 is *"Towards individual-centric emergency management systems"*. This edition wishes to highlight the particular needs of the individual stakeholder in Crisis and Emergency Management and to stimulate discussions that enable the design of individual-centric crisis and emergency management systems.

As anchors to this year's program we have three keynote speakers, (1) Marcos Bruna, MD, PhD, Hospital Universitario y Politécnico La Fe, València (Spain) who will present "Transplantation: the Spanish Model in a World of Challenges", (2) Steve Peterson, CEM®, National Institutes of Health. Bethesda, MD (USA), who will present "Addressing Complexities of Disaster Social Media Analysis" and (3) Dr. Monika Büscher, Professor of Sociology, Director of the Centre for Mobilities Research and Associate Director for the Institute for Social Futures, Lancaster University, UK who will present "Making IT Personal: Radically Reflexive Resilience."

In addition to these focal points we also have a panel on "Research Meets Practice", with two practitioners (Jennifer Chan, Northwestern Memorial Hospital, Chicago, IL, USA; and Steve Peterson, National Institutes of Health, Bethesda, MD, USA) and two researchers (Caroline Rizza, Economic and Social Sciences Department of Télécom Paristech, France; and Marcos Borges, Federal University of Rio de Janeiro, Brazil). The panel will be chaired by Valérie November, Director of Research, Technical Laboratory, Territories and Society, École des Ponts, University Paris, France.

We are pleased to present the accepted papers for ISCRAM 2019, which represent excellent contributions to a wide range of topics related to the use of information for the full cycle of emergency management.

The overall acceptance rate for the Completed Research (CoRe) papers at the conference was 60%.

- 59 CoRe papers were submitted, 35 were accepted
- 19 CoRe submissions were recommended as WiPe papers (Rejected)
- 7 CoRe submissions were suggested for consideration as a poster only (Rejected)
- 1 paper was withdrawn

The overall acceptance rate for the Work in Progress (WiPe) papers at the conference was 74%.

- 95 WiPe papers were submitted, 70 were accepted
- 25 WiPe submissions were rejected, or rejected with the suggestion for poster consideration

The program is completed with 22 posters and one demonstration.

For this year, ISCRAM defined two types of paper: Research and Insight. Research papers are intended to meet the needs of researchers by being peer reviewed to the highest academic standards. The primary aim of an academic paper is to contribute to the scientific body of knowledge. By contrast, Insight papers are intended to meet the needs of practitioners, managers, professionals, experts, and policy makers by being peer reviewed to high practical standards. The primary aim is to give an insight into what real-world problems arise during emergencies, disasters, and crises, and how such problems can be solved with the help of information systems.

The same five criteria (relevance, significance, originality, validity, and clarity) were used to judge all types of ISCRAM papers whether the paper is Research or Insight. However, some of these criteria are defined differently between Research and Insight papers.

Researchers and practitioners submitted to a range of topic areas including: Analytical Modeling and Simulation; Command and Control Studies; Ethical, Legal, and Social Issues (ELSI); Logistics and Supply Chain Management in Crisis Response; Intelligent and Semantic Web Systems; Geospatial Technologies and Geographic Information Science for Crisis Management; Planning, Foresight, and Risk Analysis; Social Media in Crises and Conflicts; Universal Design of ICT in Emergency Management – Identifying and Addressing ICT Challenges Faced by Elderly and People with Disabilities; Knowledge, Semantics and AI for Risk and Crisis Management; Community Engagement and Healthcare Systems; Tool Talks; Privacy Risk Management in Critical Infrastructures; and Protecting Critical Infrastructures in Crisis Situations. Research that did not fall under these specific areas were applied broadly to the Open Track.

Both Research and Insight papers were submitted in Full (CoRe) or Short (WiPe) form. A full paper reports on a completed project or piece of work, including validation of the results. Only full papers may be candidates for selection for the Best Research Paper, Best Student Paper, and Best Insight Paper awards.

By contrast, a short paper is intended for the reporting of part of a complete project or piece of work. For example, a short paper may describe a project or research plan, a literature survey, the design of an information system, the development and testing of software, user evaluation of developed software, deployment, a real incident, a proposed new policy.

All authors of the papers in these proceedings have agreed to the ISCRAM2019 Proceedings copyright agreement. This copyright agreement and use license state that an author retains copyright. It also permits any user – for any non-commercial purpose, including unlimited classroom and distance learning use – to download, print out, extract, archive, distribute and make derivative works of an article published in the ISCRAM2019 Proceedings, as long as appropriate credit is given to the authors and the source of the work and all derivative works are placed under the same license.

Lastly, the program co-chairs and the local chair wish to thank the track chairs, the reviewers and the ISCRAM board for offering their full participation in the body of this work.

We hope that you enjoy what we expect to be a lively conference!

ISCRAM2019 Program and Organization Chairs

Scientific Committee

Program Committee Chairs

José J. González, *University of Agder, Norway*

Zeno Franco, *Médical College of Winconsin, USA*

Workshops Chairs

Jaziar Radianti, *University of Agder, Norway*

Hemant Purohit, *George Mason University, USA*

Demo & Poster Chairs

Josune Hernantes, *Tecnun, University of Navarra, Spain*

Leire Labaka, *Tecnun, University of Navarra, Spain*

Doctoral Colloquium Chairs

Kathleen Moore, *James Madison University, USA*

Aurélie Montarnal, *IMT Mines Albi, France*

Proceedings Chair

Mª Carmen Penadés, *Universitat Politècnica de València, Spain*

Link with ISCRAM

Caroline Rizza, *Télécom ParisTech, France*

Awards Chair

Hans-Jochen Scholl, *University of Washington, USA*

Transplantation: The Spanish Model in a World of Challenges

Marcos Bruna, MD, PhD, *Hospital Universitario y Politécnico La Fe, València, Spain*

ABSTRACT. Transplantation could be defined as the process of taking an organ or tissue from somebody and implanting it in another part of the body or in another body. The history of transplantation is long and sometimes unsuccessful and difficult to understand, but year to year surgical technology, improvements in intensive care facilitated better results.

Spain has been a world leader in transplantation for the last 26 years, with near to 50 donors per million of population and, for instance, more than 5,000 organs transplanted during 2017. These numbers are achieved thanks principally to the generosity of donors and their families, and also to the capacity of the Spanish Transplantation System (STS) to cope with the emergency that the existence of a new donor represents.

The STS, also known as the "Spanish Model", is built on top of a complex organization with great profitability. Team work, education, professional training, registration, reward and security are some of the keys to its success and export to other countries. But, above all, there is no success without donors: we need donors to give an opportunity to people waiting for a new organ to continue living. The characteristics of donors and recipients have changed during the last decades, and so the methods have evolved, too.

In order to maintain this model´s efficiency and its high survival rates, it is necessary to incorporate different approaches, treatments, advanced knowledge and new technologies like artificial intelligence in this medical practice. In this talk, we will review the latest advances in the last decades. We will also outline what are the challenges open, and how the ISCRAM community of researchers and practitioners can play a key role in the overall process. The future will be exciting because there are many opportunities and new ways to explore to optimize the results of transplantation programs.

ABOUT THE SPEAKER. Marcos Bruna is a Specialist Surgeon in the General and Digestive Surgery Service at the "Hospital Universitario y Politécnico La Fe", in València since March 2019. Before joining this service, he worked in a similar position at the "Hospital General Universitario de València", where he was also Coordinator of the Transplantation Unit (2013-2019). He holds a degree in Medicine (Universidad Autónoma de Madrid, 2003) and a Doctorate in Medicine (Universitat de València-Estudi General, 2015). In his work, he has applied advanced AI techniques to support the selection of the best recipient for

an organ. Marcos is member of several international associations, and has participated in numerous technical and administrative committees at local, national and international levels.

Addressing Complexities of Disaster Social Media Analysis

Steve Peterson, CEM®, *National Institutes of Health, Bethesda, MD, USA*

ABSTRACT. Citizen reliance on social media during disasters has increased in recent years. As global acceptance and adoption of social media by practitioners continues to grow, dependable solutions for employing social media during disasters remain elusive. There is a dimension that increasing citizen reliance on social media implies more demand from citizens that practitioners respond to social media during disasters. In the face of difficulties compounded by limited personnel availability and data dynamics driven by the type, scope, magnitude, and severity of the disaster, practitioners seek evidence on how to more effectively tackle these challenges and ultimately develop sound social media operational procedures.

The presentation will include a scenario which examines real world social media analytical complexities from past disasters. The scenario will also highlight the potential risks involved in coordinating across multiple agencies and volunteer organizations. This is especially germane when social media analytics surface time-sensitive actionable intelligence, such as social media calls for help.

The research community continues to conduct valuable retrospective disaster research, and carry out respected studies, on the use of social media. These efforts raise awareness of the value social media provides practitioners during disasters. The presentation will conclude by revisiting the scenario and examining sample research questions that highlight underexplored areas. Further examination of these issues may lead to unique findings that are more informative than those tendered by standard retrospective research.

By establishing mutually beneficial collaborative relationships, practitioners and researchers could gain enhanced insights into social media analytical complexities experienced during disasters. And this might well form the basis for future joint research in this area of concentration.

ABOUT THE SPEAKER. Steve Peterson is a Certified Emergency Manager (CEM) employed at the National Institutes of Health. He serves as the Chair of the Department of Homeland Security' s (DHS) Social Media Working Group for Emergency Services and Disaster Management. His professional specialization has focused on emergency communications policy development in both the public and private sectors, including authoring the Current and Future State of Emergency Communication sections of the

DHS National Emergency Communications Plan. He has spoken to local, national, and international audiences exploring various dimensions of social media phenomena. His conceptualizations address not only the current state of social media, but its unrealized potential to impact the effectiveness of emergency operations. Steve has also served as president of the Montgomery County, Maryland Community Emergency Response Team (CERT). Under his leadership this team received international recognition for its efforts in providing surge support in determining situational ground truth for Cyclone Pam damage (near Australia) and the notorious 7.9 Nepal earthquake. Steve received his Bachelor of Science degree in Computer Studies from the University of Maryland and attained his Certified Emergency Manager designation from the International Association of Emergency Managers.

Making it Personal: Radically Reflexive Resilience

Monika Büscher, *Lancaster University, UK*

ABSTRACT. The 21st Century has been labelled the century of disasters. Yet individuals and societies are doing too little, too late to prepare for or prevent disasters. One reason is a lack of personalisation. People do not feel that disasters will affect them. This is particularly true with regard to slow-motion disasters such as climate change, biodiversity loss, soil erosion, or antimicrobial resistance, but acute emergency warnings and evacuation orders can also be met by optimistic bias ('It won't happen to me/here'). Personalisation and intelligent context-driven computing can triangulate personal risk factors (such as location and vulnerability) with predictive disaster risk data to dynamically issue personalised warnings and guidance. It can save lives. However, a 'solutionist' turn to computational personalisation could further entrench problematic patterns of disaster risk governance and a false sense of security.

As the Anthropocene unfolds, many slow-motion disasters are producing more, and more intense, acute disasters, from extreme weather to epidemics. These arise from the cumulative personal lives of 7.7 billion humans, with risks highly unequally distributed. In this talk, I show that attention to grassroots creativity that makes responsibility for risk and risk governance personal can enhance communities' capacity to live well with risk. Technologies of participation that support crisis informatics, citizen science, and collective intelligence, for example around environmental monitoring, can join with efforts of personalisation. By delineating hopeful projects that develop technologies of humility, we can widen the scope for innovation and raise the bar of ambition for personalised and context-driven computing to support radically reflexive resilience.

ABOUT THE SPEAKER. Monika Büscher is Professor of Sociology at Lancaster University in the UK, Director of the Centre for Mobilities Research. She is the academic lead for the UK ESRC Social Research Impact Accelerator Account at Lancaster University (2019-2022) and leads research on social practices of mobility and risk governance in a range of projects, e.g. isITethical? (2017-2018), SecInCoRe (2014-2017), BRIDGE (2011-2015).

Monika initiated the www.isITethical.eu platform, which develops guidance for digital ethics and responsible innovation in collaboration with the Public Safety Communications Europe Network. She received an honorary doctorate from Roskilde University, Denmark for her work on participatory design. She edits the book series Changing Mobilities (Routledge) with Peter Adey.

Professional Day – Panel "Research meets practice"

Two practitioners and two researchers brainstorm needs, challenges and opportunities for practice-oriented research.

Practitioners:

Jennifer Chan, *MD, MPH Director, Global Emergency Medicine, Northwestern Memorial Hospital, US Chicago, IL, USA*

Steve Peterson, *Emergency Management Specialist, Division of Emergency Management, National Institutes of Health, Bethesda, MD, USA*

Researchers:

Caroline Rizza, *Associate Professor in Information and Communication Sciences, Economic and Social Sciences Department of Télécom Paristech, Paris, France*

Marcos Borges, *Professor at the Federal University of Rio de Janeiro, Department of Computer Sciences, Rio de Janeiro, Brazil*

The panel will be facilitated by Valérie November, *Director of Research, Technical Laboratory, Territories and Society, Ecole des Ponts, University Paris, France.*

Workshops

The aim of the ISCRAM 2019 Workshops is to allow researchers, technologists, practitioners as well as the representatives from funding agencies to host a dedicated session on the specific, emerging topics for crisis management and related technologies.

WS1. Encouraging Productive Interaction between Practitioners and Researchers

This workshop will bring together practitioners and researchers to identify and brainstorm solutions to the obstacles that impede better interaction between the two groups. The goal is to arrive at a small number of collaborative projects around which groups of practitioners and researchers would work together.

Organized by:

Edward G. Happ, *University of Michigan, USA*

Andrea H. Tapia, *Penn State University, USA*

Format: Researcher-Practitioners dialogue

WS2. Incorporating social media analysts in emergency dispatch centers

The workshop will bring together international practitioners and researchers in the global emergency dispatch community for discussions opportunities, challenges, and best practices for incorporating social media analytics and analysts in emergency dispatch centers.

Organized by:

Rob Grace,*Penn State University, USA)*

Lieutenant colonel Olivier Galichet, *DGSCGC, Ministère de l'Interieur, France*

Caroline Rizza, *Télécom Paristech, France*

Format: Semi Tutorial, Researcher-Practitioners dialogue

WS4. 2nd International Workshop on Intelligent Crisis Management Technologies for climate events -ICMT

Organized by:

Anastasios Karakostas, *Information Technologies Institute, Greece*
Claudio Rossi, *Istituto Superiore Mario Boella, Italy*
Evangelos Sdongos, *Institute of Communication and Computer Systems, Greece*
Angelos Amditis, *Institute of Communication and Computer Systems, Greece*

Format: Semi Tutorial

WS5. Physical and cyber threats: the new challenges for TLC Critical Infrastructures

Organized by:

Federica Battisti, *Roma Tre University, Italy*

Federica Pascucci, *Roma Tre University, Italy*

Format: Semi Tutorial

Track Chairs

Track 1. Analytical Modeling and Simulation

Christopher Zobel, *Virginia Tech, USA*

Josey Chacko, *Mount St. Mary's University, USA*

Track 2. Command and Control Studies

Björn JE Johansson, *Linköping University, Sweden*

Peter Berggren, *Linköping University, Sweden*

Nicoleta Baroutsi, *Swedish Defence University*

Track 3. Ethical, Legal and Social Issues

Monika Büscher, *Lancaster University, UK*

Katrina Petersen, *Trilateral Research, TLD*

Caroline Rizza, *Télécom Paristech, Paris, France*

Track 4. Logistics and Supply-Chain Management in Crisis Response

Bernd Hellingrath, *University of Muenster, Germany*

Gyöngyi Kovács, *Hanken University, Finland*

Adam Widera, *University of Muenster, Germany*

Track 5. Intelligent and Semantic Web Systems

Julie Dugdale, *University Grenoble Alps, France*

Fiona McNeill, *Heriot-Watt University, UK*

Francisco José Quesada Real, *University of Edinburgh, UK*

Hemant Purohit, *George Mason University, USA*

Track 6. Geospatial Technologies and Geographic Information Science for Crisis Management (GIS)

João Porto de Albuquerque, *University of Warwich, UK*

Alexander Zipf, *University of Heidelberg, Germany*

Flávio E. A. Horita, *Federal University of ABC, Brasil*

Track 7. Planning, Foresight and Risk Analysis

Murray Turoff, *New Jersey Institute of Technology, USA*

Victor A. Bañuls, *Pablo de Olavide University, Spain*

Track 8. Social Media in Crisis and Conflicts

Starr Roxanne Hiltz, *New Jersey Institute of Technology, USA*

Amanda Lee Hughes, *Brigham Young University, USA*

Imran Muhammad, *Qatar Computing Research Institute, Qatar*

Christian Reuter, *Technische Universität Darmstadt, Germany*

Track 9. Universal Design of ICT in Emergency Management

Terje Gjøsæter, *Oslo Metropolitan University, Norway*

Jaziar Radianti, *University of Agder, Norway*

Weiqin Chen, *Oslo Metropolitan University, Norway*

Erion Elmasllari, *Fraunhofer Fit Institute Bonn, Germany*

Track 10. Knowledge, Semantics and AI for Risk and Crisis Management

Hedi Karray, *INP-ENIT, University of Toulouse, France*

Antonio De Nicola, *ENEA, Italy*

Nada Matta, *Université de Technologie de Troyes, France*

Track 11. Community Engagement & Healthcare Systems

Zeno Franco, *Medical College of Wisconsin, USA*

Bas Linjse, *Radboud University, Netherlands*

Reem Abbas, *Auckland University of Technology*

Sheikh Iqbal Ahamed, *Marquette University, USA*

Track 12. Tool Talks

Bas Linjse, *Radboud University, Netherlands*

Jürgen Moβgraber, *Fraunhofer IOSB, Germany*

Anastasios Karakostas, *Centre for Research and Technology Hellas*

Track 13. Private Risk Management in Critical Infrastructures

Jordi Forné Muñoz, *Universitat Politècnica de Catalunya, Spain*

Javier Parra Arnau, *Universitat Rovira i Virgili, Spain*

Track 14. Protecting Critical Infrastructures in Crisis Situations

Stefan Schauer, *Austrian Institute of Technology*

Stefan Rass, *Alpen-Adria-Universität Klagenfurt*

Track 15. Open Track

José J. González, *University of Agder, Norway*

Hossein Baharmand, *University of Agder, Norway*

ISCRAM 2019 Best Paper Awards

The conference organization will award most meritorious papers in three categories:

(1) Best CoRe Paper

(2) Best Insight Paper

(3) Best Student Paper

Chair: Hans Jochen Scholl, *University of Washington, USA*

Committee: Frédérick Bénaben, *École des Mines d'Albi-Carmaux, France*

Julie Dugdale, *Université Grenoble Alpes, France*

Christopher Zobel, *Virginia Tech, USA*

Mihoko Sakurai, *International University of Japan, Japan*

Best CoRe Paper Award

Integrating Social Media into a Pan-European Flood Awareness System: A Multilingual Approach, Valerio Lorini, Carlos Castillo, Francesco Dottori, Milan Kalas, Domenico Nappo and Peter Salamon

Best CoRE Paper Nominees:

- *Integrating Social Media into a Pan-European Flood Awareness System: A Multilingual Approach,* Valerio Lorini, Carlos Castillo, Francesco Dottori, Milan Kalas, Domenico Nappo and Peter Salamon
- *Simulation Analysis of Fire Hydrant Usability Levels after Large Earthquake*, Toshihiro Osaragy and Noriaki Hirokawa
- *The Dynamics of Cyber Resilience Management*, Juan Francisco Carías, Leire Labaka, José María Sarriegi, Andrea Tapia and Josune Hernantes
- *CrisisDPS: Crisis Data Processing Services*, Firoj Alam, Muhammad Imran and Ferda Ofli

Best Insight Paper Award

Identifying Disaster Damage Images Using a Domain Adaptation Approach, Xukun Li, Doina Caragea, Cornelia Caragea, Muhammad Imran and Ferda Ofli

Best Insight Paper Nominees:

- *Identifying Disaster Damage Images Using a Domain Adaptation Approach*, Xukun Li, Doina Caragea, Cornelia Caragea, Muhammad Imran and Ferda Ofli
- *Management of Sensor Data with Open Standards*, Philipp Hertweck, Tobias Hellmund, Hylke van der Schaaf, Jürgen Moβgraber and Jan Blume
- *Opportunistic Affiliation in Spontaneous Volunteer Management*, Daniel Auferbauer, Roman Ganhör and Hilda Tellioğlu
- *Simulating Spontaneous Volunteers: A System Entity Structure for Defining Disaster Scenarios*, Sebastian Lindner, Stefan Sackmann and Hans Betke

Best Student Paper Award

Simulation Platform for Unmanned Aerial Systems in Emergency Ad Hoc Networks, Patrick Lieser, Julian Zobel, Björn Richerzhagen and Ralf Steinmetz

Best Student Paper Nominees:

- *Challenges in Community Resilience Planning and Opportunities with Simulation Modeling*, Abbas Ganji, Negin Alimohammadi and Scott Miles
- *Simulation Platform for Unmanned Aerial Systems in Emergency Ad Hoc Networks*, Patrick Lieser, Julian Zobel, Björn Richerzhagen and Ralf Steinmetz
- *Combining a social science approach and GIS-based simulation to analyse evacuation in natural disasters: A case study in the Chilean community of Talcahuano*, Susanne Kubisch, Johanna Stötzer, Sina Keller, María T. Bull and Andreas Braun
- *Detecting Disaster Recovery Activities via Social Media Communication Topics*, Yaya Shibuya and Hideyuki Tanaka

ABSTRACT

Owing to the complexity of Critical Infrastructures and the richness of issues to analyze, numerous approaches are used to model the behavior of CIs. Organizations having homeland security as mission often conduct desktop-based simulations using judgmental assessment of CI interdependencies and cascading failures. Expert estimates concern direct effects between the originally disrupted CI sector and other sectors. To better understand the magnitude of aggregate cascading effects, we developed a system dynamics model that uses expert estimates of cascading failures to compare the aggregate effect of cascading failures with the primary direct cascading failures. We find that the aggregate effect of compounded cascading failures becomes significantly greater than the primary cascading failures the longer the duration of the original disruption becomes. Our conceptually simple system dynamics model could be used to improve desktop-based exercises, since it illustrates consequences that go beyond judgmental assessment.

Keywords

Critical Infrastructure, Cascading failures, Expert assessment, Desktop exercise, Tabletop exercise, Modeling and simulation, Dynamic complexity

INTRODUCTION

Critical Infrastructures (CIs) are essential resources for the performance of society, including its economy and its security, understood as safety of citizens and security of society's assets. They are slightly differently defined in different countries. However, there is general agreement that CIs include government, telecommunication based on ICT (information and communication technology); financial sector; energy supply; water supply; transportation systems; health sector; and security services (first responders, police, military).

CIs are interconnected and, hence, interdependent (see e.g., Macaulay, 2008). As consequence, the performance of any CI influences the performance of other CIs and depends on the other CIs performance. The behavior over time of CIs is extremely complex. There are two kinds of complexity: *detail complexity* and *dynamic complexity*. Detail complexity is related to the system size (number of components and functions of each CI). Beyond detail complexity, the system of CIs is *dynamically complex* (Sterman, 2000, p21-23). Dynamic complexity is characterized by a set of criteria, which all are satisfied by any system of CIs. The system's behavior is time-dependent and changing ("dynamic"); the system is tightly coupled and, hence, governed by feedback effects; the relations between the CI components are mostly nonlinear; managerial interventions are typically resource intensive and costly, thus precluding taking other interventions and determining the future course ("path dependence"); the complexity of the interconnected CIs challenges the human ability to understand them, often resulting in counterintuitive system behavior, inviting interventions that fail or even worsen the situation ("policy resistance"); feedback in the system typically shows up time-delayed, which can lead to long-run responses that are very different from the short-run outcomes, to the extent that solutions that work in the short run may become harmful in the long run.

Detail complexity can be overcome by breaking the problem in subproblems that are easier to solve ("divide and conquer"). The dynamic complexity of systems cannot be mastered by breaking the system in smaller systems, since the complexity arises through the interconnections and interdependencies across any imagined boundary

between subsystems.

In the event of a disruption occurring in some CI, the interdependencies among CIs pave the way for secondary disruptions in other CIs, called cascading effects (Franchina, Carbonelli, Gratta, Crisci and Perucchini, 2011) or cascading failures (Katina and Keating, 2015). The literature has identified several types of interdependencies (see ref. Ouyang, 2014, Table 1 and examples E1-E10, on p45-46)

Owing to the extreme complexity of the CI system, many different approaches, targeting different purposes, exist for analyzing cascading effects. No single approach does full justice to the problem's complexity. To the best of our knowledge, the most recent extensive review of modeling and simulation of interdependent CIs was performed by Ouyang (2014). A useful model is designed for a purpose, viz. answering specific questions, hence the model simplifies the description of reality to preserve what is relevant for the model's purpose, excluding what is irrelevant. Ouyang's review covers six modeling categories for different purposes, viz. empirical approaches, agent-based approaches, system dynamics-based approaches, economic theory-based approaches, network-based approaches, and miscellaneous modeling approaches.

One modeling category is not included among Ouyang's review, viz., desktop-based expert assessment of CI interdependencies and cascading failures, most certainly because peer-reviewed publications of such activities are missing. A desktop exercise (a.k.a. tabletop exercise) is conducted with participants sitting around a table, addressing a fictional scenario. Desktop exercises concerning risk assessment in CIs are also model-based, since they are synthesis of the mental models of practitioners representing each of the CIs as well as the mental models of people with cross-cutting expertise on CIs. The distance from the synthesized mental model for risk assessment to conducting a simulation (i.e., figuring out the consequences of the model) is short. It is in principle possible to extend the modeling exercise to figure out the consequences. Another, more powerful option, is the one we follow in this paper: using the expert estimates in a system dynamics simulation model.

Desktop-based expert assessment of CI interdependencies and cascading failures are typically performed by organizations having homeland security as mission. Hence, such assessments are important. But then, the research question arises: To what extent can expert practitioner assessments account for the aggregate impact of the cascading failures upon a disruption affecting a critical infrastructure? Indeed, since CIs are interdependent, a disruption affecting a given CI will propagate along multiple feedback loops, causing primary, secondary, tertiary, etc. cascading failures (kind of "ripple effect"). Is this ripple effects moderate, in the sense that it gets quickly damped and the contribution of the primary cascading failures dominate? Or can the aggregate contribution of higher order cascading failures make the ripple effect quite considerable, especially if the duration (or the intensity) of the original disruption is large?

To address the research question, we provide the necessary background information in section "Details of the assessment in the Norwegian desktop exercise"; in section "Expert assessment of cascading failures" we review recent work (Laugé, 2014, Laugé, Hernantes and Sarriegi, 2015) that will allow us develop a quantitative simulation model to answer the research question; in section "System Dynamics model" we explain the key equations of the simulation model and the validation process (the full description of the model is given in the appendix). In section "Assessment of the reliability of expert estimates" we present the simulation results; they provide evidence that expert estimates of cascading failures become less accurate when the length of the disruption triggering the cascading failures increases. In the final section, we provide an interpretation of our findings; in addition, we discuss the robustness of our findings, given the limitations of our study.

DETAILS OF THE ASSESSMENT IN THE NORWEGIAN DESKTOP EXERCISE

In this section, we review the findings of the expert assessment of cascading failures in a risk analysis of a cyber-attack on the Norwegian telecommunication CI sector (DSB, 2015). The corresponding desktop exercise was coordinated by the Norwegian Directorate of Civil Protection (abbreviated DSB, from the initials in the Norwegian name). The risk analysis of a cyber-attack was part of the "National Risk Analysis 2014", considering disasters that may affect the Norwegian society.

Two one-day seminars were conducted. Seminar 1, done in Oslo 12th June 2014, assembled 30 expert participants representing the following CI sectors: energy supply; transportation systems; emergency/security services; water supply; financial sector; health sector; and telecommunication sector. The scenario of seminar 1 was a cyber-attack causing complete disruption lasting 5 days of the ICT CI's transport network in Norway. The leading question posed at seminar 1 was: How will the critical functions in *your own CI sector* be affected by the disruption in the telecommunication sector.

The experts representing a given CI were asked to describe how the disruption in the telecommunication critical infrastructure would impact the performance of their own CI. The detailed answers were afterward mapped to a qualitative scale of values [small, medium, large] for the impact. Thus, the desktop exercise elicited expert

assessments of *primary* cascading failures based on judgmental methods. Note that no quantitative forecasting methods were used, i.e., no time series data were produced. No doubt because of the duration of the event (one day), less effort was dedicated for how the cascading failures further propagated to other CIs and which were the secondary, tertiary, etc. impacts. In fact, the report does not provide qualitative estimates, small/medium/large impact, for propagation of the primary cascading failures to induce secondary cascading failures, and further down to tertiary, quaternary, etc. cascading failures.

Leaving out the detailed description of the cascading failures, the overall assessment was that a cyber-attack causing complete disruption of the ICT CI's transport network for 5 days in Norway would have:

- high impact on the security CI sector;
- high impact on the financial CI sector;
- high impact on railways and airline traffic, and moderate impact on other transport CIs;
- low impact on the water supply CI sector;
- low impact on the energy supply CI sector; but then secondary cascading failures from minor disruptions on energy infrastructure would increase significantly the disruption of ICT CI;
- moderate impact on the health CI sector.

Seminar 2, conducted 1st September 2014, addressed other consequences of the hypothetical cyber-attack (how it would affect citizens; its influence on societal indicators; losses accrued). Seminar 2 is out of scope for our study.

It is not possible to answer our research question with data from the report by the Norwegian Directorate of Civil Protection (DSB, 2015): 1) the expert assessment did not go beyond assessment of the impact of primary cascading failures; and 2) no further and deeper desktop exercise was conducted that would provide a benchmark to determine the degree to which the impact assessments of the experts are off the mark.

Thus, we ask if there are studies providing estimates of cascading failures across all CI sectors? That is, we ask for estimates of cascading failures considering all possible values of *j* and *k*, how a disruption in a sector *j* (CI_j) affects other CI sector *k* (CI_k).

EXPERT ASSESSMENT OF CASCADING FAILURES

Fortunately, a Ph.D. research project conducted by Ana Laugé, with a Ph.D. thesis available electronically (Laugé, 2014) and a journal publication (Laugé, Hernantes and Sarriegi, 2015), provides the data we are looking for.

Laugé conducted a survey with CI managers to obtain estimates on a Likert scale for cascading impacts caused by disruptions of different durations in a CI_j, where the index j, running from 1 to 11, refers to the following CI sectors: Energy supply; ICT; Water supply; Food; Health; Financial; Order & Safety; Civil Administration; Transport; Chemical & Nuclear; and Space & Research, respectively. She obtained estimates for the cascading impacts on CI_k, where the index k run through all values between 1 and 11 (of course, excluding j=k). Laugé asked the experts to provide estimates of direct dependencies between any two CIs in case the disruption period was less than two hours, less than six hours, less than 12 hours, less than 24 hours, more than 24 hours and more than one week. She computed averages of the provided estimates, resulting in tables for each of the cases. As example, see Figure 1, adapted from ref. (Laugé, 2014), p175.

Now, as in the case of the Norwegian desktop exercise, the experts participating in Laugé's survey provided estimates for how much a total disruption in CI sector *j* (CI_j) impacted another CI sector *k* (CI_k). But as opposed to the Norwegian case, where only one value of *j* was considered (viz. the telecommunications Critical Infrastructure), in Laugé's case she obtained an 11x11 matrix describing all possible impacts on other CIs coming from any disrupted CI. Note that the expert estimates tacitly include expert knowledge about response measures in the affected CI sectors. In other words, notwithstanding that the net impact of the cascading failures is an assessment of failures, we must trust that the experts' knowledge included expertise about preparedness, mitigation and response capability in *their home CI*.

Using Laugé's data, it becomes then possible to use a system dynamics model embedding the cascading failures estimates from Laugé's Ph.D. thesis (Laugé, 2014) to compare how reliable the expert estimates are. The trick is to compare two simulation outcomes, viz. the outcome considering the unrestricted propagation of the cascading failures vs the outcome that only accounts for the primary cascading failures.

Effect on / Failed CI	Energy	ICT	Water	Food	Health	Financial	Order & Safety	Civil Admin.	Transport	Chemical & Nuclear	Space & Research

SYSTEM DYNAMICS MODEL

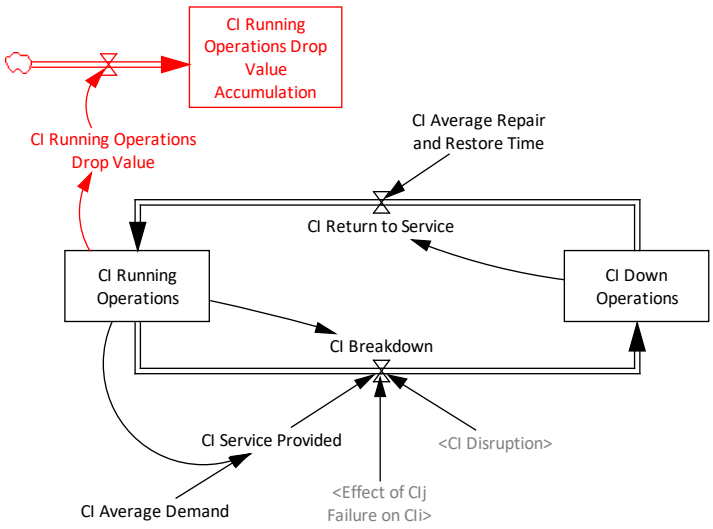

Figure 2: CI System Dynamics Structure (with vector variables – see main text)

The system dynamics model used to produce the results of this research is an extended version of the model published in Abdelgawad, Farstad and Gonzalez (2019), which was inspired by the model built by Canzani (2016). As depicted in Figure 2 (system dynamics structure in black color), in our model every CI has a CI_i *Running Operations* level which contains all this CI's functioning operations divided by its all operations capacity of this CI, i.e. the fraction of the functional operations. A disruption depletes the running operations through the CI_i *Breakdown* rate, and increases the value of the CI_i *Down Operations* level, which contains the non-functional operations fraction of all operations of this CI. A recovery process will restore the operations back to CI_i *Running Operations* through the CI_i *Return to Service* rate. Our model utilized the Vensim DSS subscripts to vectorize the same system dynamics structure/equations to be used for all above mentioned 11 CIs

included in Laugé's research (that is, the index *i* assumes values 1…11, labeling eleven CI sectors).

In the following, we provide a description of the key equations and parameters along with the validation of our model (see also Abdelgawad, Farstad and Gonzalez, 2019, p631-634). In the appendix, we provide a full description of the model, including documentation of parameters and equations.

Both $CI_i\ Running\ Operations$ and $CI_i\ Down\ Operations$ levels are respectively defined as:

$$CI_i\ Running\ Operations = \int_0^t (CI_i\ Retun\ to\ Service\ - CI_i\ Breakdown) \cdot dt + 100 \quad (1)$$

and:

$$CI_i\ Down\ Operations = \int_0^t (CI_i\ Breakdown - CI_i\ Retun\ to\ Service) \cdot dt \quad (2)$$

It should be noted that at the beginning of the simulation ($t = 0$) $CI_i\ Running\ Operations = 100$ while $CI_i\ Down\ Operations = 0$, and this is why 100 was added to the former integration.

Furthermore, $CI_i\ Breakdown$[1] and $CI_i\ Return\ to\ Service$ rates are respectively defined as:

$$CI_i\ Breakdown = CI_i\ Disruption + CI_i\ Running\ Operations \cdot \sum_{j \in J} \left(Effect\ of\ CI_j\ Failure\ on\ CI_i \cdot \frac{1 - CI_i\ Service\ Provided}{|J|} \right) \quad (3)$$

Where $|J|$ represents the cardinality (sum of all elements in a set representing the CIs considered), J is an ordered 11-tuple defined as $J = (Energy, ICT, Water, \cdots, Space\ \&\ Research)$, and:

$$CI_i\ Return\ to\ Service = \frac{CI_i\ Down\ Operations}{CI_i\ Average\ Repair\ and\ Restore\ Time} \quad (4)$$

The $CI_i\ Return\ to\ Service$ rate moves the failed operations accumulated inside $CI_i\ Down\ Operations$ level back to $CI_i\ Running\ Operations$ level over an average period of time that is equal to the average total time required to restore and repair these failed operations.

In the model, the $CI_i\ Service\ Provided$ is defined as a piecewise function:

$$CI_i\ Service\ Provided = \begin{cases} 1, & CI_i\ Running\ Operations \geq CI_i\ Average\ Demand \\ \dfrac{CI_i\ Running\ Operations}{CI_i\ Average\ Demand}, & CI_i\ Running\ Operations < CI_i\ Average\ Demand \end{cases} \quad (5)$$

he $CI_i\ Average\ Demand$ was arbitrarily assumed to be 95% of this CI's full capacity required to supply the demand of its dependent CIs.

Laugé's research presented the effects of all failed CIs on all other CI in different tables. Each of these tables represents a different disruption duration, which means that the effect of certain failed CI on another CI changes over time as far as the failure continues. The successive effects of one failed CI on another were extracted from Laugé's tables and were pushed in a separate vector for each pair of CIs using time (disruption durations) as its index. Figure 3 shows Laugé's successive tables as well as marking the effects for the ICT Energy pair. These vectors of each pair of CIs were included in the model as time-based graphical functions to account for these over-time changes or dynamics. These graphical functions were included in the model through $Effect\ of\ CI_j\ Failure\ on\ CI_i\ Data$. The graphical function of the effect of CI_2 failure on the CI_1 is shown in Figure 4 as an example (i=1 denotes Energy, while j=2 denotes ICT).

[1] In the model, a more complex equation for $CI_i\ Breakdown$ was used for technical reasons. However, the simplified version showed in the paper will act similarly in general.

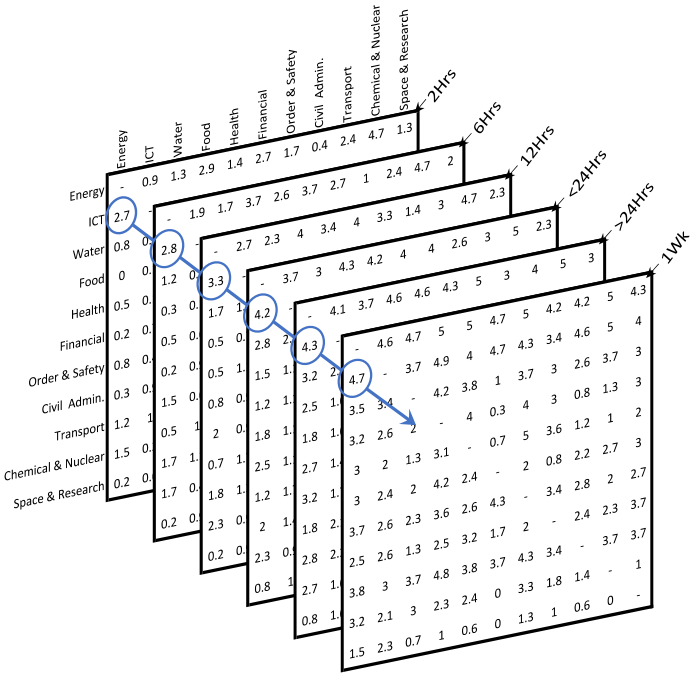

Figure 3. CI Interdependencies for Different Durations (Abdelgawad, Farstad and Gonzalez, 2019)

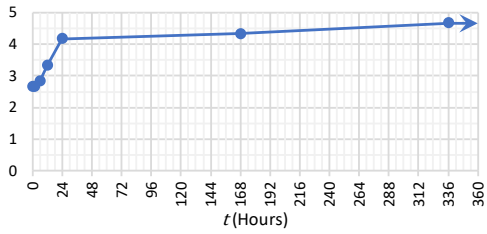

Figure 4. Effect of CI_2 Failure on CI_1 over Time (Disruption Durations) [i=1 denotes Energy, while j=2 denotes ICT] (Abdelgawad, Farstad and Gonzalez, 2019)

In the model, a disruption occurring to any of the CIs is produced in the CI Disruption structure shown in Figure 6 (structure in black color). The $CI_i\ Disruption$ is defined as:

$$CI_i\ Disruption = CI_i\ Disruption\ Magnitude \cdot \Pi_{t_d,(t_d+\Delta T)}(t) \quad (6)$$

$\Pi_{t_d,(t_d+\Delta T)}(t)$ is a Boxcar function (Weisstein), where: t denotes the time or the simulation time in the case of the model, t_d denotes the beginning of the disruption or the $CI_i\ Disruption\ Time$ in the model, and ΔT denotes the $CI_i\ Disruption\ Duration$. In piecewise notation, $\Pi_{t_d,(t_d+\Delta T)}(t)$ can be defined as (Figure 5 shows its graphical representation):

$$\Pi_{t_d,(t_d+\Delta T)}(t) = \begin{cases} 0, & t < t_d \\ 1, & t_d \le t < (t_d + \Delta T) \\ 0, & t \ge (t_d + \Delta T) \end{cases}$$

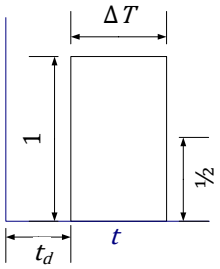

Figure 5. Boxcar function graph

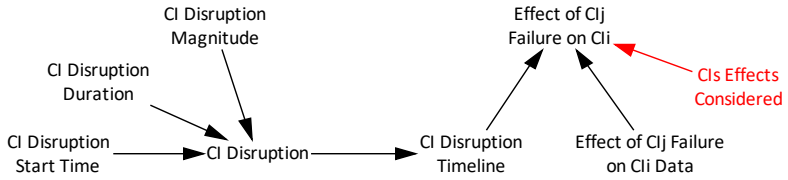

Figure 6. CI Disruption Structure

The beginning of a disruption through $CI_i\ Disruption$ triggers the above mentioned time-based graphical functions that account for the dynamics recognized via Laugé's interdependencies tables. In the model, the beginning of a disruption starts a new timeline different from the simulation timeline. This new timeline (generated inside $CI_i\ Disruption\ Timeline$) continues as long as the disruption remains and stops otherwise. Figure 7 shows the original timeline of the model (i.e. simulation time) and another disruption timeline for a CI disruption that

starts at hour 48 and ends 24 hours later.

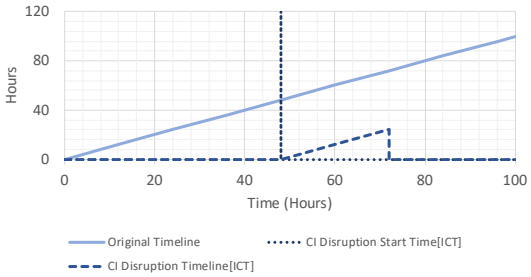

Figure 7. Generated Disruption Timeline

MODEL TESTING AND VALIDATION

To detect any issues in our model as well as increase trust in our model, we have used all the applicable tests introduced by Forrester and Senge (1996) and recommended by Sterman (2000). Our model inherited the same boundaries and basic structure of Canzani's model (Canzani, 2016), which although a simple model, includes all necessary components to study a CI disruption effect at this level of aggregation, making it possible for the model to pass the boundary adequacy test (Sterman, 2000, Forrester and Senge, 1996, Barlas, 1996) After including the fixes introduced in Abdelgawad, Farstad and Gonzalez (2019), the model is more consistent with the relevant descriptive knowledge of the system enabling it to pass the structure assessment (Sterman, 2000, Barlas, 1996).

Other than a few arbitrarily chosen values which were included in the model, all other parameters were retrieved from Laugé's survey. Accordingly, the parameters are consistent with relevant descriptive and numerical knowledge of the system (Sterman, 2000, Forrester and Senge, 1996, Barlas, 1996). Unit check of Vensim DSS (Ventana Systems, 2009) assured the model dimensional consistency (Sterman, 2000, Forrester and Senge, 1996, Barlas, 1996). Moreover, the model was tested for integration errors (Sterman, 2000), and the combination of Euler's method and time step of 0.125 was found suitable.

The model's robustness has been tested with successful results under extreme conditions (Sterman, 2000, Forrester and Senge, 1996, Barlas, 1996). To further test the model's robustness under assumed uncertainties in parameters and initial values, sensitivity analysis (Sterman, 2000, Forrester and Senge, 1996) was applied to the model using. There is no information about the probability distribution of the parameters, accordingly, we have assumed Uniform probability distribution for all parameters. We did not have any benchmark for the numerical changes in the model variables due to the change in any of the tested parameters to test our results against. However, in all sensitivity tests we have conducted, we have not spotted any change in the modes of behavior, consequently, no policy implications change due to the change in the values of the parameters. Therefore, the results were found acceptable.

ASSESSMENT OF THE RELIABILITY OF EXPERT ESTIMATES

To find the difference between the case in which the cascading failures among the CIs are taken into consideration and in which they are not, we have made some changes to the system dynamics model used in Abdelgawad, Farstad and Gonzalez (2019). The first change was adding a new variable $CI_j\ Effect\ Considered$, shown in Figure 6 (in red color). This variable is an eleven elements binary vector. Every element corresponds to a CI sector, CI_i. This vector controls which CI interdependencies to be taken into consideration during the simulation, i.e. it controls which elements of $Effect\ of\ CI_j\ Failure\ on\ CI_i\ Data$ that would be included in $Effect\ of\ CI_j\ Failure\ on\ CI_i$.

For example, in the case of considering only the direct effects caused by the failure of ICT CI on all other CIs, and not considering the propagated cascading failures of all other CIs, elements of the vector $CI_i\ Effect\ Considered$ would be all zeros except the second element (denotes the ICT CI) which would be one. i.e. $CI_j\ Effect\ Considered = [0 \quad 1 \quad 0 \quad \cdots \quad 1]$. In such a case, the value of $Effect\ of\ CI_j\ Failure\ on\ CI_i$ would be expressed as follows:

$$Effect\ of\ CI_1\ Failure\ on\ CI_i = 0 \cdot Effect\ of\ CI_1\ Failure\ on\ CI_i\ Data$$

$$Effect\ of\ CI_2\ Failure\ on\ CI_i = 1 \cdot Effect\ of\ CI_2\ Failure\ on\ CI_i\ Data$$

$$Effect\ of\ CI_3\ Failure\ on\ CI_i = 0 \cdot Effect\ of\ CI_3\ Failure\ on\ CI_i\ Data$$

$$\vdots$$

$$Effect\ of\ CI_{11}\ Failure\ on\ CI_i = 0 \cdot Effect\ of\ CI_{11}\ Failure\ on\ CI_i\ Data$$

In matrix form:

$$Effect\ of\ CI_j\ Failure\ on\ CI_i = [0 \quad 1 \quad 0 \quad \cdots \quad 1] \cdot Effect\ of\ CI_j\ Failure\ on\ CI_i\ Data$$

In this equation, only direct effects of a failed ICT CI on all other CIs are taken into consideration, however, the cascading failures from the affected CIs will not be propagated. On the other hand, in the normal case in which all cascading failures are considered, elements of the vector $CI_j\ Effect\ Considered$ will be all ones. Accordingly, the $Effect\ of\ CI_j\ Failure\ on\ CI_i$ would be:

$$Effect\ of\ CI_j\ Failure\ on\ CI_i = [1 \quad 1 \quad \cdots \quad 1] \cdot Effect\ of\ CI_j\ Failure\ on\ CI_i\ Data$$

Using this new vector $CI_j\ Effect\ Considered$, we were able to simulate the model with the higher order cascading failures OFF and ON. To clarify the difference between the two cases, we will present the detailed results of two different simulation cases, one that excludes the higher order cascading failures (denoted by: cascading OFF) and another that includes the cascading failures (cascading ON). In both cases the model was injected with a disruption in the ICT CI that started after 48 hours from the beginning of the simulation with the a magnitude of ten (which is the highest disruption magnitude defined by Canzani (2016)), and ended after 24 hours. The left graph in Figure 8 shows the Running Operations behavior over time for all CIs in case the higher order cascading failures are not included, while the right graph shows the same Running Operations in case that all the cascading failures are included.

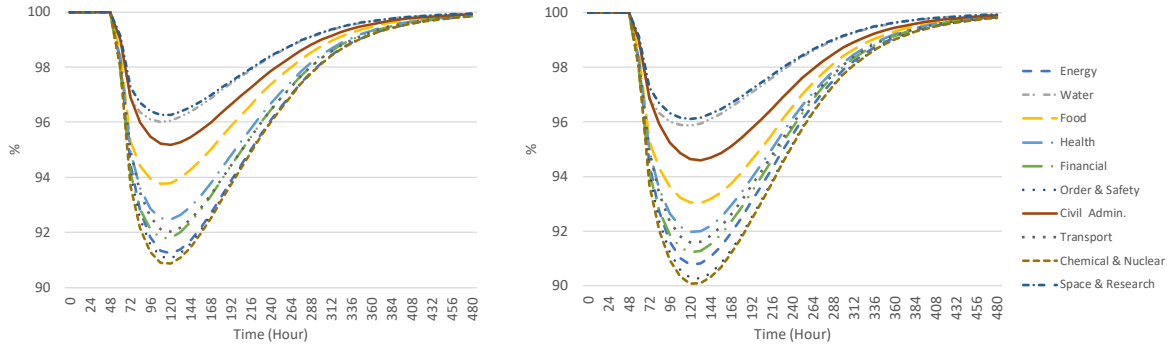

Figure 8. Running Operations (Left: Cascading OFF | Right: Cascading ON)

Figure 9 shows the Service Provided by all CIs in both simulations mentioned above, higher order cascading failures are not included in the left graph, while included in the right graph.

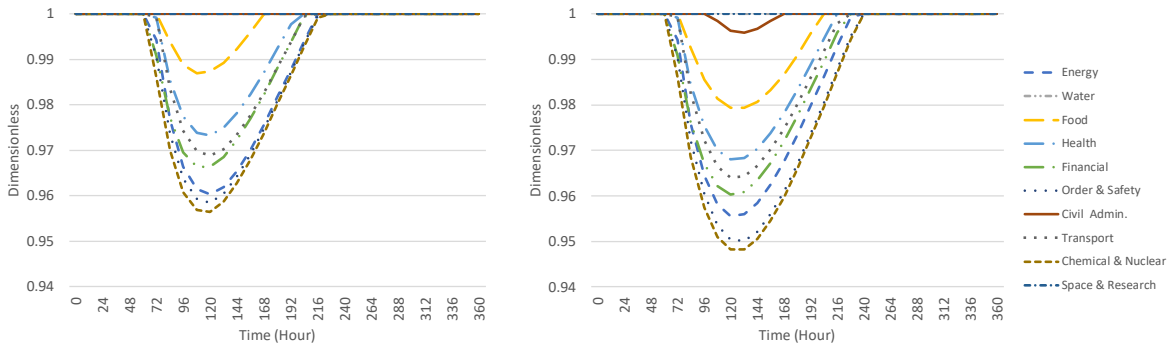

Figure 9. Services Provided (Left: Cascading OFF | Right: Cascading ON)

Differences between the two simulation cases can be visually identified through Figure 8 and Figure 9. Nonetheless, to quantitively assess the difference between them, our second addition to the model (shown in red color in Figure 2) calculates $CI_i\ Running\ Operations\ Drop\ Value$, which is defined as:

$$CI_i\ Running\ Operations\ Drop\ Value = 100 - CI_i\ Running\ Operations$$

Then the new structure calculates the area under the curve of $CI_i\ Running\ Operations\ Drop\ Value$ as well. The area under the curve is the accumulation or the integration of the $CI_i\ Running\ Operations\ Drop\ Value$ over

time, i.e.:

$$CI_i\ Running\ Operations\ Drop\ Value\ Accumulation = \int_0^t CI_i\ Running\ Operations\ Drop\ Value \cdot dt$$

At the beginning of the simulation $CI_i\ Running\ Operations\ Drop\ Value\ Accumulation = 0$ by design. Figure 10 shows the $CI_i\ Running\ Operations\ Drop\ Value\ Accummulation$ of all CIs in both cases, cascading failure are excluded in the left graph, and included in the right graph.

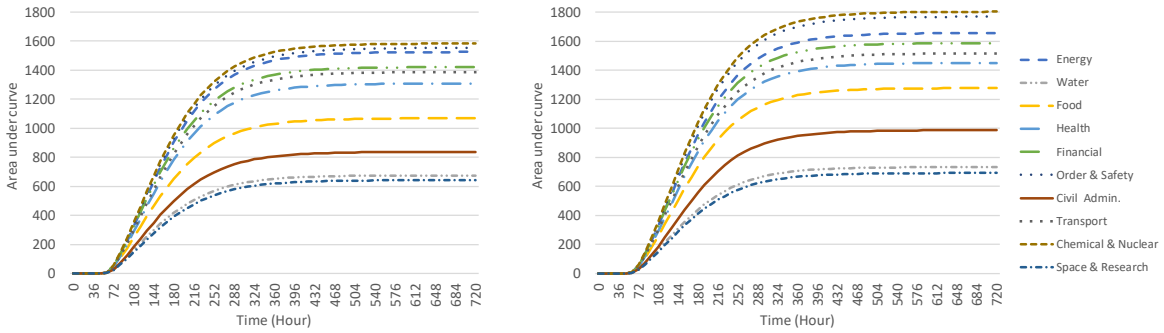

Figure 10. Area under the Curve (Left: Cascading OFF | Right: Cascading ON)

To compare the difference between the two areas under the curve per CI of both cascading ON and OFF simulations, we used the following equation:

$$\Delta = \frac{Area\ under\ Curve_{Cascading\ ON} - Area\ under\ Curve_{Cascading\ OFF}}{Area\ under\ Curve_{Cascading\ OFF}}$$

For a more comprehensive set of results, we have conducted another five experiments. In each experiment, we have changed the disruption period and kept everything else as it was. The disruption periods we have used matched Laugé disruption durations, i.e. two hours, six hours, 12 hours, 24 hours, 168 hours, and 336 hours. Table 1 shows the identified differences Δ per CI as resulted from these different ICT CI disruption durations. Figure 11 shows the same results in a graph.

Table 1. The Identified Differences Δ Resulted from Different ICT CI Disruption Durations as Defined by Laugé

ICT CI Disruption Duration / Δ per CI	2 Hours	6 Hours	12 Hours	24 Hours	168 Hours	336 Hours
Energy	0 %	0 %	4.37 %	8.62 %	23.47 %	23.69 %
Water	0 %	0 %	5.01 %	8.39 %	15.72 %	13.72 %
Food	0 %	0 %	10.49 %	19.43 %	42.73 %	39.55 %
Health	0 %	0 %	5.38 %	10.86 %	31.03 %	32.31 %
Financial	0 %	0 %	6.38 %	11.69 %	27.03 %	26.25 %
Order & Safety	0 %	0 %	6.82 %	13.87 %	39.06 %	40.62 %
Civil Admin.	0 %	0 %	9 %	17.78 %	43.74 %	40.22 %
Transport	0 %	0 %	4.90 %	9.33 %	23.13 %	22.08 %
Chemical & Nuclear	0 %	0 %	7.33 %	13.91 %	34.37 %	34.38 %
Space & Research	0 %	0 %	4.05 %	7.55 %	18.46 %	15.91 %

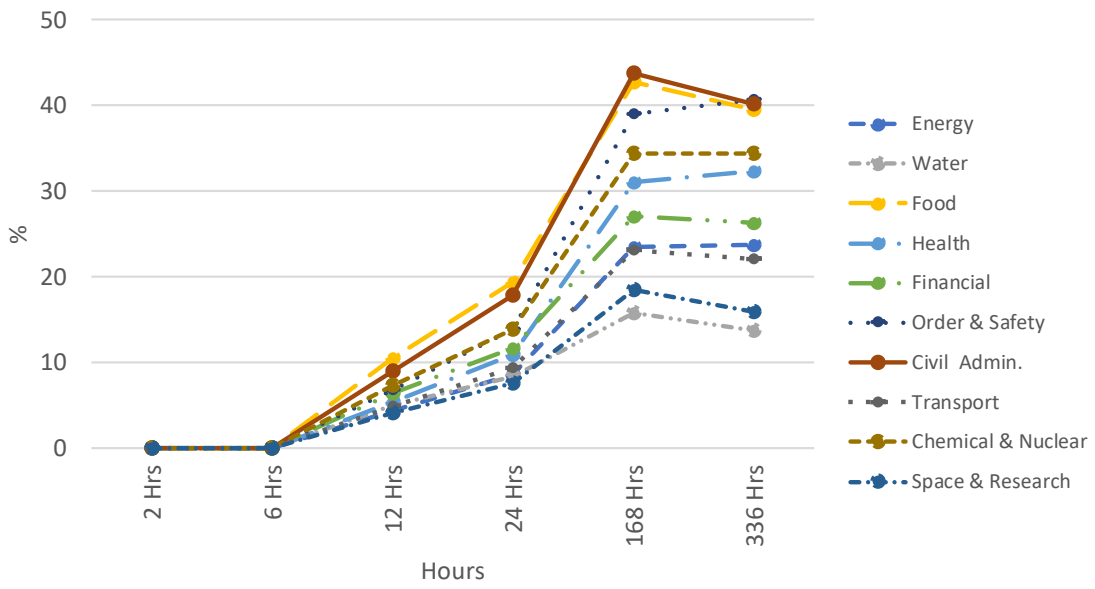

Figure 11. Behavior of the Identified Differences Δ Resulted from Different ICT CI Disruption Durations as Defined by Laugé

CONCLUSION

Desktop simulation exercises have been often employed to engage first-responders in relevant scenarios related to emergency management, with emergency understood as generic term for crisis and disaster situations (Smith, Dowel and Ortega-Lafuente, 1999). Most often, the purpose of emergency management desktop exercises is to train the different role-players in situations where they would have to act together. The literature distinguishes between two main categories of desktop simulation exercises: scenario planning and scenario-based planning (Van Niekerk, Coetzee, Botha, Murphree Michael, Fourie, Le Roux, Wentink, Kruger, Shoroma, Genade, Meyer and Annandale, 2014).

Our point of departure was a desktop modeling exercise targeting expert assessment of *primary* cascading failures, specifically, the immediate consequences upon other CI sectors triggered by a disruption in the telecommunication CI sector (the disruption being a complete breakdown of five days duration of the telecommunication CI sector owing to a sophisticated cyber-attack). We asked the questions: 1) Is the aggregate impact of the cascading failures moderate, in the sense that this "ripple effect" is quickly damped and the contribution of the primary cascading failures dominate? Or can the aggregate contribution of higher order cascading failures make the ripple effect quite considerable, especially for large values of the duration (or the intensity) of the original disruption?

To answer the question, we developed a system dynamics simulation model using estimates of primary cascading effects obtained by Laugé (Laugé, 2014, Laugé, Hernantes and Sarriegi, 2015). The simulation results show, indeed, that the ripple effect becomes more and more significant the longer the duration of the original disruption.

For an explanation, we point the reader's attention to the richness of feedback loops in a CI system. The system dynamics model in Figure 2, describing a system of 11 interdependent CI sectors has a huge number of feedback loops (a total of 308,152 loops, in fact). The "simplicity" of the model structure is deceptive, because the choice of vector variables that makes the model diagram compact hides the pathways of propagation of cascading failures along the model's feedback loops.

Owing to the huge number of feedback loops, the original disruption finds many pathways to propagate to other CI sectors and cause failures (primary cascading failures). In turn, the primary cascading failures can propagate along the many pathways to cause secondary cascading failures, etc. Intuitively, one expects damping of the failures, the higher the order of the cascading failures is. Intuitively also, one expects that the damping effect becomes less and less pronounced the longer the duration of the original disruption is. Accordingly, our simulation results should not be surprising.

Surprising results or not, our research question needed to be posed and addressed. Ultimately, the question relates to the human ability to intuitively deal with complexity. Here, the issue is the ability of human minds, even if they are expert ones, to intuitively assess the contribution of a huge number of pathways to the ripple effect. In the

light of our results, since the desktop assessment (DSB, 2015) concerned a total disruption of the telecommunication CI sector of five days duration some doubts arise as to the ability of the experts to account for the aggregate effects of cascading failures in the scenario. It is hard to expect that the experts' assessment is anchored in mental aggregation and computation of cascading failures up to higher orders.

How robust are our results? We admit that the data set from Laugé refers to assessment of cascading failures in Spanish Critical Infrastructure while our research question emerged in the context of Norwegian Critical Infrastructure. Hence, we cannot claim that the quantitative results of our simulation must be accurate renderings of the situation in Norway (or for that matter in other countries). Also, we have restricted our simulation to a plausible set of parameters for repair and restores times. But we would expect the validity of the qualitative finding of more significant ripple effect, the longer the duration of the original disruption.

Owing to the practical relevance of assessment of cascading failures and the fact that here the interests of practitioners and researchers meet, we hope to trigger the interest of these communities to elicit and test relevant data.

Once our results are confirmed by other researchers and with more solid data, we believe that the proposed system dynamics model could be a valuable addition to desktop exercises. Its diagram structure (Figure 2) is quite compact and, in a sense, simple and intuitive. Its worth for practitioners would be anchored in the model's ability to extend human assessment of primary cascading failures to include higher order cascading failures (i.e., the totality of the ripple effect).

APPENDIX

In this appendix, we present a full description of our model. The description was generated based on the model's Vensim file using SDM-DOC (the .NET version) (Argonne National Laboratory, 2014), described in (Martinez-Moyano, 2012). Some manual editing and cleaning were conducted. The following table contains the variables' counts, symbols, types, and abbreviations used in the description below.

L: Level (6/**66**) *	**F**: Flow (6)	**A**: Auxiliary (17)	**C**: Constant (18)	**T**: Lookup (1/**11**) **	**D**: Data (1)	**Sub**: Subscripts (2)

* (state variables/total stocks).

** (lookup variables/lookup tables).

Type	Variable Name and Description
#1 C	**CI Average Demand** (Dimensionless) CI Average Demand [CIi] = 95 **Description:** *An assumption is made that all CI perform on average at 95 percent of full capacity at any given time to supply their demand to each other.* **Present in 1 view:** • All CIs **Used by:** • CI Service Provided

ABSTRACT

Since large earthquakes can disrupt water supply networks, it is essential to gain an understanding of the expected usability of fire hydrants in post-quake firefighting activities. In this study, data about water supply networks was collected and a water outage simulation model was constructed in order to predict the likelihood that individual fire hydrants would become unusable in the wake of a large earthquake. The water outage simulation model was integrated with a previously developed urban zone damage simulation and a fire department activity simulation in order to carry out a simulation-based analysis of the 23 wards of Tokyo, after which a quantitative analysis of the relation-ship between use of fire hydrants and the number of buildings lost to fire was performed. This analysis revealed the benefits of hardening water lines against earthquakes, fire hydrant usage variations depending on locality, and the benefits of using water pressure sensors to identify usable fire hydrants.

Keywords

large earthquake, hydrant, water outage, fire-spread, firefighter.

INTRODUCTION

Research background

When multiple fires break out simultaneously, it is vital to identify and quickly extinguish those that have the highest risk of spreading. However, in the immediate aftermath of a large earthquake, it can be expected that responding fire departments will be delayed by street blockages and further hampered by inadequate supplies of water due to water outages at fire hydrants and/or low supplies in fire cisterns. Therefore, it is essential to establish comprehensive strategies for firefighting that not only account for fire spread but also consider street blockages, water outages, and other obstacles. Such a comprehensive study has never been done before.

In this study, we have combined a large-scale fire spread simulation model and an urban zone damage simulation model developed by Hirokawa and Osaragi (2016a, 2016b, 2017) by incorporating a street blockage simulation model into a fire department activity simulation model, and have used an index of fire spread risk (fire spread potential) to demonstrate the potential for immediate deployment of firetrucks in order to greatly reduce the number of buildings lost to fire. These models employed the assumptions of earlier studies (Fujii and Itoigawa, 2017; Sasaki and Sekizawa, 2014) that showed water would only be available from sources other than fire hydrants (fire cisterns, rivers, etc.). More specifically, they did not sufficiently scrutinize the actual usage availability of fire hydrants. However, efforts have been made to harden fire hydrants against earthquakes in recent years, so an investigation of the usability of fire hydrants incorporating water outage considerations is needed in order to facilitate a more exhaustive examination of firefighting activities in the event of a large earthquake.

The Tokyo Fire Department (TFD) (2015) and Takada et al. (2005) have published studies regarding the use of fire hydrants after a large earthquake. The TFD analysis was based on an exhaustive simulation model incorporating activities initiated upon learning of a fire, activities in gathering of fire department personnel, time for preparing the hose, and other factors. However, that fire hydrant usage analysis focused on early fire extinguishing activities by residents rather than by TFD firefighting teams. Additionally, the modeling of water outage consequences went no further than a simple representation in which the number of fires expected to be extinguished was multiplied by the rate of ordinary water delivery conditions (1.0 – water outage rates). The

analysis was based on the mean rate of water outages for each city, ward, town, or village according to damage estimate for Tokyo (Tokyo Metropolitan Government, 2012). Accordingly, as will be described later in this study, no details related to water line damage between water supply points and fire hydrants were considered.

Takada et al. (2005) examined records from the Great Hanshin Earthquake, in which numerous fire hydrants became unusable, and stated that personal suffering would have been significantly reduced if those fire hydrants had been operable. In their detailed analysis of the reasons for failures to prevent fires from spreading (insufficient water, etc.), in which they examined the times of fire breakouts and firetruck arrival times, among other factors, they provided much to consider in the drafting of this fire hydrant usability investigation. Nevertheless, prior to this study, the usability of fire hydrants to stop spreading fires in the immediate aftermath of a large earthquake has only been examined in a qualitative fashion.

Turning to studies with water outage simulations, post-quake Tokyo damage estimates (Tokyo Metropolitan Government, 2012) examined both the types and diameters of water lines, block-by-block, throughout Tokyo, along with ground velocities and potential of liquefaction indexes (*PL* values) in an effort to predict water outage rates. According to the Japan Water Research Center (2011), water outage rates can also be estimated using the characteristics of ground surface layers instead of the liquefaction index. In these studies, the damage occurring, in terms of the rate of water outages and other problems, was estimated using data about the lengths of buried pipes, information about the ground surface layers, and other data tabulated for each portion of the cell in the model. However, actual damage such as water outages does not occur in the cell units. Instead, they are considered as components of a networked structure (the water supply network) branching out from the water supply point. More specifically, this approach did not account for the downstream effects of damage to water mains at the network origin (i.e., near the water supply point), and could well have underestimated water outage rates at fire hydrants far downstream from the water supply point.

Research objectives

When there are no limits on the volume of available water and a high density of installed fire hydrants are available for use, we can expect firefighters to perform their duties efficiently, which will reduce the damage resulting from fires. However, a review of previous studies has turned up no investigations of the actual usability of individual fire hydrants in a water supply network structure that has suffered damage in the immediate aftermath of a large earthquake. The assumption that only fire cisterns, rivers, streams are available can be thought of as one possible assumption, when we consider an uncertain disaster situation after the occurrence of a huge earthquake. It can also be thought of as one reasonable assumption to lead the serious evaluation of disaster. Nevertheless, even any small resources that might be available after the disaster should be utilized to assist firefighting activities.

Therefore, in this study, we constructed a simulation model of fire hydrants in a water supply network suffering outages in the aftermath of a large earthquake. In order to analyze with consideration of the availability of each individual fire hydrant, it is necessary to construct a model that can describe the damage of each water pipe. The most unique viewpoint and the principal originality of this research is that we constructed the detailed simulation model which describes water outages by modeling the damage of individual water pipe, that has not been discussed yet in the previous research. Also in order to accomplish comprehensive and complex simulation analyses, we utilized some sophisticated models developed by Hirokawa and Osaragi (2016a, 2017, 2016b). They integrated previously proposed urban zone damage simulation models and a TFD activity simulation model, and used the result to observe ways in which the spread of fire could be halted in order to examine strategies for firefighting during a water outage. Since the installation of water pressure sensors was assumed to have been completed (Nikkei, 2016) by the TFD, it was also assumed that water outages at hydrants could be remotely detected. This novel analysis never done before is outcomes based on the detailed simulation model of water outages developed in this research. Using the analysis results, the reduction in the number of buildings lost to fire was demonstrated and the potential for retaining the usability of fire hydrants was examined.

SIMULATION OF THE WATER SUPPLY NETWORK AND OF A WATER OUTAGE

Water outage simulation overview

Our simulation of a water outage at fire hydrants consisted of (1) the assumed water supply network, (2) the assumed damage to individual water lines, and (3) the hydrants assumed to have been cut off from the water supply. However, since actual data about the water supply networks are unavailable due to security considerations, street network data were used to deduce the water supply network layout. Next, the water lines assumed to have suffered damage were selected on the basis of the *PL* value, the peak ground velocity (*PGV*), and the physical properties of the pipes. Finally, the water supply network was reconstructed while treating the damaged water

lines as unable to carry water, and the possibility of water supply from the purification plant to every fire hydrant was calculated to identify the unusable hydrants.

Method for deducing water supply network layout

Kobayashi et al. (2013) proposed a method for deducing the layout of water supply networks from street network data based on the fact that the supply lines for water, natural gas, and other utilities are generally buried beneath streets or roads. They showed that as long as grade separated intersections do not overlie the buried water lines and that the private roadways that are not included in district data are neglected, this method can provide highly precise data for densely inhabited districts (DID), which have pronounced needs for water lines.

Since most of Tokyo meets the DID definition, this study also employed the above procedure for deducing the water supply network locations (Fig. 1(1)). Next, the purification plants and fire hydrants were located on the street network data (Fig. 1(2)) and the directions of water supply through the networks were estimated from each network origin (purification plant) to the endpoint at each fire hydrant. It was assumed that water supply would be by the shortest route from a purification plant to a fire hydrant, and that route was found using Dijkstra's algorithm (Dijkstra, 1959) for searching for a path (Fig. 1(3)). Additionally, since there were multiple purification plants, calculations were carried out while assuming multiple independently operating water supply networks with origins at each purification plant.

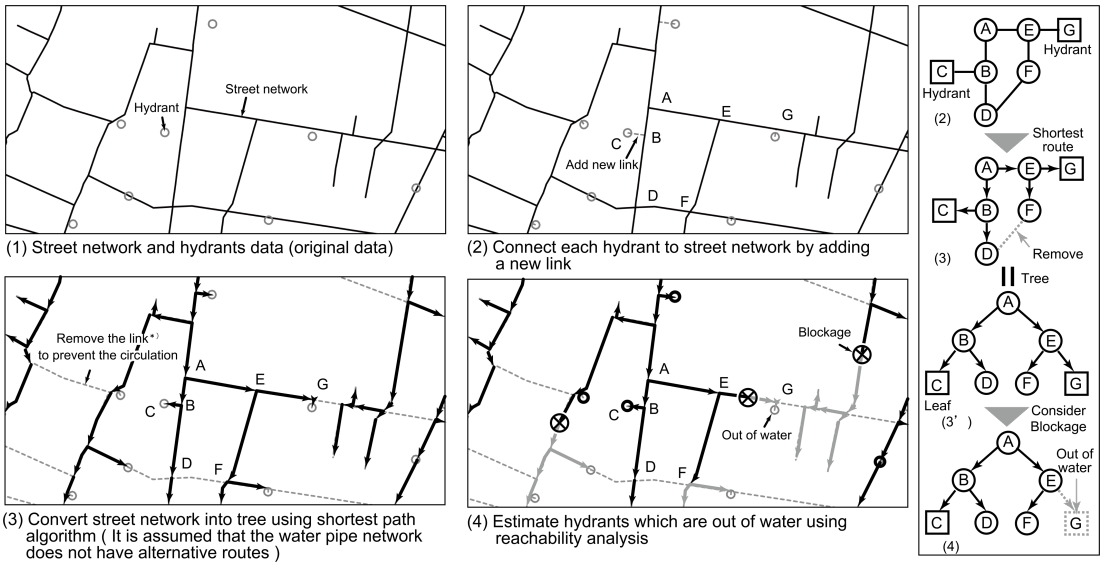

Figure 1. Construction of water pipe network and estimation of water outage

Damage prediction method for individual water lines

The occurrence of damage to any single water line is independent of the conditions of other lines. In this study, the damaged locations were predicted using the water line damage model contained in the damage estimate for Tokyo (Eq. (1)), which considered local *PL* values in order to provide exhaustive damage predictions (Tokyo Metropolitan Government, 2012).

$$E_D = 2.24 \times 10^{-3} \times C_{PL} \times C_D \times (PGV - 20)^{1.51} \times L \qquad (1)$$

where E_D is the number of damaged locations in a water line. *PGV* is the peak ground velocity (cm/sec), *L* is the length of each pipe section (m), and C_{PL} is a correction coefficient based on the *PL* value for the soil surrounding any given water line (Fig. 2). The *PL* values were estimated by converting the image data provided in the damage estimate for Tokyo into vector data. C_D is a correction coefficient that varies with pipe type and diameter. However, since these data were unavailable, it was assumed that the pipe type was ordinary ductile cast iron (without earthquake-resistant joints) and pipe diameters were estimated from street widths.

$$P_D(k) = \frac{(-E_D)^k \, exp(-E_D)}{k!} \qquad (2)$$

$$1 - P_D(0) = 1 - exp(-E_D) \quad (3)$$

Furthermore, assuming that the probability of breakage at each part in the water distribution pipe is uniform and independent for each part, the probability that the number of damaged parts is k at the length L (km) becomes Poisson distribution, and it can be expressed by Eq. (2) using the value of E_D. That is, the probability of occurrence of one or more breakages is expressed by Eq. (3).

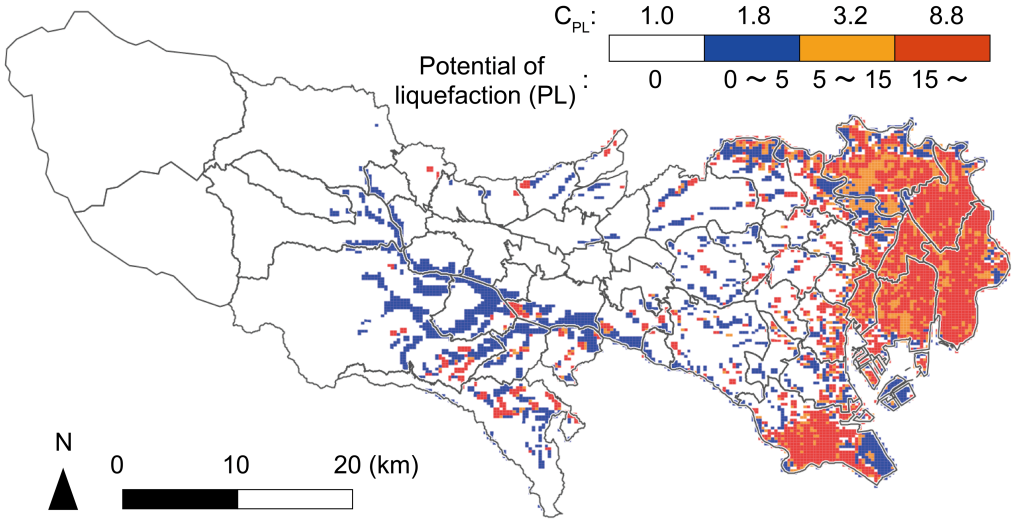

Figure 2. Potential of liquefaction (PL) in Tokyo Metropolitan area

Method for predicting outages at fire hydrants

Water outages were predicted based on the potential for damage along the water supply route from the purification plant to the fire hydrant and taking into consideration the possibility that damaged water lines in the network will no longer carry water (Fig. 1(4)). However, outages were specified only for fire hydrants that were determined to have become unable to receive water from any connected purification plant.

URBAN ZONE DAMAGE SIMULATION AND FIRE DEPARTMENT ACTIVITY SIMULATION

Overview of urban zone damage simulation

Using the urban zone damage simulation models and integrated a new model that allows users to predict physical damage due to collapsing buildings, street blockage, and spreading fires in urban zones, etc., at the level of individual buildings and streets. More specifically, the extent of destruction in the examined urban zone is estimated by the procedure shown in Fig. 3 using the ground surface response (Bureau of Waterworks Tokyo Metropolitan Government , 2016; Wakamatsu and Matsuoka, 2008; Fujimoto and Midorikawa, 2003; Matsuoka and Midorikawa, 1994; Si and Midorikawa, 1999), building collapse data (Midorikawa et al., 1994; Murao and Yamazaki, 1999), street blockage data (Murao and Yamazaki, 2000; Ministry of Land, Infrastructure and Transport, 2003), and the breakout and spread of fires (Ieda et al., 1998; Tokyo Fire Department, 1997, 2001).

First, the data about the ground surface layers, buildings, and earthquake source parameters were loaded into the ground surface response model on a 250-m cell. The seismic response at the ground surface (*PGV*, peak ground velocity) was then estimated at the level of individual buildings. Next, the number of buildings suffering complete collapse was predicted using the estimated *PGV* and the data for construction year (five classifications: prior to 1970, 1971-1980, 1981-1990, 1991-2000, 2001, and thereafter), and construction type (three classifications: wood, ferroconcrete/steel-framed reinforced concrete, and steel frame).

Based on these results, predictions were made as to which streets which would be blocked due to the complete collapse of adjacent buildings, which allowed us to envisage which streets would be rendered impassable for firefighters. This calculation was carried out for all the streets in the examined region. The outbreak or absence of building fires was calculated from the probability of an outbreak, which depended on the use of the building, the season, time of day, and the degree of structural damage. Outbreak times were distributed according to the TFD

survey results. The fire spread in the urban zone was estimated using a model that incorporates factors including the fire resistance properties of a given building to combustion itself, heat radiation from neighboring buildings, and spacing between neighboring buildings.

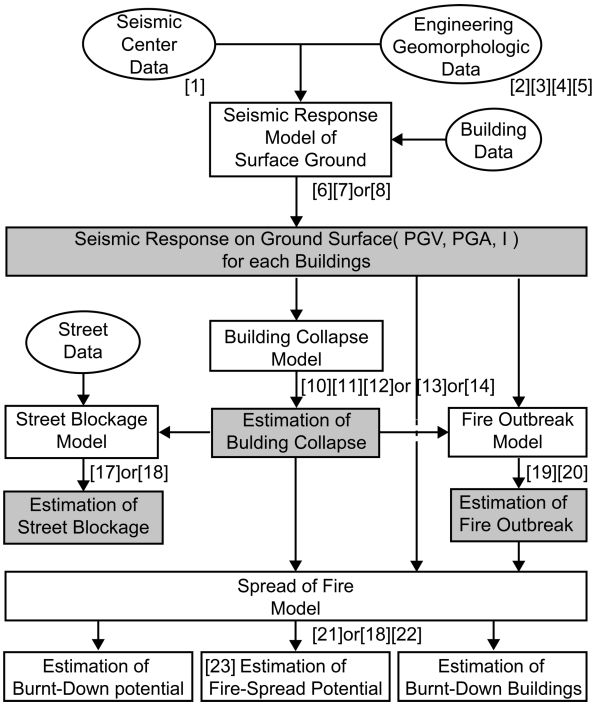

Figure 3. Outline of urban zone damage simulation model

Estimation of time limit for arrival of fire department to prevent fire spread

The time by which a fire department must arrive at a fire in order to prevent its spread (arrival time limit) is estimated based on the current fire spreading condition (fire circumference) in the fire spread simulation, whereas the maximum containable fire circumference is estimated by the number of responding firetrucks. In the simple method proposed by the TFD, a circle is drawn around the fire whose area equals the actual total floor area of the building on fire, and the circumference of this circle is used (Tokyo Fire Department, 2015). The TFD method is simpler but tends to underestimate the fire circumference as the fire spreads, which leads to overestimations of the arrival time limit. The method more closely represents the area to be sprayed with water under actual firefighting conditions (Fig. 4 left) should be used, however it requires very complicated calculation. In order to simplify analyses in this study, we only used more simple method by approximating the fire circumference with a convex envelope (Fig. 4 right). In the other, the fire circumference is represented by the length of the straight lines making up a convex envelope containing all the vertices of the polygon corresponding to the building on fire.

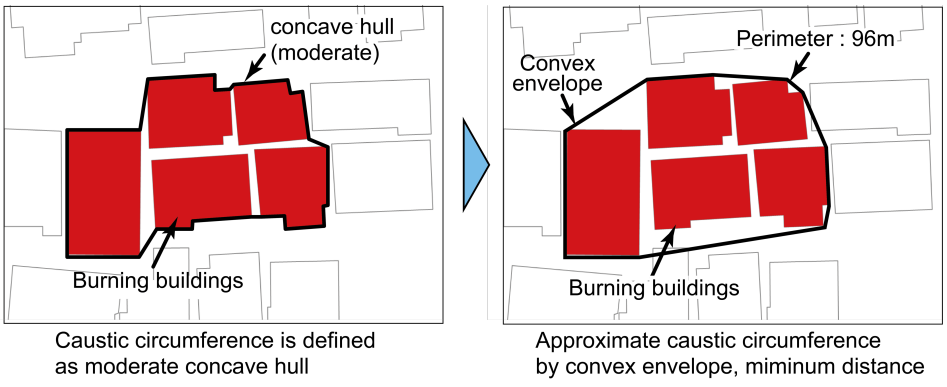

Figure 4. Approximate caustic circumference based on fire-spread simulation

Figure 5 shows the relationship between the elapsed time t since the fire breakout and the fire circumference $L(t)$ based on the mean values found in fire spread simulations incorporating all the buildings in Tokyo. D is the containable fire perimeter, the total actual portion of $L(t)$ that can be covered by the firefighters on site. D is determined by the number of responding firetrucks and the length of the sector assigned to each firefighting team. Then, Eqs. (4) and (5) determine the arrival time limits T_{lm}:

$$D = n \times d_a + m \times d_b \quad (4)$$

$$T_{lm} = L^{-1}(D) \quad (5)$$

where d_a represents the length of the sector assigned to a single fire department hose team and d_b represents the length of the sector assigned to a volunteer firefighter team. n and m indicate the respective numbers of hoses. In this study, it was assumed that a hose team was assigned two hoses and a fire front of 15 m (d_a = 15, n = 2), whereas a volunteer firefighter team was assigned one hose and a fire front of 10 m (d_b = 10, m = 1), and D was 40 m.

It should also be noted that even when the firetrucks arrived later than the arrival time limit (specifically, when [the sum of the time elapsed from the occurrence of the disaster to dispatch + travel time] was greater than [the sum of time elapsed from the occurrence of the disaster to fire breakout + arrival time limit]), by spraying selected portions of the fire, it is still possible to reduce the number of buildings lost to fire. However, that consideration was neglected in this study to avoid complications in calculating the number of losses.

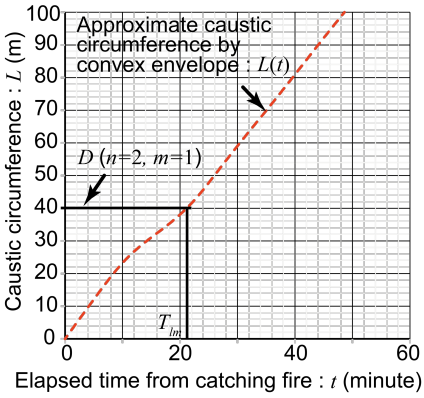

Figure 5. Average ratio of water outage and location of water purifying plant

Definition of fire spread potential inside a single building

The fire spread potential (Hirokawa and Osaragi, 2017), which is an index of the fire spread risk inside a single building, was defined using the results of fire spread simulations. The fire spread potential P_{Fi} of building B_i is defined using Eq. (6), and represents the final, total number of buildings that could be totally lost to fire if building B_i continued to burn freely.

$$P_{Fi} = \sum_{j \in BS} \delta_{ij}, \quad (6)$$

where variable δ_{ij} takes the value 1 if fire spreads from building B_i to building B_j and the value 0 otherwise, and BS is the set of all the buildings to be of concern.

Strategies for selecting dispatch destinations using fire spread potential

Because there is a fire which occurs after the time lag, we have to wait for a while and gather the information to judge fires with a relatively high fire spreading risk. In such a strategy based on standby, there is a danger of failing to prevent spreading fire. Therefore, using the fire spread potential and fire-outbreak probability for each building, we predict the ranking of the danger degree of a fire among all the fires that may occur as the result. Specifically, we calculate the expected value of the number of fires and its standard deviation by applying Eqs. (8) - (10) to the set of buildings whose fire spread potential within the jurisdiction k represented by the expression (7) is EP or more (Fig. 6). Thus, we can obtain the value of the fire spread potential, EP_k^*, that minimizes the value of Eq. (11).

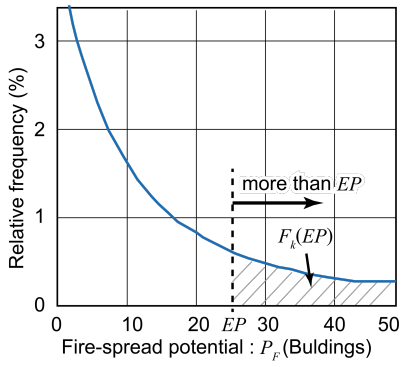

Figure 6. Relative frequency of Fire-spread potential

$$Bs_k = \{ (ep_{ki}, use_{ki}, I_{ki}) \mid ep_{ki} \geqq EP \} \quad (7)$$

$$E(X_k) = \sum_{b_{ki} \in B_{sk}} P(b_{ki}) \quad (8)$$

$$V(X_k) = \sum_{b_{ki} \in B_{sk}} P(b_{ki})(1 - P(b_{ki})) \quad (9)$$

$$P(b_{ki}) = P(use_{ki}, I_{ki}, S) \quad (10)$$

$$EP_{k*} = argmin_{EP} \left(|E(X_k) + \gamma_k \sqrt{V(X_k)} - Np_k| \right) \quad (11)$$

where, Bs_k is a set of buildings whose fire spread potential is EP or more within the jurisdiction k. ep_{ki}, use_{ki}, I_{ki} are the fire spread potential of the building B_{ki}, use and seismic intensity, respectively. X_k is a stochastic variable representing the number of fire in jurisdiction k, and its expected value and variance are denoted by $E(X_k)$ and $V(X_k)$, respectively. $P(b_{ki})$ is the probability of fire outbreak of the building B_{ki}, and S is a variable common to all buildings such as season and time. Np_k is the number of firetrucks in jurisdiction k, and γ_k is a parameter to be set according to characteristics of the urban area in order to cope with the fluctuation of stochastic event.

Fire department activity simulation accounting for water outage

The series of activities of a fire department responding to a fire were modeled as follows: The firetruck moves to an optimal water source for fire extinguishing activities, and the firefighting team carries a hose from the water source to the burning building (Fig. 7). The firetruck and the firefighting team speeds were set to different values ($speed_{Ve}$ and $speed_{Ff}$, respectively), and the passable streets (streets at least 4 m in width, all streets) were differentiated between for the firetruck and firefighting team. The optimal water sources were determined using Eq. (12).

$$WS_* = argmin_{ws \in WS} \left(\frac{D_n(ff, ws)}{speed_{Ve}} + \frac{D_e(ws, fire)}{speed_{Ff}} \right) \quad (12)$$

where WS_* represents the optimal water source, WS is the set of all water sources, $D_n(A, B)$ represents the distance from A to B in the network, $D_e(A, B)$ represents the straight-line distance from A to B, and *ff*, *ws* and *fire* represent the locations of a firefighting team, a water source, and a burning building, respectively. Four cases can be anticipated when selecting a water source: (1) No fire hydrant usage (use only of fire cisterns, rivers, streams, etc.); (2) fire hydrant use (no water outages); (3) fire hydrant use (possibility of water outages); and (4) use of fire hydrants (known water outages). When anticipating the use of fire hydrants (Cases (2), (3) and (4)), fire cisterns, rivers and streams are used in addition to fire hydrants. In Case (3), if the fire hydrants at the destination have no water pressure, fire hydrant use must be abandoned and other sources must be sought. Case (4) assumes that individual fire hydrants have been installed with water pressure sensors (Nikkei, 2016) and that water outages at hydrants can be remotely detected.

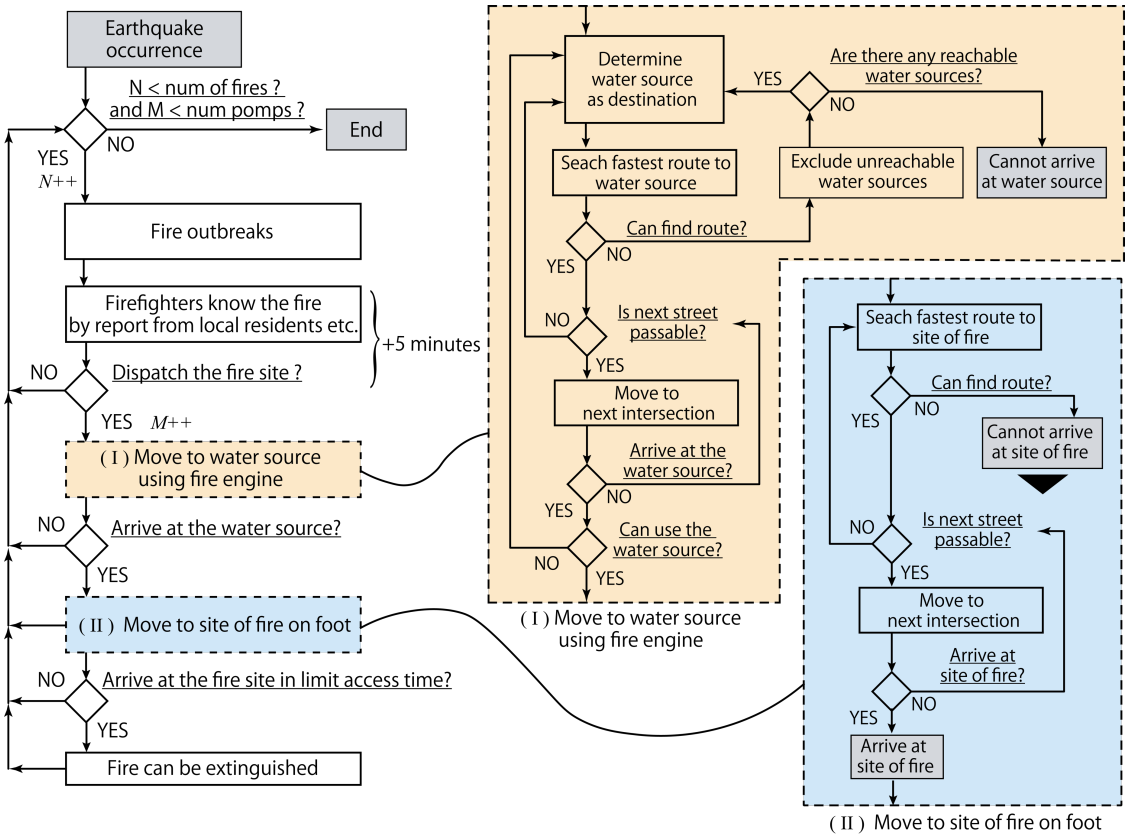

Figure 7. Outline of firefighter simulation model

In the urban zone damage simulation, it is also assumed that some streets will be blocked when calculating the time necessary to arrive at a burning building. Specifically, the simulation uses the following process. First, a path to the optimal firefighting water source is identified while assuming that all streets are passable. If blockage makes a street along the way impassable, a new path is then plotted from that location to the optimal firefighting water source. This process is assumed to take 30 seconds for the path search, course revision, etc. All the impassable streets found along the way are stored in memory and avoided when conducting new path searches. Additionally, when the firetruck has arrived at the firefighting water source and it turns out to be an unusable fire hydrant, the firetruck proceeds to another firefighting water source.

It is assumed that a combined team or number of teams, each consisting of a single fire station team and a volunteer firefighter team, are dispatched. The number of teams is the number of firetrucks held by the responding station and the branch fire stations. Considering the distribution of the clock times of fire breakouts in past damage data (Tokyo Fire Department, 2015) and the time needed for spraying, it was assumed that firetrucks are not deployed to other burning buildings after a fire has been controlled and that sufficient water is available for spraying the burning building being serviced. Note that half of the total number of fires that ultimately break out after a disaster do so within about 15 minutes after its occurrence, and 80% do so within the first 60 minutes.

SIMULATION CONDITIONS FOR THE COMPLETE TOKYO AREA AND WATER OUTAGE RATE PREDICTIONS

Target region for analysis and conditions for simulation

Urban zone damage simulations incorporating all of the buildings (2,784,101) and streets in Tokyo were carried out. The total of 1,000 simulations predicted varying physical damage situations (building collapse, street blockage, fire breakout/spread, and water outages) were conducted. A large earthquake with a magnitude of 7.3, centered in the north portion of Tokyo Bay on a winter evening (when the number of fire breakouts is likely to be the highest) was assumed. Other assumptions include a north wind of 8 m/sec and a humidity level of 50%.

The mean number of buildings lost to fire was estimated using the predicted physical damage, destinations for the fire stations (burning buildings) and arrival times in a Monte Carlo simulation (1,000 runs). The final numbers of buildings lost to fire were classified into those to which no firefighters were dispatched (free-burning fires) and

those to which firefighters were dispatched but were unable to prevent fires from spreading. However, a very consistent number of buildings succumbed to free-burning fires in these simulations. More specifically, the final numbers of buildings lost to fire depended solely on the number of burning buildings tackled by fire stations. Therefore, this discussion focuses solely on the number of buildings lost to fire due to failure to prevent fires from spreading.

Estimates of rate of water outages in water outage simulation

Figure 8 shows the figures for each ward in Tokyo for the fraction of the total number of unusable fire hydrants (rate of water outages) estimated by the water outage simulation. These rates were found to be high in the east and south parts of Tokyo, where liquefaction damage is expected to occur (Fig. 2) and in the west part of Tokyo, which has no nearby purification plants, while they were low in the north part of Tokyo, which has a number of local purification plants. The damage estimate for Tokyo predicted a water outage rate of 46.7% in wards with dense networks of water pipes and relatively numerous water supply points, while the authors' water outage simulation predicted a rate of 50.3% for the same locations. The discrepancy between these predictions is well within 10%. This consistency suggests that the outage estimates by our simulation were plausible.

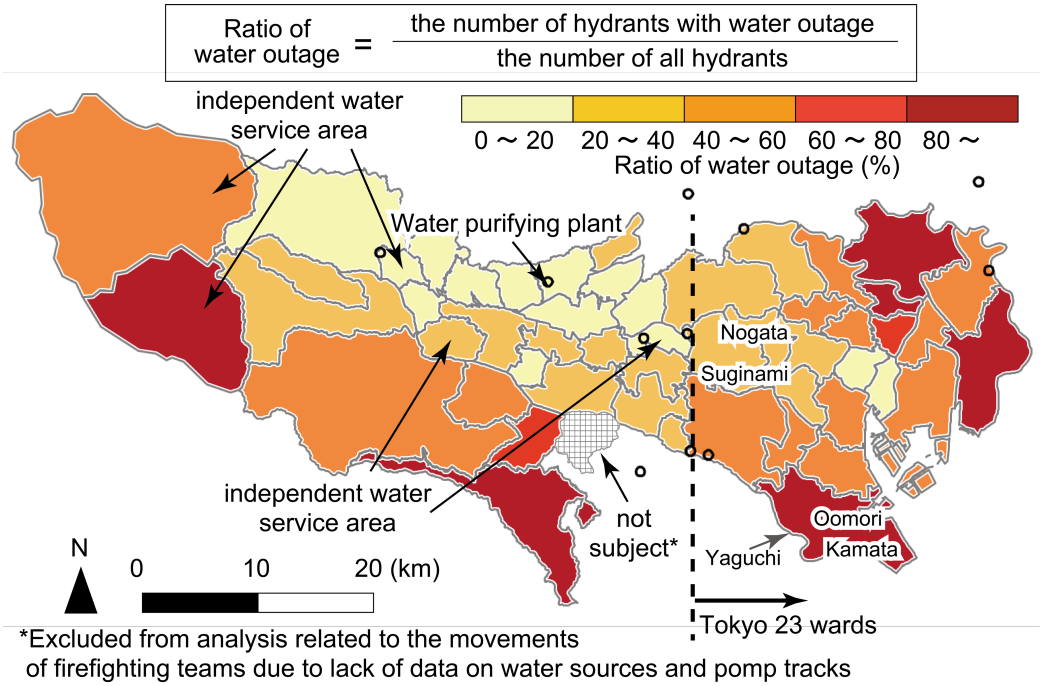

Figure 8. Average ratio of water outage and location of water purifying plant

INVESTIGATION OF USABILITY OF FIRE HYDRANTS IN FIREFIGHTING ACTIVITIES

Investigative method overview

In order to validate the effectiveness of utilizing fire hydrants for reducing the maximum number of buildings lost to fire, we examined that number while comparing the cases defined in 3.5 above. Comparing between Case (1) no usage of fire hydrants and Case (2) use of fire hydrants and no water outages, Case (2) corresponds to a situation in which individual water lines have been hardened against earthquakes (with earthquake-resistant joints, etc.) and will continue to function. Next, in order to examine the usability of fire hydrants during a water outage, we compare Case (1) no fire hydrant usage with Case (3) fire hydrant use and possible water outages. Finally, we observe the benefit of using fire hydrants by comparing Case (4) fire hydrant use (known water outages), which assumes that water outages at hydrants can be remotely detected with water pressure sensors that have been installed by the TFD, with Case (1) in which no fire hydrants are usable.

Effectiveness of fire hydrant used in reducing building losses

As an analysis reference of the effectiveness in reducing the number of buildings lost to fire, Fig. 9(1) provides

the spatial distribution of buildings lost due to the failure to prevent fire from spreading under Case (1). Here, it can be seen that the areas in which these losses were high form a wide ring within the 23 wards of Tokyo. Examination of the position densities of firefighting water sources other than fire hydrants (cisterns, etc.) in Fig. 10(1) show that many of the jurisdictions are underequipped with such sources. Comparing Case (1) with Case (2), it can be seen that the number of buildings lost to fire could be reduced in virtually all the jurisdictions (Fig. 9(2)). Figure 11 shows how the reduction in the number of buildings lost to fire varies with the water outage rates. Specifically, some jurisdictions could see reductions by about 100 buildings, and the jurisdiction with the maximum reduction in losses would see about 400 buildings saved (Fig. 11(1)). On the other hand, some of the jurisdictions with high fire hydrant densities showed little benefit in terms of the reduction in the number of buildings lost to fire (Figs. 9(2), 10(2)). This was ascribed to the small number of buildings lost to fire caused by the failure to prevent fire spread in the central portions of Tokyo and neighboring cities and to the fairly efficient positioning of firefighting water sources other than fire hydrants (firefighting water cisterns, etc.) (Fig. 9(1)).

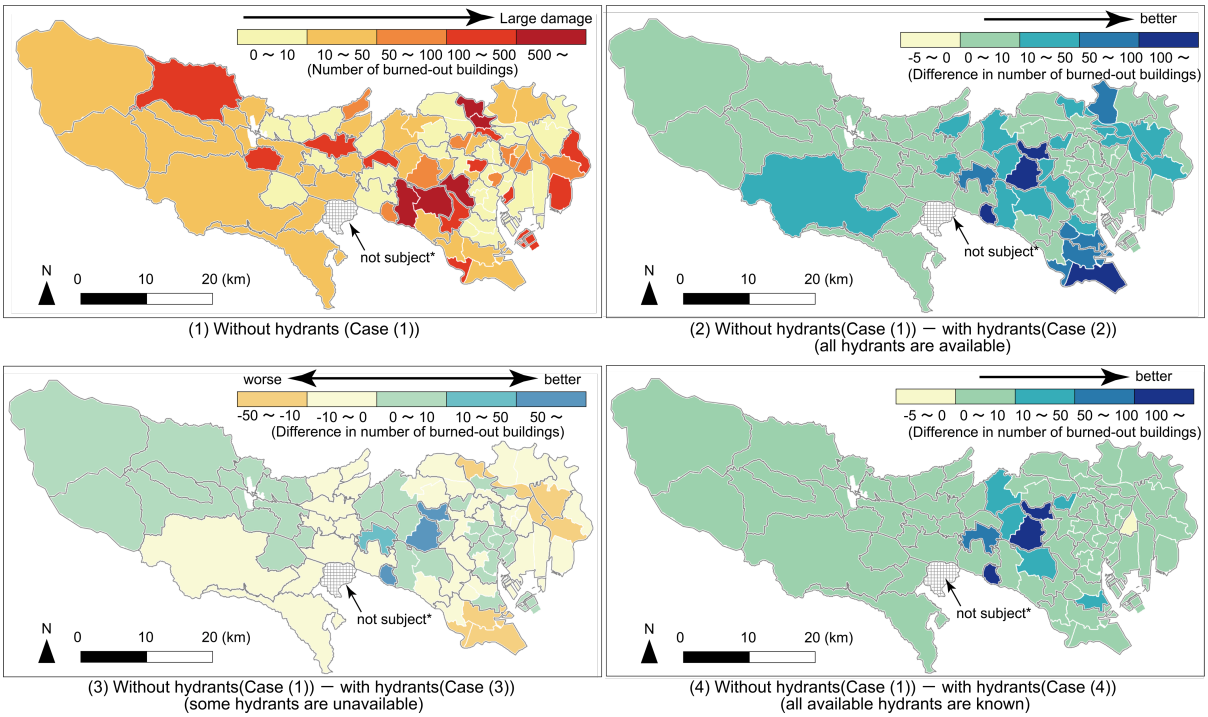

Figure 9. Difference in the number of burned-down buildings in each condition

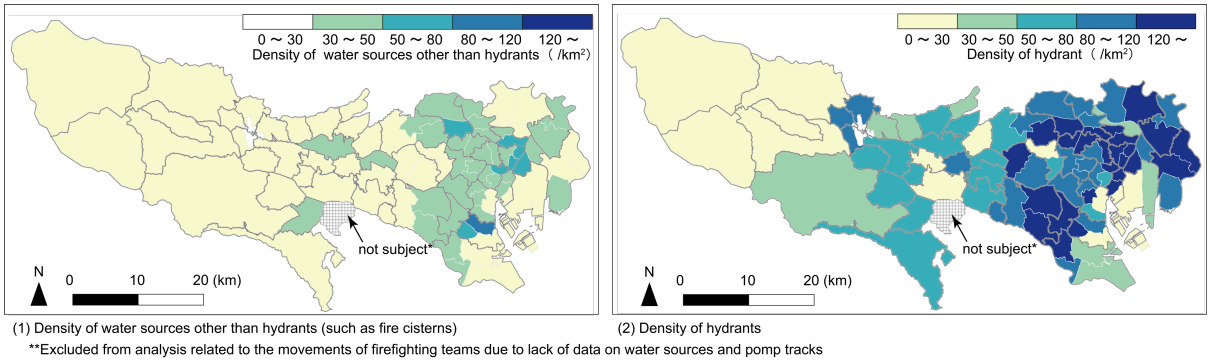

Figure 10. Density of water sources

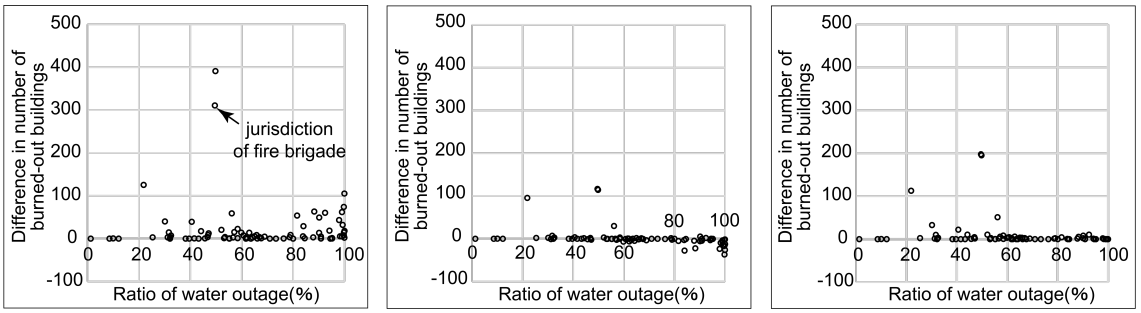

Figure 11. Relationship between difference in the number of burned-down buildings and the ratio of water outage

Influence of fire hydrants suffering water outages on number of buildings lost to fire

In Case (3), the use fire hydrants during potential water outages was attempted, but the number of buildings lost to fire increased in a total of 46 (56.1%) jurisdictions (Fig. 9(3)). However, the increase only exceeded 10 buildings in eight jurisdictions (9.76%), and was about 37 buildings at most (Fig. 11(2)). Additionally, some jurisdictions suffering water outage rates of around 50% were still able to save over 100 buildings, thus showing an advantage of using fire hydrants.

Benefit of reducing number of buildings lost by tracking unusable fire hydrants

Thanks to the introduction of water pressure sensors (Japan Water Research Center, 2011), in cases in which fire departments can verify which fire hydrants remain functional before they arrive at a fire (Case (4)), nearly all the jurisdictions were able to reduce building losses (Fig. 9(4)). Jurisdictions where water outages were less severe were able to reduce losses by nearly 200 buildings (Fig. 11(3)). However, since the jurisdictions that were able to cut losses by nearly 100 buildings under Case (2) were those suffering more severe water outages, we infer that there would be no benefit in terms of reducing building losses conferred by this technology under Case (4) (Fig. 9(4), Fig. 11(1), (3)). In such regions, i.e., regions with insufficient fire cisterns (Fig. 10(1)), the severe water outages mean fire stations cannot count on being able to use fire hydrants. Therefore, it is imperative to take other measures such as hardening water lines against earthquakes, constructing more fire cisterns, and so on.

Potential for use of fire hydrants during water outages

Here, while considering the above observations, we investigate the utility of fire hydrants in firefighting activities in spite of a water outage. If fire hydrants remain usable, some jurisdictions will be able to reduce the number of buildings lost by more than 400 units. However, the central portions of Tokyo and neighboring cities have fairly efficiently distributed firefighting water sources other than fire hydrants (fire cisterns, etc.), so many of those jurisdictions are in a position to carry out sufficiently effective firefighting activities in the event of a water outage without depending completely on fire hydrants. Nevertheless, assuming that water outages can be remotely detected, it is highly probable that the number of buildings lost to fire could be reduced in nearly all the jurisdictions, even after a large earthquake, which means that the introduction of water pressure sensors will be extremely beneficial.

Additionally, since jurisdictions that are less vulnerable to water outages were also able to save nearly 200 buildings, there needs to be more investigation of the use of fire hydrants in such areas. Figure 12 shows the numbers of buildings that posed difficulties for firefighting activities when no fire hydrants were available, as estimated from the locations of firefighting water sources other than fire hydrants and firefighter hose lengths. There are approximately 20,000 buildings in the complete area of Tokyo which will be difficult to access by firetrucks if no fire hydrants are available. Thus, fire hydrants are crucial. In contrast, regions that have sufficient numbers of fire hydrants but are prone to water outages will benefit less from information about local water outages, so in those areas it is important to harden water lines and construct more fire cisterns.

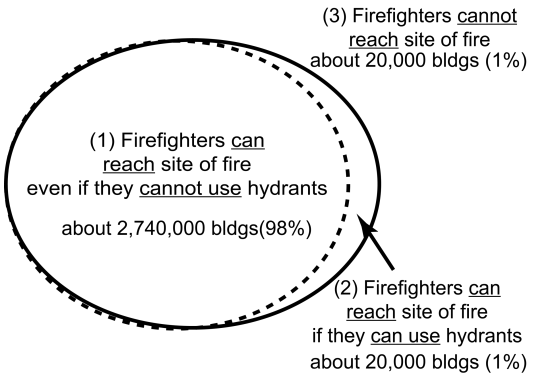

Figure 12. The number of burned-out buildings and difference in firefighters' reachability be-tween with/without hydrant

SUMMARY AND CONCLUSIONS

A simulation model was constructed in order to investigate the usability of fire hydrants during water outages following a large earthquake and to predict the occurrence of water outages at individual fire hydrants in a water supply network after such an earthquake. The authors also combined previously proposed simulation models of urban damage and fire department activities to quantitatively analyze the effects and benefits of fire hydrant usage in terms of reducing the number of buildings lost to fire.

From the results of the water outage simulation, it was determined that water outage rates will be higher in the east and south parts of Tokyo, where serious damage is expected due to soil liquefaction and in the west part of Tokyo, which is far from water purification plants. One of the most important results of this study has been the simulation model describing the phenomena of water outages occurring in water supply networks, which was used in place of the cell model previously employed for such simulations.

The simulation noted fire department jurisdictions in which more than 400 buildings were saved from complete fire destruction after a large earthquake because of the hardening of water lines that had been performed in those areas, which helped prevent water outages. A few jurisdictions saw a slightly greater damage rate when attempting to use fire hydrants during water outages, but jurisdictions that had low rates of water outage were able to reduce the number of buildings lost to fire by over 100. It was also determined that the central portions of Tokyo and neighboring cities are somewhat better equipped with firefighting water sources other than fire hydrants (fire cisterns, etc.) than the Tokyo suburbs.

Once Tokyo has completed its ongoing installation of water pressure sensors and water outages can be remotely detected as soon as they occur, nearly all jurisdictions will be able to save many more buildings from destruction by fire. Jurisdictions with lower rates of water outages (around 50%) will be able to save approximately 200 buildings. Additionally, there are about 20,000 buildings that fire departments would be unable to service without fire hydrants. Jurisdictions that are underequipped with fire cisterns and other backup sources of water should prepare to track water outages and plan to rely on fire hydrants.

In order to simplify water outage predictions, the water outage simulation in this study did not account for pressure losses due to leaks or the potential to continue some supply of water downstream of a breakage. Furthermore, it was assumed that the water supply network has a tree format when it actually has an interlinked format. Future research must include construction of a more exhaustive simulation model as the urban zone damage simulation mode used in this study did not account for effects such as street blockages or delays due to fleeing population, abandoned automobiles, or traffic jams. For that model, an approach using a physical model must also be examined.

ABSTRACT

Natural disasters regularly impede communication infrastructure, leaving civilians without reliable means of communication. In such cases, ad hoc networks enable basic communication inside the affected areas. However, low human mobility and group formation limit their performance, as messages are confined to distinct communication islands. Autonomous Unmanned Aerial Vehicles can help in spreading messages across multiple such islands, as proposed in the literature. Evaluating the resulting Unmanned Aerial System (UAS) under real-world conditions requires significant resources, e.g., field tests and prototypes. For a systematic assessment of a UAS and its support strategies under controlled conditions, simulations are the preferred method. To this end, we propose the first simulation platform that combines ad hoc communication on the ground and the corresponding human mobility models with an extensible model for a networked UAS and their respective support strategies. We implement and evaluate two representative strategies, showcasing the capabilities of the proposed platform.

INTRODUCTION AND MOTIVATION

Recent disasters such as Hurricane Harvey in 2017 or Hurricane Florence in 2018 demonstrated the highly destructive force of natural disaster, and they revealed the strong dependencies of the civilian population on critical infrastructures such as energy supply or information and communication technologies (ICT). Particularly in the aftermath of a disaster the communication volume increases and the communication infrastructure can no longer cope with the high communication demand (Klinsompus and Nupairoj 2015). In such resource-constrained situations, however, where communication is key for successful emergency response operations, there is a need for civilian-centric emergency communication networks.

In 2017, we conducted a large field test throughout one day to show the capabilities of smartphone-based communication networks for emergency response (Álvarez et al. 2018). The field test took place at the military training area *Senne* near Paderborn in Germany in conjunction with experts from the German Federal Office of Civil Protection and Disaster Assistance (BBK), the German Federal Agency for Technical Relief (THW), local fire departments, and other NGOs. A large set of emergency services (Lieser, Alvarez, et al. 2017), such as SOS Messages, Person-Finder, or a Resource Market were available for 125 participants to cope with various scripted

*Equally contributing authors

Figure 1. The layout of the field test area (Álvarez et al. 2018).

disaster events in a realistic environment consisting of three different villages (Figure 1). The smartphones of the participants were used to build a large communication network which was based on the store-carry-forward principle known from delay-tolerant mobile ad hoc networks (DTN-MANETs) (Uchida et al. 2013). Message propagation was achieved in a flooding-based manner, where duplicates of all stored messages are forwarded every time a node discovers a new node in communication range. The field test demonstrated, on the one hand, that smartphone-based ad hoc networks can successfully be utilized to support emergency response efforts. On the other hand, the field test revealed the limited communication capabilities of DTN-MANETs which are highly dependent on the users' mobility to distribute messages.

Due to the high distance of Village B and C to Village A ($\approx 3.5\,km$ beeline, $\approx 5\,km$ by foot) and the natural human behavior of forming groups, the network was highly intermittent with large communication islands in and around the villages. Within these islands, communication performed well. Messages were distributed within a few seconds throughout an entire island. However, to achieve communication between distinct islands mobility is required for message transport. Participants, thus, would have to act as communication bridges between islands, but only a few of them actually moved between the villages, especially between the distant ones. Furthermore, if participants moved between the distant villages, it took them more than 60 minutes in most cases. Thus, lifetimes of most of the carried messages were already expired on arrival. Figure 2 displays the best and a median number of reached participants (out of 125) and the corresponding delivery delay within the message lifetime of 60 minutes. Instantaneous jumps indicate the distribution of a message when a new communication island is encountered, but the distances between those jumps show that it takes a long time for an encounter to happen.

During the field test, the interaction with the provided emergency services resulted in a total number of 1,835 unique messages which were duplicated and forwarded 18,418 times in the network. With a higher message lifetime, the number of reached participants would have further increased. However, this would also increase the amount of duplicates and therefore the network load resulting in more needed message storage space on the nodes. Furthermore, the relevance of a message or the relevance of the contained context information can decrease over time (Lieser, N. Richerzhagen, Luser, et al. 2019; Lieser, Alhamoud, et al. 2018).

Moreover, especially for high priority messages like SOS calls and warnings in emergency response services a timely delivery is crucial. Another example of the need to provide fast communication are tsunami warnings. For example after the Great East Japan Earthquake in March 2011, the affected population could not be warned sufficiently quickly of the upcoming tsunami because the effects of the earthquake had disrupted the communication in various regions (Ranghieri and Ishiwatari 2014). Thus, improving the performance of DTN-MANET emergency communication with regard to fast, reliable and thorough message propagation can significantly improve the efficiency of disaster relief and emergency response services and eventually saves lives.

In recent years, the increasing availability and popularity of small, commercially available Unmanned Aerial Vehicles (UAVs) has attracted remarkable attention from researches and practitioners. Besides their use for leisure activities, they proposed UAV application for example in search and rescue missions (Rémy et al. 2013; Scherer et al. 2015) or to relay communication of rescue team members on incident sites (Morgenthaler et al. 2012; Baumgärtner et al. 2017). Regarding the field test results, it became clear that inter-island communication cannot be efficient relying only on uncontrollable node movement. An Unmanned Aerial System (UAS), where multiple autonomous UAVs collaborate to efficiently support physical message transport between intermittent communication islands,

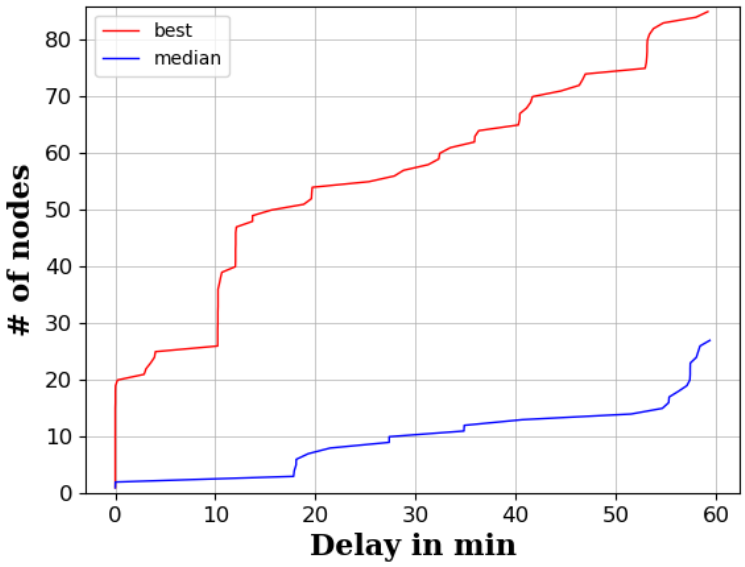

Figure 2. Number of reached nodes and the corresponding propagation delay during the field test. Messages had a lifetime of 60 minutes (Álvarez et al. 2018).

could provide a much more performant emergency communication. As drafted in Figure 3, a UAV could act as a communication bridge between otherwise intermittent communication islands and thereby, eliminate the necessity for ground nodes to move between islands for message dissemination.

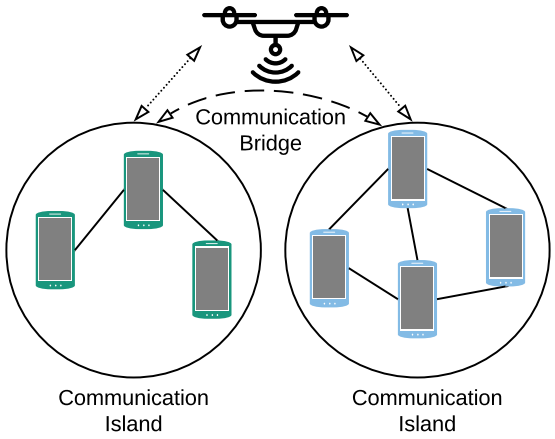

Figure 3. Communication amongst intermittent communication islands in a DTN-MANET requires nodes to act as communication bridges. UAVs are either acting as message relays by positioning themselves in communication range between two near islands, or by providing more efficient means of physical message transport between remote islands due to their mobility.

To design and to evaluate the applicability of such a system, field trials with prototypes or small testbeds are often conducted, and are indispensable to test the applicability of UAVs under realistic environmental conditions such as extreme weather conditions. However, this process has several drawbacks. On the one hand, an elaborate field test cannot be repeated on a regular basis due to the high costs and organizational complexity. Moreover, on the other hand, it would require already existing working prototypes to test them in the field, or at least in an experimental testbed.

Due to poor scalability, reproducibility, and possible law-restrictions, as well as the requirement of expensive hardware prototypes for experimental evaluations, performing simulations, is the preferred method for the development of complex systems. There exists no simulation platform that combines the possibility to simulate and evaluate Mobile Ad Hoc Networks on the ground in combination with Unmanned Aerial Systems, as discussed in the following

section. This paper, therefore, introduces a simulation platform for Unmanned Aerial Systems as an extension of the discrete-event open-source simulation and prototyping platform SIMONSTRATOR.KOM (B. Richerzhagen et al. 2015) for mobile networks. It can be used for the implementation, simulation, and evaluation of a large-scale UAS in combination with mobile communication networks on the ground. The modular system design allows the simulation of various behavioral strategies and a multitude of different UAV parameter settings.

As a proof of concept, we implemented and evaluated an Unmanned Aerial Communication Support System for civilian-centric post-disaster emergency communication networks based on our field test (Álvarez et al. 2018). Two simple, yet diverse behavioral strategies are provided in the prototype implementation, to show the potential extensive scope of systems our simulation platform allows to develop. The results show that we can significantly improve the communication characteristics of the DTN-MANET on the ground, by improving the message propagation while also decreasing the delivery delay. Our simulation platform can further be used to determine optimal UAS settings, such as the minimal amount of UAVs required to reach an intended message delivery rate or delay.

The remainder of this paper is structured as follows. In the next section, related work is described, followed by the concept and design presentation of our UAS simulation platform. Afterward, we present two possible behavioral strategies and their proof-of-concept evaluation in two different scenarios. Eventually, we conclude the paper and discuss future work approaches.

RELATED WORK

The possible destruction of ICT infrastructures in the aftermath of disasters led to the development of many infrastructure-independent post-disaster communication systems based on DTN-MANETs and a variety of different applications. George et al. 2010 propose the use of wireless sensor nodes for the provision of real-time situational awareness on site for search and rescue mission teams. The system combines on-demand and delay-tolerant routing for heterogeneous nodes with good performance results shown in simulations.

Serval Mesh (P. Gardner-Stephen, Challans, Lakeman, Bettison, D. Gardner-Stephen, et al. 2013), *Twimight* (Hossmann et al. 2011), and *TRIAGE* (Luqman et al. 2011) are also multi-purpose infrastructure independent communication system that can be used in the case of a disaster. These systems also support different prioritization mechanisms to handle the limited bandwidth in DTN-MANETs. As already proven in the field test (Álvarez et al. 2018) and other prototypical hardware demonstrations (Meurisch et al. 2017), decentralized civilian communication systems for post-disaster scenarios are possible by utilizing the ubiquity of civil smartphones. The SIMONSTRATOR.KOM platform (B. Richerzhagen et al. 2015) allows to simulate large-scale civilian ad hoc networks as shown, e.g., for decentralized resource allocation in disaster scenarios (Lieser, N. Richerzhagen, Feuerbach, Meuser, et al. 2018).

Dedicated communication modules such as the Serval Mesh Extender (Lieser, Alvarez, et al. 2017; P. Gardner-Stephen, Challans, Lakeman, Bettison, Lieser, et al. 2017) make it possible to communicate over long distances (tested with 4 km distance) independent of any fixed infrastructure. In principle, such devices would be ideal to connect communication islands, but they need a line of sight to reach the specified communication distances which are often not possible. Furthermore, experts need to have access to strategic places, such as the edge of a communication island for a meaningful deployment of the communication modules. The locations of the islands are also strongly dependent on the course of a disaster and are therefore difficult to predict.

Besides these system examples for post-disaster communication there exist a variety of different applications, specifically designed for DTN-MANETs. With the goal to help the affected population to cope with the aftermath of a disaster, such services allow civilians to send out distress signals (Al-Akkad et al. 2014; Mokryn et al. 2012), have text-based conversations, make it possible to find friends and family, or to share resources at a digital market-place (Lieser, Alvarez, et al. 2017; Lieser, N. Richerzhagen, Feuerbach, Nobach, et al. 2017). To boost message delivery rate in a wide-spread, sparsely populated DTN-MANET environment, Uchida et al. 2013 insert cars with WiFi capabilities as additional nodes into the network, similar to Zhao et al. 2004. The simulation was conducted in the ONE simulator[1] with the cars moving on the streets with up to $50\ \frac{km}{h}$. Results indicate that even with 100 cars it took more than 30 minutes on average for messages to travel 4 km between two rescue shelters. Furthermore, only 80% of the messages are delivered at all.

Proposed applications for Unmanned Aerial Systems include Search and Rescue missions (Rémy et al. 2013; Scherer et al. 2015), forest fire localization (Belbachir et al. 2015), inspection of infrastructure like power lines (Erdelj et al. 2017), aerial contamination measurement (Daniel et al. 2009), LTE coverage provision (Rohde et al. 2013; Li et al.

[1] http://akeranen.github.io/the-one/

2015), and message relaying for rescue team members on incident sites (Morgenthaler et al. 2012; Baumgärtner et al. 2017).

However, most of these applications used unique hardware prototypes to show their feasibility, or build mathematical models to provide insight into possible advantages and drawbacks, very few use simulations. A very basic simulation for UAV trajectories is used by Belbachir et al. 2015 and Erdelj et al. 2017 but neither the simulation tool nor the capabilities for realistic UAV simulations are stated. A discrete event simulation for UAVs is presented in Dietrich et al. 2017a including a 3D visualization. However, the tool is specifically designed to evaluate maintenance processes for long-term UAV deployments. Communication happens without limitations and with perfect reception only between a mission controller and the UAVs. In Mori et al. 2015 a large-scale simulation of very different nodes such as balloons, cars, and UAVs is shown. Entities build up a mesh network to provide communication between users. The simulator and its details, however, is not specified and nodes are either static or only use a random waypoint movement model, which insufficiently represents real-world behavior.

In conclusion, there are some approaches for the simulation of Unmanned Aerial Vehicles or comprising systems. However, they are limited in their applicability to general system development or lack certain features like realistic node movement or communication models. Most often, simulations are implemented specifically for the tested approaches and do not allow for the implementation of other systems.

Thus, a simulation tool which provides broad access to different movement and communication models allows the realistic simulation of different kinds of nodes like UAVs or smartphone users, and in particular is fit for the implementation and evaluation of diverse UAS as required for quick and large-scale development of such systems. There exists no simulation platform fulfilling these requirements.

SIMULATION PLATFORM FOR UNMANNED AERIAL SYSTEMS

The open-source SIMONSTRATOR.KOM (B. Richerzhagen et al. 2015) simulation platform provides several models for wireless communication, message transport, node mobility, and energy consumption relying on the network simulator PEERFACTSIM.KOM (Stingl, Gross, et al. 2011; Stingl, B. Richerzhagen, et al. 2013). Furthermore, SIMONSTRATOR.KOM allows simulating a large number of heterogeneous nodes with different properties at the same time. It can also use map data from OpenStreetMap[2] (OSM) to simulate, e.g., urban environments where node movement can be restricted to walkways, bike lanes, or roads, respectively.

This simulation environment constitutes a well-suited basis which we extended towards a fully fledged simulation platform for Unmanned Aerial Systems[3]. The added extensions and their interactions are shown in Figure 4. The PEERFACTSIM.KOM simulator is extended by required UAV components such as batteries, actuators, and controllable movement models, which eventually form the entire simulated vehicle. Besides the possibility to simulate UAVs, we also added a base station that provides necessary infrastructure like battery recharging and landing pads for the UAVs. On the application layer at the SIMONSTRATOR.KOM platform, mission planning, and coordination were added to the base stations and controlling strategy execution to the UAVs. In the following, we discuss the extensions in detail.

Energy Consumption and Battery Recharging

PEERFACTSIM.KOM already provides a battery model including the power consumption of device components such as displays, communication interfaces like WiFi, or miscellaneous equipment like GNSS sensors. Power consumption is adjustable for each device, respectively, using voltage and power draw in different states, for example, *TRANSMIT* or *RECEIVE* in case of a WiFi chip. Batteries are defined by their capacity in Joule. We added a new component modeling the actuators required for the UAV propulsion, where the power consumption is regulated continuously between a minimum and a maximum parameter. This is necessary to abstract situations such as constant flight speed and altitude, where only friction has to be compensated, or ascent, where actuators require more power to accelerate the UAV. Parameter settings for power consumption depend on the actual UAVs—or more specifically the used actuators—that are modeled, as mentioned by Dietrich et al. 2017b.

Due to the limited battery capacity, a long-term UAV deployment requires the possibility to recharge or to entirely replace a drained battery. We include a charger model to the simulator, which continuously recharges a UAV's battery by a fixed amount of Joule per second, modeling, for example, a contactless induction charger as proposed by Hu et al. 2008. However, continuous recharging is not the most efficient solution regarding vehicle utilization due to the long downtimes during the recharge process (Erdelj et al. 2017). We, therefore, added another model that

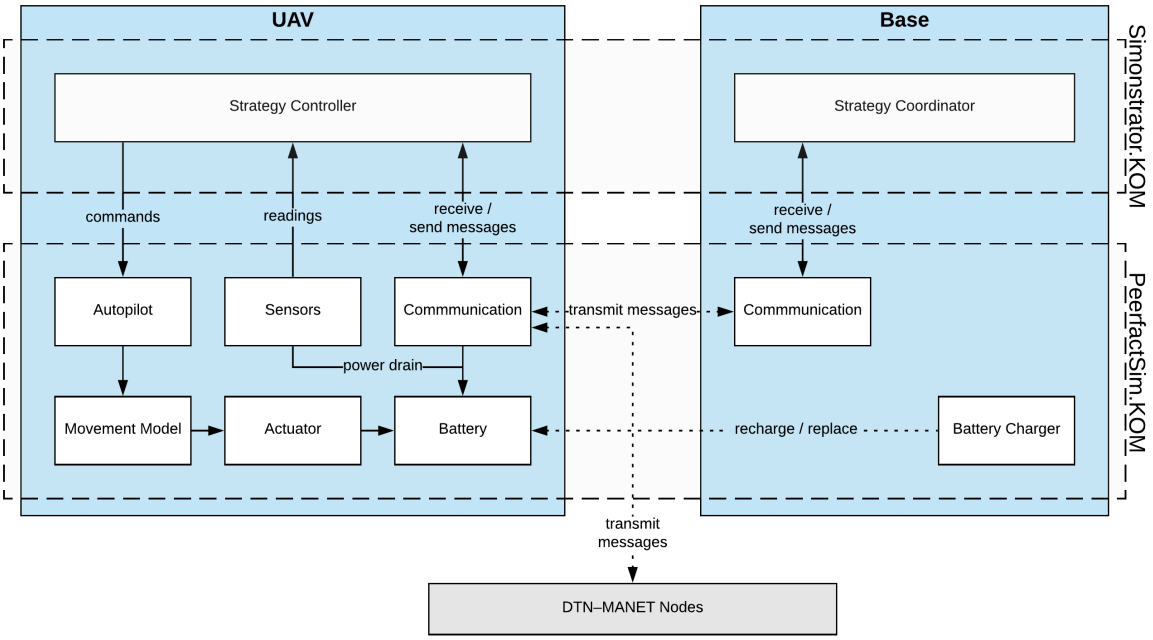

Figure 4. Overview of system components for UAVs and base stations comprising the UAS in the simulation platform, with their respective location in SIMONSTRATOR.KOM and PEERFACTSIM.KOM architecture. Dependencies between components are indicated by lines and arrows, dotted lines show non-permanent connections like message transfer over the network or during the battery recharging process.

is emulating manual or automated battery replacement. The default time to replace the entire battery is set to 60 seconds, based on the results in Fujii et al. 2013 and Ure et al. 2015, but can be customized if required. As in a real deployment, chargers are part of base stations.

UAV Autopilot and Movement Model

Available models for node movement included simple approaches like random walk or random waypoint, but also more sophisticated models like social movement between attraction points in an urban environment (N. Richerzhagen et al. 2017). Realistically, the application cannot directly control the movement of a user. Thus, the movement models in the simulator are fully separated from the application layer. However, this separation is not given in the case of a UAV, since vehicle movement is controllable by an autopilot. We therefore added a controllable UAV movement model.

In our platform, we premise all UAVs to be capable of fully autonomous flight, performed by an autopilot. All autopilots offer a generic interface to the application layer, through which commands like *'move to coordinate x'* or *'change altitude'* can be issued. The autopilot then autonomously executes the commands within the capabilities of the UAV. These capabilities are specified by a UAV movement model. We first implemented a model for multicopter UAVs due to their straightforward and precise maneuverability, their ability to hover, and because they constitute the majority of commercially available UAVs (Namuduri et al. 2018). The models define basic procedures like take-off, touch-down, ascent, and descent, but also flight maneuvers such as hovering, circling a position, or route traversal. Furthermore, variables like minimum and maximum speed, reachable flight altitudes, and movement limitations, in general, are defined therein.

Communication

Devices for wireless communication such as Bluetooth and WiFi are already implemented in PEERFACTSIM.KOM. Available communication devices can be used for various purposes, such as for control and coordination messages between UAVs and the Base Station, for communication between multiple UAVs, and the communication between UAVs and the DTN-MANET nodes on the ground. The modular setup of communication devices in PEERFACTSIM.KOM allows using multiple, possibly different devices in parallel, which enables the full separation of channels, if necessary. For example, we can use a WiFi device on the UAVs to exchange messages with the nodes on the ground in accordance with the employed DTN-MANET protocol. Another WiFi device then is used

for UAV-to-UAV communication allowing decentralized coordination of the UAVs or to build up a distinct relay network (Morgenthaler et al. 2012). A long-range control channel may also be deployed by a third device, e.g., using LoRa[4].

System Application

These extensions on the simulator layer now provide the capabilities which are necessary to develop and evaluate a mobile aerial system in SIMONSTRATOR.KOM. We utilize the interfaces given by the simulator to define a modular system design that is independent of the simulated UAV and thus of its hardware. On each UAV, a Strategy Controller is responsible to execute a given strategy and fulfill the states mission objectives. Controlling the autopilot and using communication devices is available through provided interfaces. Sensor readings like the vehicle's location or battery levels can also be obtained and may be included in the strategy execution.

Base stations, in contrast, run a Strategy Coordinator in the application layer. It is responsible for managing all strategies currently in execution. Several strategies can run in parallel, each of them with its distinct set of UAVs. Executed strategies on the base station are responsible for the coordination and control of their respective UAVs. Hence, each strategy used in the application requires a definition for UAVs and another for the base station.

SUPPORT STRATEGIES FOR POST-DISASTER COMMUNICATION NETWORKS

As shown in our previous work Álvarez et al. 2018, the typical human behavior of forming groups and loitering around important locations, in the field test three different villages, leads to heavily intermittent communication islands in the DTN-MANET. Conventional dissemination methods that rely on occasional and uncontrollable encounters of nodes, therefore, cannot provide sufficient communication performance. Especially for high priority messages such as emergency calls, long propagation delays are unacceptable (Álvarez et al. 2018; Baumgärtner et al. 2017).

Small, commercially available UAVs could be used as controllable communication bridges between separated islands. The simulation platform for Unmanned Aerial Systems presented in this paper empowers the assessment of the feasibility and the impact of such a deployment. System behavior is defined by strategies which can be customized and exchanged, allowing to evaluate the advantages and disadvantages of different strategies. Furthermore, adapting parameter settings in the simulation enables the assessment of each strategy with different UAVs or under varying environmental influences. Thus, this platform provides an extensive scope of potential systems that can be developed and evaluated.

As a proof-of-concept, we designed a UAS for the support of civilian-centric post-disaster emergency communication networks. Two basic strategies with distinct features and requirements were implemented to show the wide range of possible UAV deployments (c.f. Figure 5), namely a full-coverage relay mesh requiring large numbers of UAVs (Morgenthaler et al. 2012) and a message ferry approach with only a few UAVs moving between fixed locations (Zhao et al. 2004). Both strategies use multicopter UAVs and are evaluated for their impact on a ground-based network using the DTN-MANET protocol HyperGossip (Khelil et al. 2007).

The idea of the relay mesh strategy is to provide a provisional communication infrastructure to an affected area. Ground devices communicate with the UAVs which act as relay nodes within the dedicated aerial relay network (Morgenthaler et al. 2012). UAVs collect messages and further disseminate them through the relay network, other UAVs then distribute the messages down to the DTN-MANET nodes. The advantage of this strategy is the complete coverage of the affected area, with short delivery delays and also exhaustive message distribution. However, the large amount of required UAVs is a considerable drawback. To provide full-coverage service in a 4 km^2 area with an approximated 75 meters transmission range for the WiFi communication given by the simulator, the distance between UAVs should not exceed 150 meters. Thus, at least 178 UAVs are required to staff each location in a quadratic equidistant relay mesh. For continuous service, however, additional UAVs are required as replacements, otherwise vacancies in the mesh will have a negative impact on the performance. By executing simulations with the graphical representation, as shown in Figure 6, we figured out that 200 UAVs are sufficient to provide continuous service in the complete area without vacancies in the mesh.

The message ferry approach (Zhao et al. 2004) utilizes UAVs as controllable and highly mobile nodes to amplify the communication performance amongst intermittent communication islands forming around important locations. On each of the islands, UAVs hover for some time—in our simulation set to 30 seconds—while collecting and distributing DTN-MANET messages. After that, they move to the next island in the sequence, where the procedure is repeated. UAVs are therefore simple data carriers, but due to their high velocity and independence of roads they

[4]https://lora-alliance.org/

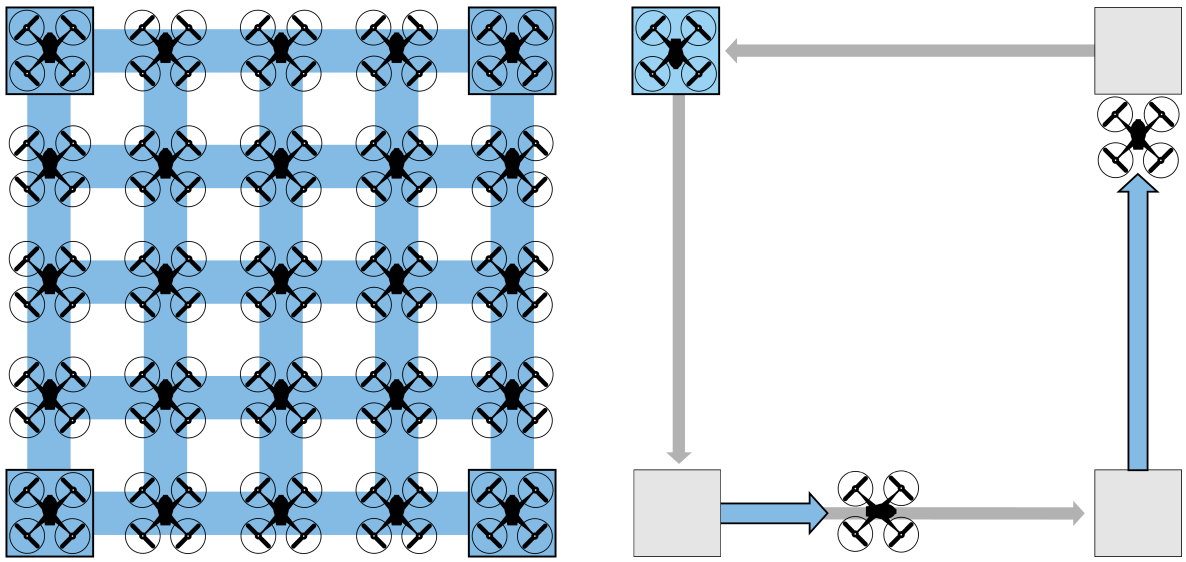

Figure 5. Visualization of two basic, but very different support strategies. Left: Full coverage mesh with equidistant relay node positioning, high requirements on the number of available UAVs. Right: Message ferry strategy, few UAVs can carry data between communication islands but it requires physical transport of each message.

can distribute their messages significantly better than achievable by foot or by car. The advantage of this strategy is a faster message dissemination compared to the conventional DTN-MANET store-carry-forward principle. Furthermore, the strategy can also be executed with only a single UAV, but we expect performance to increase with more UAVs. The drawbacks are a longer and less thorough message dissemination in comparison to the relaying mesh, and most significantly the necessity to know the location of communication islands in advance. In this implementation, a single shortest route connecting all islands and the base station is calculated. Locations are approached sequentially in the same order by each UAV. Performance increases by using multiple or different routes are open for further research.

Both strategies are evaluated with the parameters summarized in Table 1. A 2 km x 2 km inner-city area is simulated for 5 hours with 100 ground nodes moving as pedestrians on walkways. Nodes choose their targets from important locations such as market places, parks, or hospitals. On arrival, nodes stay at the location for a certain pause time between 5 minutes and 5 hours. These pause times model human behavior like social grouping and tasks that have to be executed at these locations, as shown in the field test (Álvarez et al. 2018). A workload generator creates a broadcast message to all nodes every 10 seconds on a randomly chosen node. After a defined message lifetime (time-to-live, TTL) of 30 minutes, messages are discarded and removed from all nodes. As evaluation metrics, we measure the recall, as the percentage of nodes that have received a message within the TTL, and delivery delay, representing the time it took to reach all nodes. Evaluation results are shown in Figure 8 for recall and delivery delay, comparing the DTN-MANET without support against the mesh and the ferry strategy, respectively. Simulations were repeated ten times with varying random seeds. Boxes indicate the 25th and 75th percentile with the median value as bold dash and whiskers indicate the 2.5th and 97.5th percentile. The horizontal axis shows the different pause time, ranging from 5 to 60 minutes minimum pause time, and also without movement between islands.

It can be observed that the unsupported DTN-MANET is behaving as expected. With less inter-island movement, recall drops due to fewer encounters with other nodes, to a point when messages are only distributed within an island when there is no node movement. However, even with 30 minutes TTL and node movement, messages are distributed to 4 of 5 islands at best. Furthermore, more than 50 percent of delivered messages require more than 9 minutes, and 25 percent need more than 20 minutes for their dissemination. As seen in the setting without movement, message dissemination within a communication island is very fast. Measured values show a delivery delay of a few milliseconds on average.

The mesh strategy achieves a perfect recall and very short delivery delays. In some cases, nevertheless, dissemination can take a few minutes to reach every single node on the ground. This results due to packet collisions during the message propagation to or within the DTN-MANET, since relay nodes only push new messages down to the ground nodes once. In accordance with the HyperGossip protocol (Khelil et al. 2007), messages are stored and only forwarded if a previously unknown node is met. Thus, the forwarding is only triggered by nodes moving to a new communication island.

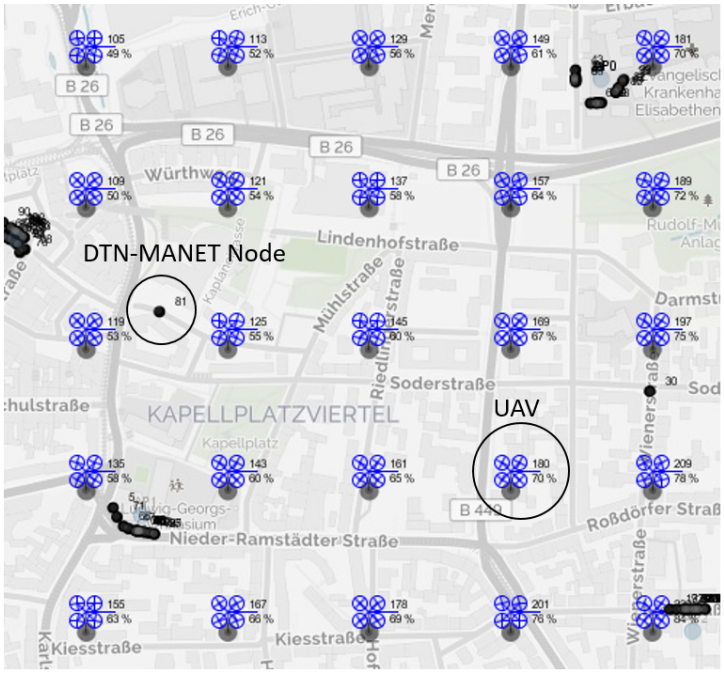

Figure 6. UAVs form a relay mesh in an urban environment. The graphical representation of SIMONSTRATOR.KOM shows UAVs hovering above the map and DTN-MANET nodes on the ground. Nodes use pedestrian walkways when moving or gather around important locations. UAVs are visualized with their current battery levels.

As shown in Figure 7, message ferries follow a predefined path. Since the physical movement of the messages is required for the dissemination, there are significant delivery delays in comparison to the mesh strategy. However, delays are much smaller than for the pure unsupported DTN-MANET environment, most of them in the range of 5 to 10 minutes. With node movement, delays are considerably higher due to the lack of node encounters while they move between islands. This also has a small negative influence on recall, if the message lifetime is exceeded while a node moves. As a consequence, the message ferry approach performs best when the ground network topology is not changing and every node is part of a communication island.

In conclusion, the relay mesh strategy outperforms the ferry strategy in both recall and delivery delay. However, the mesh strategy is highly inefficient in environments with communication islands, due to the large sparsely frequented areas in between where no UAVs are needed for communication support. As the number of UAVs influences both the complete system costs in acquisition and maintenance, the amount of required infrastructure such as landing pads and battery chargers, as well as the size of necessary power sources, an efficient utilization of the available UAVs is key. The message ferry strategy on the other hand requires significantly less UAVs and specifically targets

Parameter	Setting
Simulated Time	5 hours
Simulated Area	2 km x 2 km
Number of Islands	5
Number of Nodes	100
Node Movement	1 – 2 $\frac{m}{s}$
Pause Time	5 – 300 minutes
Message Lifetime (TTL)	30 minutes
Message Generation	1 broadcast every 10 seconds
Mesh Strategy	200 UAVs, 150 meters mesh distance
Ferry Strategy	10 UAVs, 15 $\frac{m}{s}$ speed
UAV Flight Time	20 – 25 minutes
UAV Flight Altitude	30 meters
UAV Battery Replacement	60 seconds

Table 1. Simulation parameter settings for the urban scenario.

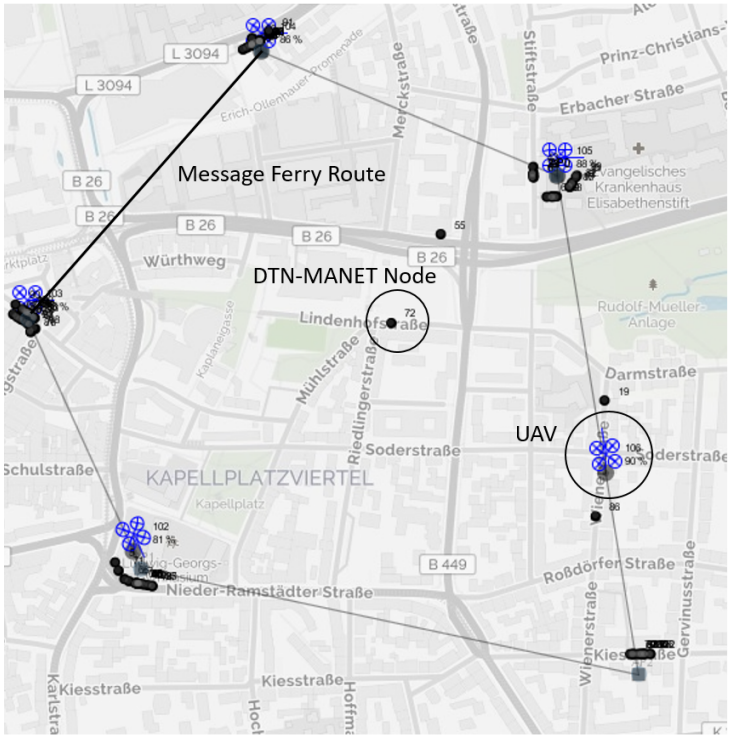

Figure 7. Message ferry UAVs move between five communication islands. They hover above each location while exchanging messages with the DTN-MANET nodes on the ground, before moving to the next. UAVs only visit statically defined islands, thus, nodes out of transmission range cannot be reached.

the dissemination between communication islands. However, for a practical real-world application, the system must be configured such that it performs well in the considered scenario by using the available resources in a meaningful way. We therefore analyze the impact of the number of available UAVs on the ferry strategy. Therefore, we map the environmental characteristics of the field test (Álvarez et al. 2018) into the simulation platform as displayed in the visualization in Figure 9. This contains the underlying map of the area, the number of participants and the movement patterns between the three different villages.

With normal movement speed, it takes a node approximately 12 minutes to walk from Village B to Village C and approximately 50 to 70 minutes to walk from Village C to Village A. In the field test area, there was no direct walking path connection between Village B and Village A. We use 10 different seeds for the simulation to alternate the movement and the workload generator. Available UAVs were varied between 0 and 20 and a TTL of 10, 30, and 60 minutes was considered, respectively. Although a 10 minutes TTL is too short for common DTN-MANETs, results give insight into the possibilities of quick dissemination regarding emergency calls enabled by UAV support.

As indicated by the straight lines in Figure 9, UAVs fly directly between villages. The flight duration between Village B and Village C is 45 seconds, between B and A 4.4 minutes, and 4.1 minutes between A and C, respectively. UAVs need 18 seconds between the UAS Base Station and Village C, and furthermore, will hover over each village for a dissemination time of 30 seconds. Because the combination of flight and hover time will consume more than 53% of the full battery capacity, a UAV will not be able to complete more than one iteration. Thus, it will return to the base station after visiting Village C, B, and A consecutively, for a 60-second battery exchange phase. The total time it will take a UAV to complete one full iteration including dissemination and battery exchange, therefore, is around 12 minutes.

Figure 10 depicts the results for recall and delivery delay, starting with no UAV support up to 10 message ferry UAVs. Boxes indicate the 25th and 75th percentile with the median value as bold dash and whiskers indicate the 2.5th and 97.5th percentile. The results for 11 up to 20 UAVs are not displayed in the figure, because only minor changes in the delivery delay are perceived.

With no UAV support and a TTL of 10 minutes, messages only spread in the village where the message is generated, resulting in approximately a third of the nodes receiving the message with a very low delivery delay. With a TTL of 30 and 60 minutes, the movement of the nodes is sufficient to deliver messages between the different villages, resulting in a median recall value of 0.7 and 0.8, respectively. However, Figure 10 shows that one or two UAVs

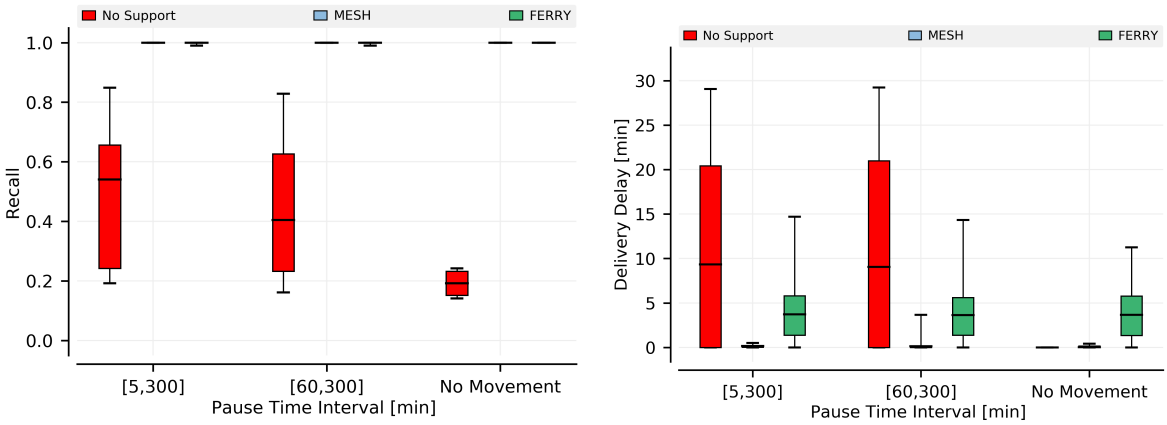

Figure 8. Recall (left) and delivery delay (right), comparing the DTN-MANET without support to the relay mesh strategy and the message ferry strategy, respectively.

Figure 9. Simulation of the field test environment in SIMONSTRATOR.KOM. Similar to the behavior perceived in (Álvarez et al. 2018), most nodes group within the three villages. Only a few nodes move between the villages using the roads connecting Village A and C (approximately 5 km) and Village B and C (approximately 1 km). The UAV Base Station is located near Village C. Straight lines indicate the route UAVs take, reducing the distance between Village B and C to around 660 meters as well as the distance between Village A and C to under 3.7 km. The full route including the distance to the UAS Base Station is around 8.6 km long, one UAV takes around 12 minutes to complete one full iteration, including the time for dissemination and battery exchange.

increases the recall significantly, regardless of the applied TTL. As this requires the physical transport of messages transmitted to other communication islands, the perceived delivery delay also increases, best seen in the results for 10 minute TTL. The utilization of additional UAVs further increases the recall while reducing the delivery delay. However, due to the fixed route between villages and the base station, which the UAVs traverse, more UAVs will only result in decreased intervals between visits of UAVs in the villages. The route traversal time stays the same, nevertheless, which leads to a saturation of the system. Thus, no more significant changes in both recall and delivery delay are perceived. Furthermore, the optimal recall of 1.0 cannot be reached for a TTL of 10 or 30 minutes due to nodes moving in between communication islands. Messages that are generated during the transit can expire before the node reaches an island, with increasing negative influence for smaller TTL settings. This problem cannot be solved by the used message ferry strategy, e.g., by increasing the used UAVs, but requires more complex strategies that are left open for further research.

Evaluation results like this can be used to design and optimize a Unmanned Aerial Communication Support System for specific scenarios. Regarding the characteristic of the supported DTN-MANET, required strategy properties can be determined. For example, when supporting a DTN-MANET with a TTL of 60 minutes 2 UAVs are sufficient to achieve optimal recall in our scenario. Utilizing additional UAVs result in lower delivery delay, however, more than 7 UAVs do not yield significant improvements, reaching a delivery delay of less than 10 minutes for approximately 75% of the messages.

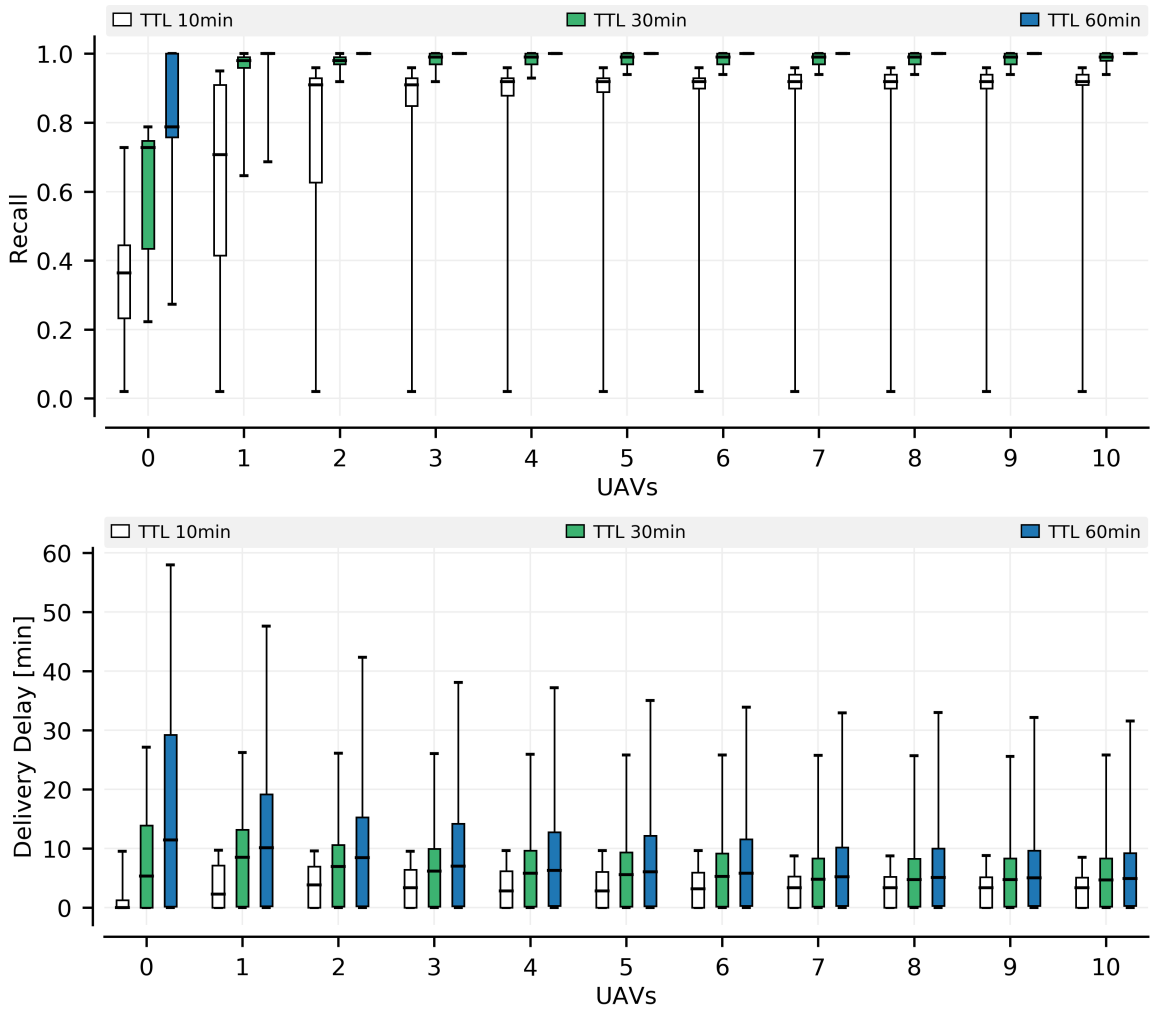

Figure 10. Recall and delivery delay variance shown for increasing numbers of UAVs. The TTL was set to 10, 30 and 60 minutes, respectively. As indicated, a few UAVs already significantly increase the communication performance, especially with longer TTL. The setting '0 UAVs' shows the unsupported DTN-MANET performance.

CONCLUSION, DISCUSSION & FUTURE WORK

In this paper, we motivated the need for efficient UAV-based communication bridges between DTN-MANET communication islands in post-disaster scenarios based on our findings from a large-scale field test (Álvarez et al. 2018) and other related work. However, to assess the performance of individual strategies for the deployment and coordination of UAVs, it is not feasible to repeat such tests on a regular basis. To address this issue, we proposed a discrete event-based simulation platform for Unmanned Aerial Systems (UASes) in this work, combining models for an individual UAV's behavior and its communication abilities with a fully-fledged network simulator for DTN-MANETs for the first time.

To showcase the capabilities of our platform, we discussed two representative strategies for large-scale UAV support of a DTN-MANET in post-disaster scenarios. We evaluated both strategies in an urban environment, highlighting their individual cost vs. performance profiles. Additionally, we provided an in-depth discussion w.r.t. the meaningful utilization of resources by modeling the conducted field test in our simulation platform and evaluating the message ferry strategy with different amounts of UAVs. Our evaluation successfully demonstrates the ability of our proposed platform to assess the performance of UASes and the determination of critical strategy properties in combination with various DTN-MANET scenarios.

For future work we plan to integrate additional models, such as channel models for long-range communication (e.g., LoRa) and other UAV types (e.g., fixed-winged UAVs) into our platform. Furthermore, we want to assess the ability of UAV support strategies to adapt to changes in the DTN-MANET caused by human behavior and changing communication demands (Klinsompus and Nupairoj 2015) and message type priorities (Lieser, N. Richerzhagen, Luser, et al. 2019) over the course of the disaster. Therefore, monitoring techniques in a resource-constrained environment are of great interest.

ACKNOWLEDGMENT

This work has been co-funded by the following projects: the LOEWE initiative (Hesse, Germany) within the NICER[5] and the Natur 4.0 project, the German Federal Ministry of Education and Research (BMBF) within the SMARTER[6] project.

ABSTRACT

Crisis Management (CM) refers to the ability to deal with crisis tasks in different phases and iterations. People working in a crisis are generally under stress to make the right decision at the right time. They have to process large amounts of data and to assimilate the received information in an intuitive and visual way. Visual Analytics (VA) is potentially useful to analyze and understand the huge amount of data in several areas including in a crisis. We designed a survey protocol to understand which themes influence visualizations to support CM. In previous work, we carried out systematic mapping studies, analysis of official documents, ethnographic studies, questionnaires during the large events held in Brazil in recent years. In this work, we interviewed eight CM specialists. We analyzed this data qualitatively with the coding technique. Then we evaluated the coding results with the focus group technique. With the results, we identified the relationships between the visual needs and other main themes of influence for CM. This thematic synthesis enabled us to build a draft model based on VA. We hope that, after future cycles of validations and improvements, the agencies that manage crises might use this model as a reference in their activities of knowledge production and decision-making.

Keywords

Crisis Management, Decision-Making, Visual Analytics, Computational Model.

INTRODUCTION

Crises have very complex and dynamic contexts where the response process should suit unforeseen situations without causing social harm or jeopardizing people's lives (ESRI, 2009). Examples of crises that greatly stimulated research interest in this area were the attacks of September 11, 2001 and Hurricane Katrina in 2005 both in the United States. More recently, the Hurricanes Harvey, Irma and Maria and a sequence of terrorist attacks in European cities, mass shootings in U.S. among others have reinforced the interest in this area. Crisis management (CM) refers to the ability to deal with crisis tasks in all their phases and iterations. In general, this is done by multiple government agencies, which do not work together routinely. These agencies usually use the doctrine of Command and Control (C2) to help in the coordination of activities (Turoff *et al*., 2004). C2 is the exercise of authority and direction by a properly designated commanding office over assigned resources in the accomplishment of a common goal (Builder *et al*., 1999).

CM varies because the context, events and information are never the same from one crisis to another. Each management task requires many different types of information about the incident from several sources (Turoff *et al*., 2004), such as information systems, external proprietary databases, resources in the field, internet of things sensors, social media and other open source media. Nowadays, C2s are equipped with breakthrough technologies, especially visual systems, such as the latest generation mobiles, tabletops, video walls and e-caves (Dusse *et al.,* 2016). This union of data sources and novel technologies provides C2 with huge amounts of information of great heterogeneity.

Decision making during a crisis requires having the right information, provided in the right way, to the right people, at the right time. While crisis managers working in a crisis are generally under stress, they have to make effective and agile decisions. Having reliable and up to date information is essential in order to help in the making of such decisions (Yates and Paquette, 2010). Crisis managers need to assimilate the received information in an intuitive way and the information needs to be adaptable in the context of the current crisis. In addition, if the information is not presented in effective ways, it can be hard to analyze it, or in the worst cases, it can be misinterpreted. Literature shows that suitable information visualization techniques improve the understanding of crisis information (Ciolkowski *et al*., 2003; Thom *et al*., 2012; Bosch *et al*., 2013).

Recently, researchers have been using Visual Analytics (VA) to support understanding in this subject (Andrienko *et al*., 2007; Tomaszewski and MacEachren, 2012; Chae *et al*., 2014; Marbouti *et al*., 2017). VA is potentially useful for analyzing and understanding the huge amount of information produced in a crisis (Keim *et al*., 2008). The benefits brought by VA to the analysis of crisis information also come along with certain challenges. These include: (1) how to map VA concepts with the countless variables of a crisis to support the managers in quickly identifying reliable information to make decisions; (2) whether researchers and practitioners are using VA techniques and tools effectively to tackle challenge 1; and, (3) how to enhance VA applications with minimal impact on current CM activities.

This paper extends our previous work (Dusse *et al.,* 2018), in which we presented the data collection from the literature through a systematic mapping study and *in-vivo* studies such as ethnographies and questionnaires. In this present work, we interviewed eight CM experienced professional from different C2 Centers. We crosschecked and analyzed this dataset qualitatively with formals techniques, coding and focus group in particular. These investigations are the initial part of a broader work that aims to define a computational model (see Figure 2). The main objective of this model is to use VA to enhance decision-making in CM. The research question of the broader work is "What aspects of visualizations are under-exploited in supporting decision-making in Crisis Management?" The data analysis reported in this paper is geared to answering this question.

We concluded in our previous work that the full potential of VA is not being applied in the state-of-the-art and state-of-the-practice of CM domain. In this present work, our data analysis identified the relevance of other themes, such as context, processes and human behavior, which are fundamental to decision-making. We concluded that researchers and practitioners do not pay due attention to key themes that they should be aware of and incorporate these into visualization tools. Thus, we used the results of this analysis to build a draft model based on VA. We hope that, after future cycles of validations and improvements, the agencies that manage crises might use this model as a reference in their activities of knowledge production and decision-making.

The rest of the paper is structured as follows. In the following section, we present the research design used in this work. We then describe the research execution and research evaluation, respectively. Then we discuss the lessons learned from this study and contributions achieved in this research. In closing, we suggest future research directions and we summarize our conclusions.

RESEARCH DESIGN

This work originated from three sources: i) the Brazil-European Union Rescuer Project (Villela *et al*., 2014), ii) a partnership that we have with the Public Security Secretariat of the State of Bahia (SSP-BA, in Portuguese) and, iii) the large events that occurred in recent years in Brazil, namely the 2014 Soccer World Cup and the 2016 Olympics Games. Below, we explain how this came about.

Background Information

From 2013 to 2016, we collaborated as a coworker with the Fraunhofer Project Center for Software and Systems Engineering at Federal University of Bahia (UFBA, in Portuguese)[1] and other Brazilian and European institutions in the scope of the RESCUER Project[2]. The RESCUER project involved developing a smart and interoperable computer platform for using crowdsourcing information mashed up with open data to support CM. In the scope of RESCUER, we decided to carry out a Systematic Mapping Study on how information visualization is applied in CM. We aimed to understand this area from literature reviews and visiting C2 centers in Brazil and Europe. Our goal was to find gaps and trends in the area.

Due to our partnership with SSP-BA, we had access to Intelligence and Operation Center (COI, in Portuguese)[3], which is a branch of the Secretariat. Located in the city of Salvador of the state of Bahia in Brazil, COI was

[1] http://www.fpc.ufba.br

[3] http://www.ssp.ba.gov.br/2016/07/1237/Centro-de-Operacoes-inicia-nova-fase-da-Seguranca-Publica.html

created in 2016, taking the place of the Regional Command and Control Integrating Center in the State of Bahia (CICCR-BA, in Portuguese). Previously in 2011, the Federal Government of Brazil created the Extraordinary Secretary of Security for Large Events (SESGE, in Portuguese)[4], which is a branch of the Brazilian Ministry of Justice. The main purpose of SESGE is to coordinate the activities of the agencies involved in public security and civil defense during large events that have taken place in Brazil in recent years. In 2013, SESGE set up C2 centers in headquarter cities of large events. The old CICCR-BA was one of these. In these centers, multi-agencies work together in the coordination and sharing of resources (human, equipment, software).

In our previous work (Dusse *et al.,* 2018), we explored the CM activities in COI and visited two other Brazilian C2 centers and another in Europe: Regional Command and Control Integrating Center of the State of Rio de Janeiro (CICCR-RJ, in Portuguese), Command Integration Center of the City of Porto Alegre (CEIC, in Portuguese), Defense Zone of the Paris Police Prefecture (DZPPP, in French). Visiting C2 centers was very useful to compare and map similarities and inconsistencies among them. Practitioners in C2 environments work under strict time constraints, they work under a rigid schedule in scheme 24/7/365(6), i.e. without work stoppages. Hence, we planned to explore the best way the time spent of the visits. Thus, we carried out parallel researches: we made observations through ethnographic studies, we ran on-line questionnaires and we interviewed experienced crisis managers through a *survey protocol*. In this present paper, we report on the continuation of this previous work, specifically detailing with the interviews and the results obtained.

Survey Protocol (Interviews)

We conducted semi-structured interviews with eight crisis managers (domain specialists) from different places and countries: seven Brazilians and one French, from four different C2 centers, four specialists from COI, two specialists from CICCR-RJ, one specialists from CEIC and the last one from DZPPP. Since the interviewees had strict time constraints, the interviews took no more than 40 minutes on average.

We formalized the interviews in a survey protocol based on the rules in (Claes *et al*., 2000). The survey process consisted of six steps:

- **Step 1. Survey Definition:**

We determined the goal of the survey based on the objectives of this work. This is to investigate what the themes are and how they influence CM decision-making and how we can treat these themes using VA.

- **Step 2. Survey Design:**

We designed the survey defining interviewees, terms, materials, tasks, criteria, attributes, among others. We defined the techniques for data collection, the techniques for data analysis and the techniques to evaluate the results of the survey

We decided to conduct semi-structured interviews with at least three subjects (domain specialists). Semi-structured interviews are open-ended, more dynamic and allows for improvisation on the part of the interviewer and scope for a fuller exploration of the studied objects (Runeson and Host, 2009).

We decided to use only practitioners as subjects because they are familiar with the challenges of CM and face them every day in practice. We prepared two terms: term of consent and term of authorization of data publication. In the first one, the subject consents his/her participation with full knowledge of the nature of the procedures, with free will and without any coercion. The second term authorizes the authors to publish the collected data as they see fit, respecting individual data such as name and workplace.

Based on previous work (Dusse *et al*., 2018), we defined **three preliminary key factors** to guide the data collection and analysis. Table 1 describes these factors.

We formulated the questions and decided to do a pilot interview (Wohlin, 2000). The pilot was to make sure that the survey design was strict and reliable. The pilot led to an improved the survey protocol, if we detected problems or omissions in its procedures. We invited three domain specialists. The first interviewee was selected to perform the pilot study. After some improvements in the design, we carried out the other two interviews (subjects). At the end of the interviews, we asked the subjects to recommend other potential subjects; in total, we interviewed eight specialists. The survey design — which includes the preparation of the interview with the questions, the terms and other materials — is available on-line[5].

Table 1: Preliminary Key Factors

Id	Key factors	Description
1	Raw Data	This refers to a set of values of variables collected from a source with no handling with which one obtains information to support factor 2.
2	Information Visualization	This factor defines the area that we are investigating to support factor 3.
3	Decision-making	This factor defines the main process that our study aims to support in the CM area.

We decided to use the *coding* technique to analyze the data. This is as an established technique in the literature to analyze qualitative datasets, such as transcriptions of interviews (Saldaña, 2015). It classifies the data in codes and clusters them into categories and major themes.

Lastly, we designed a *focus group* session to validate our analyses. We involved two researchers, one as moderator and the other as observer, and a group of specialists, some were interviewed (subjects) and others were not.

- **Step 3. Survey Implementation:**

We prepared the material necessary for the interview (subject invitation, room, audio recorder, pen, paper, etc.). In this step, we also did a pilot interview to refine the Protocol. It is important to highlight that this interview was not part of our analysis. As we mentioned in Step 2, we used it for the sole purpose of evaluating the strictness of the survey design. The pilot study allowed us to train the survey protocol and to improve the task description and goals.

- **Step 4. Survey Execution:**

In this step, we carried out the interviews. As mentioned, we carried out seven interviews (eight with the pilot) with practitioners, from four different C2 centers and two different countries. We recorded all the audios of the interviews. In the opening of the interview, as we designed, we asked the subjects to sign two terms: the consent form and authorization form. All subjects signed the consent form but two subjects signed the authorization form with reservations. They said that we could use what was spoken but without making any reference to the name of the interviewee nor where he/she works.

- **Step 5. Survey Analysis:**

Between the interviews and the analysis, we transcribed the interviews verbatim by listening and re-listening to the recording. We carried out the interviews in Portuguese, apart from one in English. Concerning this specific interview, after the transcription, we translated it to Portuguese. The transcripts of the seven interviews produced 127 pages of text.

We discarded one interview because the subject's answers were too superficial and, despite our attempts, he was not able to make the link between the preliminary key factors. We found that this subject did not have adequate knowledge to meet our goals defined in Step 1. We assumed that discarding this interview would not affect the results.

After the transcription of all the interviews, we sent emails to the subjects, attaching the transcribed text of their interview. In general, in an interview, people do not have much time to think about their answer. The purpose of the emails was to give them the opportunity to review their answers in their own time. As the interviewees work with strict time constraints, few returned our emails. Those who replied to our emails did not make relevant comments.

We also interacted with the subjects, days after the interviews, mainly with the ones that worked in COI. Whenever doubts arose regarding what some subject meant at some point in the interview, we looked for the subject and tried to clarify the doubts. These informal conversations with the specialists took no more than 2 minutes on average and they were repeated countless times. These informal conversations do not constitute the same scientific evidence as the survey protocol, for example, we did not plan nor record them. However, the data collected in these conversations were important for our study, mainly to mitigate some threats to the validity.

In a preliminary analysis, we found that according to the subjects managing a crisis is very complex. Many factors can influence the whole process, from the planning of the data collection to decision-making and its

operability. About the visual tools themselves, they outlined that tools are not prioritized, as they should be. They added that they need investment and research in this area. We conclude that in a multidisciplinary domain, such as CM, it is very hard to prioritize the factors that influence decision-making and it largely depends on the context and human aspects. You cannot neglect any factor, otherwise the response can be disastrous.

We analyzed the data in depth using a qualitative analysis technique. We identified specific segments of text to code, categorize and translate into major themes. As mentioned in Step 2 of the survey protocol, to analyze the data collected we decided to use the coding technique. Lastly, we evaluated our analysis findings using the focus group technique. We shall explain the data analysis in the following sections.

- **Step 6. Survey Packaging:**

The objective of the packaging step is to report the survey so that external parties can understand the survey scope and the results. We published the initial steps of our work (Dusse *et al.,* 2018). We also consider this text as part of the packaging.

It is important to cast light on the respondents' experiences. Their narrated experiences are very hard to gather from documents or observations. In the next sections, we shall explain in detail the research execution, i.e. the analyses of the data with the coding technique and we shall report the research evaluation, i.e. the evaluation of our findings, with specialists too, using the focus group technique.

DATA ANALYSIS

We analyzed the interview data using a qualitative analysis technique denominated coding.

Coding is an analytical technique used to extract quantitative data from qualitative datasets, such as **transcriptions of interviews**, observation field notes, journals, documents, photographs, video, websites, e-mail correspondence, and so on. A code is mostly a word or short phrase that symbolically assigns a summative, salient, essence-capturing, and/or evocative attribute for a portion of language-based or visual data (Saldaña, 2015). Our coding process can be divided into three sequences of data clustering: audio excerpts into codes, codes into categories and categories into themes.

Clustering audio excerpts into codes

We based our code inclusion criterion on the preliminary key factors defined in the survey protocol (see Table 1). We recorded the audio of the interviews to listen and re-listen to them. Then, we transcribed the interviews verbatim. **If the subject mentioned, directly or indirectly, one of the key factors in the interview**, then we extracted the exact excerpt from their speech and, after summarizing it, we described it with one or more codes.

In order to facilitate this scheme, we performed **tasks** that we believe were productive in the coding extraction (see Figure 1).

1. We extracted excerpts from the transcribed interview and stored them in a first spreadsheet. If the interview was carried out in other language, we translated it into Portuguese (task 0);
2. We mapped each row of the spreadsheet with a excerpt id;
3. We copied this content in a second spreadsheet and summarized each line, without losing the spoken information by eliminating connection phrases, repeated or meaningless words;
4. We changed some words using synonyms and jargon of the area in order to standardize the excerpts;
5. We rephrased negative phrases into affirmative ones without losing the original meaning (e.g. “the room is not light” we rephrased to “the room is dark”);
6. We selected keywords from each row and summarized them again in a third spreadsheet;
7. Based on the keywords, we defined our codes in a fourth spreadsheet. A set of keywords can derive one or more codes;

From task 1 to 6, we simplified multi-line excerpts into a small set of keywords. This greatly helped our coding process. Using keywords, it was easier to code each row of the third spreadsheet. In some cases, we defined more than one code per row (task 7). In these cases, we split the row according to the number of codes. In each new row, we mapped a unique code with one, some or all keywords, depending on the case.

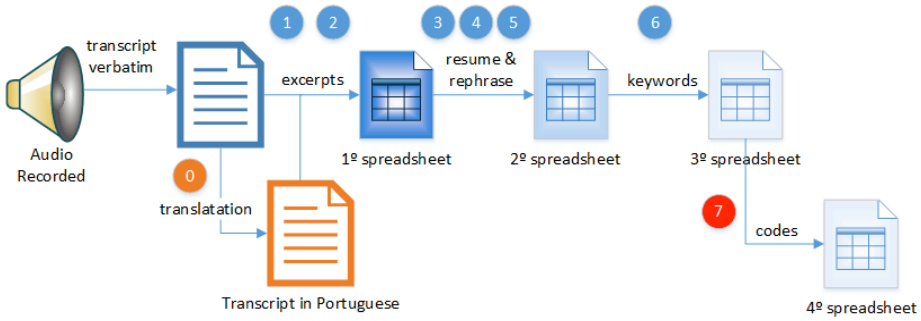

Figure 1: Coding Extraction Tasks

Clustering codes into categories

After the extraction, we organized and grouped similarly coded data into categories because they share some characteristic (patterns). We used constant comparison, scoring, filtering and clustering of codes in the analysis of each dataset collected from the interviews. That is, when we found a reference to a particular category during this analysis, we could either create a new category or refine ones that already existed. Thus, we improved the coding classification with only relevant categories.

After the categorization of all codes, we applied an exclusion criterion that we defined in our survey design: we eliminated categories that only have codes from the same subject. When this happened, we tried to reallocate the codes in other categories that have codes from a distinct subject. However, in some cases it was not possible, so we excluded the category and consequently the codes. In other words, we only maintained a category if at least two codes from different subjects belonged to this category, i.e., two subjects have to mention it. We believe that this reduces individual and biased opinions held by the subjects. Therefore, each code belongs to one or more category, and one category contains at least two codes.

Clustering categories into themes

Then, in order to discern and label the coding categories, according to the needs of the investigation, we clustered the categories into major themes. Themes reduce large amounts of codes into a smaller number of analytic units. The thematic analysis process consisted of identifying, analyzing and reporting patterns (themes) within the coding category. Using Boyatzis, (1998) approach of building a quantitative description of the frequency of themes and forming clusters of them, we identified relationships and patterns and grouped summarizing the coding categories into themes. As well as the relationship between codes and categories, each category belongs to one or more theme, and one theme contains at least two categories.

This sequence of steps, i.e. the code inclusion, categorizing the codes, category exclusion and clustering the categories into themes, is our code process that comprised the overall coding classification. A couple of samples of out coding process is available online[6]. This process was not trivial, because a code may belong to more than one category, which in turn may belong to more than one theme. In total, we built about 300 codes. We did refinement iterations and at the end of the coding process, we reduced this to 178 codes. We classified the codes into 44 categories, of which 36 are unique (i.e. the same category could be in more than one theme), which in turn we translated into 6 major themes.

We defined a coding classification for the relevant factors that might exert some influence on CM decision-making and how visualizations can address these factors. Table 2 shows part of this classification (without the codes). The whole classification is available online (in Portuguese)[7]. In some cases, a code can have the same name of a category that in turn can have the same name as a theme, e.g. "Processes" category (id 08) and "Processes" theme. This duality of name happens in all themes except for "Context". The ids of categories "Data Management", "Information Visualization" and "Decision Making" begin with the character 'P' to indicate that they are examples of processes. In Table 2, we highlighted the categories that belong to more than one theme. Bold categories are those that are repeated in two different themes, e.g. "**Technology X Employees**". Bold and Italic categories are those that are repeated in three different themes, e.g. "***Information Visualization***". Bold, italic and underlined categories are those that are repeated in four different themes, e.g. "***Decision-Making***". No category is in five or six themes.

Lastly, we scheduled a focus group session, based on the guideline proposed by Sobreperez, (2008). The objective is to validate our analysis, mitigating some threats to its validity, e.g. biases of the researchers.

FOCUS GROUP

We looked for domain specialists to evaluate our data analysis. We decided to carry out a focus group to mitigate our findings doing double-check with specialists, e.g. categories and themes identified by the coding.

We executed the focus groups session following similar guidelines used in the interviews. We audio recorded all the session. In the opening of the session, we asked the specialists to sign the same two terms of the survey protocol: the consent form and authorization form. After the session, we transcribed it verbatim by listening and re-listening to the recording (we carried it out in Portuguese). We also sent the session transcription to the specialists to review their positions in their own time. We decided to send the session transcription to all the subjects of the interviews. We were interested in their opinions; however, we received no email feedback.

The focus group was semi-structured and guided by six open-ended questions. As with the interviews, the discussions were not restricted by the questions, they were open-ended, dynamic and we used some improvisations on the part of the interviewer within our scope of interest. We present the questions asked below.

- Question 1 (Q1): Are any of the major themes proposed that you do not consider relevant? Please, explain your answer.
- Question 2 (Q2): Are any of the categories proposed that you do not consider relevant? Please, explain your answer.
- Question 3 (Q3): Are there any relevant themes that in your opinion are missing? Which ones? Please, explain your answer.
- Question 4 (Q4): Are there any relevant categories that in your opinion are missing? Which one? Please, explain your answer.
- Question 5 (Q5): Are there any categories in a wrong theme? Please, explain your answer.
- Question 6 (Q6): Do you have any other comments, recommendations or suggestions for improving our classification?

We held the focus group meeting on February 8, 2018 at COI, during a large event called Carnival of Salvador. We set up the meeting with two researchers and three specialists. One researcher played the role of moderator and the other one observer taking notes during the session. One specialist participated in the interviews (Specialist A), another did the pilot interview (Specialist B) and the third specialist did not participate, until that moment, in the survey (Specialist C).

We previously arranged with Specialists A and B to be silent at the beginning, so Specialist C was the first to assess the result of the coding. It was the first contact of Specialist C with our study. Therefore, to mitigate bias, i.e. to mitigate that he/she just confirmed the opinions of Specialists A and B, we decided to do this.

After a brief explanation of our goals and what we had done until that moment, we asked Specialist C if the categories and the themes are representative (Q1, Q2, Q3, Q4, and Q5). Specialist C agreed. Then Specialists A and B also validated our preliminary results positively. They gave some compliments and queried some missing categories but, after a brief discussion, everyone accepted that the 35 existing ones represented the categories they thought were missing (e.g., they missed a *'Budget Constraints'* category, however, they agreed that the "Lack of Resources" category covered this).

Regarding Q6, Specialist A synthesizes in two opinions.

"*Brazil chooses the military practices of Command and Control. Perhaps, in the last decade, due to immaturity, it was the right model, but today it is more than proven that this model is saturated"*. (Specialist A)

"*Militarism is too rigid. The problems, nowadays, are dynamics. We need flexible actions, flexible tools, each case has its particularities, which cake recipes do not solve. So I think that your model is complete and has the flexibility we need to operate in the various (crisis) cases*". (Specialist A)

In addition, Specialist B concluded.

"*The current tools do not support effective actions to reduce response time or operational errors. I think it is the reason why there are so many negative opinions in this topic. I agree with him* (with Specialist A). *I think you are researching themes that we do not give due attention*". (Specialist B)

Figure 2 summarizes our survey protocol. We started collecting data from interviews focusing on **3 key factors** (raw data, information visualization and decision-making). We selected the excerpts of the interviews where the subject mentioned one of the key factors and carried out the coding technique. We categorized the codes looking for patterns (e.g. blue code β and red code γ are in the same category). We excluded the categories that only have codes from the same subject (e.g. yellow code α). We clustered the categories in **6 themes.** We carried out a focus group with domain specialists to validate our findings. These were the steps used to develop the draft model.

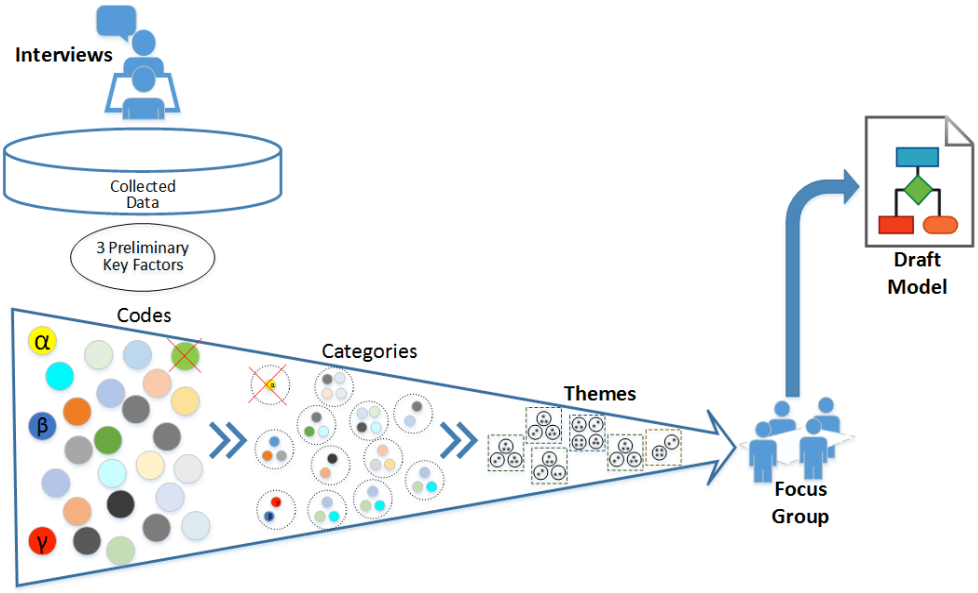

Figure 2: Summarization of the Survey Protocol

RESULTS

The use of empirical techniques based on the qualitative research approach enriched the results of this work. The partnership between domain specialists and us facilitated contact with them and helped in the execution of the activities. The tasks applied such as documents analysis, semi-structured interviews, transcriptions, translations, codings and others were not automated. It adds qualitative value to the results and decreases the possibility of errors.

Regarding the overall survey tasks: the transcriptions, translations and codings were time consuming. We spent on average five hours transcribing every 30 minutes of recorded audio. We had to repeat some audio excerpts many times pausing, going back, going forward and so on. We spent on average one hour per page translating from English to Portuguese. Our coding tasks required that all the interviewee transcriptions were in the same language. We decided to translate the interviews from English to Portuguese, and not the opposite, for two reasons: firstly, to save time because six interviews (seven with the pilot) were in Portuguese and only one in English, and secondly, we did not have authorization to publish all the data. If we had authorization to publish, this would justify the effort of doing several translations to English instead one to Portuguese for obvious reasons, since English is a universal language in academia.

As we said in **survey design**, one interview we used as a pilot study, we discarded another one, so six interviews were coding analyzed producing 116 pages of text (about 60.000 words). On average, we spent four hours on preliminary coding for each transcript (first spreadsheet in Figure 1). The other tasks, which include filling the other spreadsheets, the identification of codes, categories and themes, we spent at least 3 months in total on these tasks. The transcription of the focus group sessions was also time consuming. The session lasted about 70 minutes and its transcription produced 31 pages of text (about 15.000 words).

The main result of the data analysis is the coding classification. We build a classification with these three items (codes, categories and themes). The main idea of the coding is to synthesize the interview data (into codes) and to find patterns (categories and in turn themes) to understand the main themes for CM decision-making. With the coding result, we could identify what aspects are relevant in this area based on the knowledge of those who are familiar with the challenges of CM and face them every day in practice: the crisis managers. Thus, based on three preliminary key factors (Table 1), we built 178 codes, 44 categories and 6 major themes (Table 2).

We refined the key factors into six coding themes (**Context**, **Processes**, **Human Behavior**, **Data Management**, **Information Visualization** and **Decision-Making**). In other words, our data analysis identified the relevance of other themes, such as context, processes and human behavior, which are fundamental to decision-making. We concluded that researchers and practitioners do not pay due attention to key themes that they should be aware of and incorporate these into visualization tools. Therefore, we found out that tackling information overload is necessary but not sufficient to contribute effectively in this research area. We need to tackle another problem that we call non-dedicated information (e.g. information about crisis context, processes and human behavior).

Besides this, we believe that information visualization is necessary but insufficient to tackle both problems. During our research, we also identified gaps and trends in the area. One of these trends is the use of Visual Analytics (VA). We found works in the literature, which addressed VA in crisis contexts that, according to the authors, generated excellent results (Andrienko *et al*., 2007; Chae *et al*., 2014; Tomaszewski and MacEachren, 2012). VA enables people to detect the expected and discover the unexpected (Cook and Thomas, 2008). Keim *et al*., (2008) adjusted Shneiderman's mantra (Shneiderman, 1996) from: "*Overview first, Zoom, Filter and Details on demand*" to: "*Analyze first, Show the Important, Zoom, Filter and Analyze further, Details on demand*". In other words, this mantra is calling for the astute combination of analytic approaches together with advanced visualization techniques. VA concepts led us to research this area in our work, so our solution addressed the two problems above: information overload and non-dedicated information.

While useful, the use of VA concepts in CM may add activities to management processes that may not be easy or fast to adopt. The benefits brought by VA to analyze crisis information also come along with certain challenges. These include: (1) how to map VA concepts with the countless variables of a crisis to support the managers in quickly identifying relevant and reliable information to make decisions; (2) whether researchers and practitioners are using VA techniques and tools effectively to tackle challenge 1; and, (3) how to enhance VA applications with minimal impact on current CM activities. We believe that a computational model can be used to tackle these challenges. In turn, now, our challenge is how to develop and apply such a model.

THREATS TO THE VALIDITY

A fundamental issue of any evaluation is to discuss how valid its results are (Wohlin *et al*., 2000). The threats to the validity of our study and how we mitigated them are described below.

Poor survey design based on a poor theoretical basis could figure. To mitigate this, we did a pilot interview to evaluate our survey protocol. CM is complex and dynamic therefore; research data collection in this area is also complex. The dataset collected might be incomplete or inconsistent. We mitigated this threat by collecting data from different research sources and using different approaches; i.e. literature, documents, software, observations, questionnaires in our previous work (Dusse *et al.,* 2018) and interviews with specialists, in this present work. In addition, we compared, crosschecked and triangulated all the collected data.

Concerning the results, we coded the collected data based on our own discernment. Due to resource and time issues only one researcher carried out the coding technique analysis (ideal would be at least two researchers to carry out independently and in case of disagreement a third opinion to reach a consensus). We might have classified it incorrectly or in a biased manner. In order to mitigate this threat, we interacted repeatedly with the subjects by email, informal conversations and carried out a focus group to validate our work. Moreover, the subjects could also be biased. Hence, we only included a coding category if two or more subjects mentioned it to eliminate any individual and biased opinion of a subject. In addition, concerning the results of the research evaluation, due logistical issues, all the specialists of the focus group session came from the same institution (COI). We invited specialists from other C2 centers and we planned to make web-conference but we gave up due the complexity involved. We mitigated this threat by sending emails with the session transcription attached to other CM specialists in the world to share with them and to know their considerations.

We believe that the data collected is representative of CM. In other words, we propose that any crisis manager, in any city around the world, can use our results, in a generic way, to support decision-making. We attempted to mitigate this threat because we collected data from more than one C2 center. In addition, the qualifications and work experience of the specialists minimized the impact of this threat.

FUTURE WORKS

As we mentioned, this work is part of a broader work. In this paper, we present the results of a survey based on past works (Dusse *et al*., 2018) and mainly on interviews with specialists in Crisis Management to understand the main themes that influence the information visualization, especially VA, to support decision-making. The objective of this broader work is to develop a computational model which; independent of standards, technologies and people, and regardless of the type of the crisis; may help crisis managers to make decisions

quickly and more assertive. In this section, we briefly present a draft model designed by us with our aim towards a robust computational model based on VA for CM.

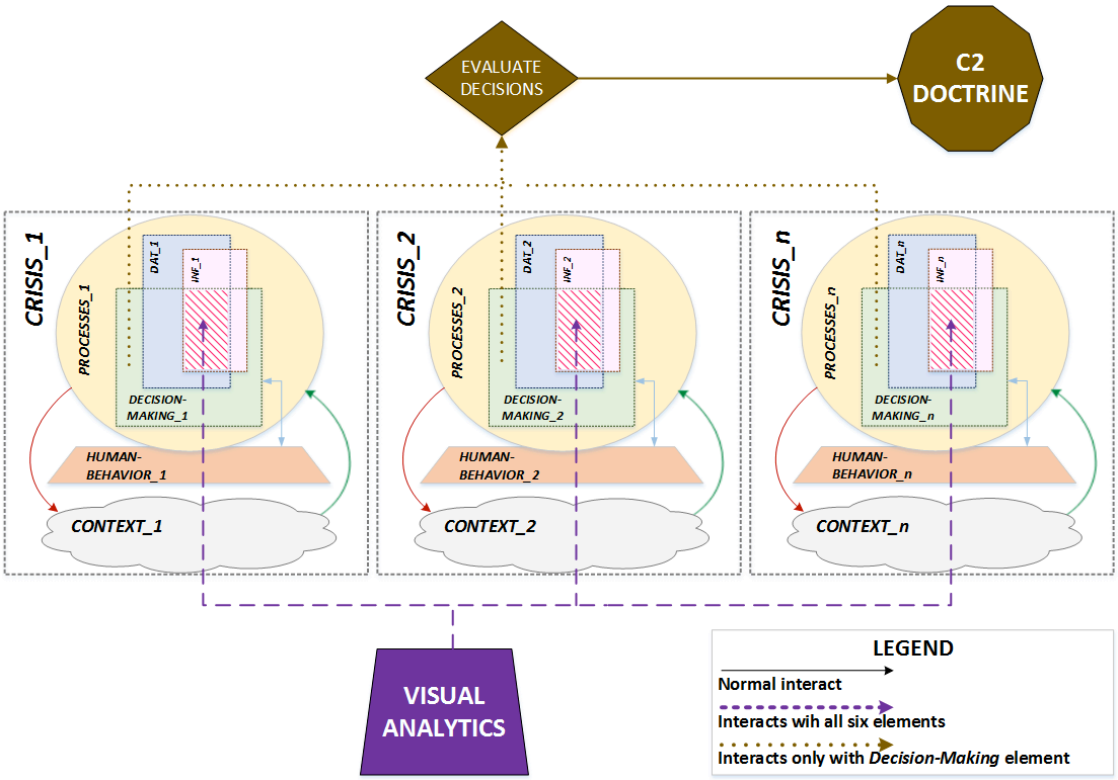

Figure 3: Draft Model

In Figure 3, we show a draft version of the model; there are two types of elements: internal to the crisis and external to the crisis. The squares are a given Crisis *n* to be managed. Within them, there are internal elements of the crisis, i.e. the six themes and their relationships. These elements are the thematic synthesis of the coding technique. From bottom to up, the first element is CONTEXT (gray cloud); as the name suggests it represents the context of the CM. The next element is *HUMAN-BEHAVIOR* (orange trapezium); in our model this element is the basis of the element *PROCESSES* (yellow ellipse), which are the process of the CM executed by humans. Within *PROCESSES*, our model represents three processes *DAT* (blue rectangle), *INF* (rose rectangle) [8] and *DECISION-MAKING* (green rectangle) elements.

The *PROCESSES* element always interacts with *CONTEXT* element (red and green arrows). In real life, the context defines which process tasks will be executed. The red and green arrows represent these interactions between the CM context with CM processes. *HUMAN-BEHAVIOR* interacts with *INF* (dark blue arrow) and *DECISION-MAKING* (light blue arrow).

The spatial positions of the three rectangles in the model are intentional. *DAT*, *INF* and *DECISION-MAKING* elements have intersections among them. The dark pink hatched area represents the intersection of these three elements. They have intersections in two by two elements and non-intersection areas. These spatial positions mean that decision-making process uses tasks of data management and information visualization processes. This modeling setting represents that information visualization is necessary for decision-making, but it is not sufficient. Other processes may support decision-making; however, this is not within the scope of our work. Moreover, information visualization tasks may be used by other processes, besides decision-making, which are not represented by our model (this is not within the scope of our work either).

Regarding the external elements (Figure 3), *VISUAL ANALYTICS* interacts with all six elements in each crisis, for obvious reasons; VA is the basis of our model. *VISUAL ANALYTICS* pass through *CONTEXT*, *HUMAN-BEHAVIOR*, *PROCESSES*, *DECISION-MAKING*, *DAT* and *INF* elements. The purple dashed line represents these interactions. The visualizations follow the VA concepts and are adapted depending on several aspects, for example, human behavior.

[8] Due to spatial position reasons, we abbreviate the name of two elements: *DAT* is Data Management and *INF* is Information Visualization.

C2 DOCTRINE is another external element. We believe that decisions made with the support of our model have the potential to improve the C2 Doctrine. We consider that our model can encourage new research in the CM area and in turn in C2 Doctrine. Specialists in CM may evaluate a set of decisions made in a set of *n* crises and may propose changes and improvements in C2 Doctrine. The brown dotted lines represent these interactions among *DECISION-MAKING* element with *C2 DOCTRINE*.

In this section, we present a first (draft) version of our aim towards model. For each of the six internal elements (themes), we will model sub-elements and relationships between other elements (internal and external). Next steps, we shall carry out other validations and improvements to the model.

CONCLUSIONS

We carried out a survey protocol to understand the overall dynamics of CM activities in depth, comprising the main themes of how managers analyze crisis information for decision-making and primarily if we can improve it by using visualization techniques causing the least impact on the structure that exists nowadays.

The **survey** was carried out in stages: the design of the survey; the execution of the survey, we interviewed eight CM specialists; the interview data analysis using the coding technique; and the evaluation of the survey, we used the focus group technique.

Our survey transformed the collected data into classes of visual needs for CM. It was possible to identify the relationships between these visual needs and other main themes of influence for CM. We found that practitioners and researchers are neglecting important themes that need to be represented in visualizations tools for decision-making (e.g. information about crisis context, processes and human behavior). In our research, we identified that the concepts of VA can tackle these themes.

As we mentioned, we will use the results of this work to guide future research directions that is the full development of the draft model presented in the previous section. Our aim is to apply the model in simulation crisis or even in real crisis case studies, improving the model.

ABSTRACT

With the latent problem of security breaches, denial of service attacks, other types of cybercrime, and cyber incidents in general, the correct management of cyber resilience in critical infrastructures has become a high priority. However, the very nature of cyber resilience, requires managing variables whose effects are hard to predict, and that could potentially be expensive. This makes the management of cyber resilience in critical infrastructures a substantially hard task.

To address the unpredictability of the variables involved in managing cyber resilience, we have developed a system dynamics model that represents the theoretical behaviors of variables involved in the management of cyber resilience. With this model, we have simulated different scenarios that show how the dynamics of different variables act, and to show how the system would react to different inputs.

Keywords

Cyber resilience, System dynamics, Critical infrastructure protection (CIP).

INTRODUCTION

Society's welfare is dependent on the effective performance of Critical Infrastructures (CIs) to provide our energy, water supply, transportation, sanitation and telecommunications (National Research Council (U.S.), 2009). CIs are defined as systems, services and assets that are vital for the welfare of society, and whose disruption or destruction has severe impact on the health, security, safety or economic well-being of citizens and on the effective functioning of government (Commission of the European Communities, 2005). Natural disasters, terrorist attacks and cyber incidents are the main threats to which CIs are exposed to. Actually, the latter are considered by the World Economic Forum as one of the most likely global risks, with high impact in case of occurring (World Economic Forum, 2018).

The cyber-attack on a power grid occurred in 2015 in Ukraine is an example of the impact of these threats. Hackers were able to successfully compromise information systems of three energy distribution companies in Ukraine and temporarily disrupt electricity supply to the end consumers. Thirty substations were switched off, and about 230 thousand people were left without electricity for a period from 1 to 6 hours. First, the hackers compromised the network using spear-phishing emails with the BlackEnergy malware. Then, they seized control of the SCADA system, which let them switch substations off remotely, disable the IT infrastructure components and destroy files

with the KillDisk malware. Finally, they carried out a denial of service attack against the company's call center to deny consumers up-to-date information on the blackout (Lee *et al.*, 2016).

Furthermore, CIs have grown in size, complexity and interconnectivity to guarantee a high level of reliability and safety in their services, but in doing so they have also increased their vulnerability, providing more surface areas for criminal hackers to exploit. Moreover, the perspective for the next years is not satisfactory, since it is expected that the number of cyber-attacks will continue increasing causing a significant negative effect on countries and industries (ENISA, 2016). Besides, the problem could be analyzed from the all hazards approach and not limit the cyber crises to cyber-attacks. Instead, considering that cyber incidents could be "acts of God" (for example, natural disasters that compromise the systems) or "acts of man" (that could be unintentional or intentional) (Björk *et al.*, 2015), the cause of cyber incidents could be black-boxed and have a broad spectrum of threats to the functionality of the CI's systems. This context has led to increasing concern about the reliability and security level of CIs, making the creation of resilient CIs that are able to cope with crises an issue of paramount importance (Federal Register, 2015).

In the last years, there has been an evolution in the approach to address the cyber threats. The cyber security approach, which focused on protection strategies, has evolved to a more strategic and long term thinking approach called cyber resilience (World Economic Forum, 2017). Cyber resilience is defined as the "ability to withstand and recover quickly from unknown and known threats" (Linkov *et al.*, 2013). To deal with future cyber incidents it is vital to integrate physical and cyber management, strengthen resilience leadership and organizational processes, and leverage supporting technologies (World Economic Forum, 2017). In this context, cyber resilience provides a holistic approach that focuses on systems rather than individual organizations (Kaplan *et al.*, 2015).

In this paper, we present a System Dynamics model that includes the policies identified by the frameworks in the literature. This model aims to increase CI providers' awareness about the importance of investing on cyber resilience policies considering a holistic approach. This simulation model aims to show the relationships between the technical, social and regulatory factors in the cyber resilience building process that have been identified in these frameworks. The aggregated perspective of the problem given by an SD model can help security managers to design and implement more effective policies, seeking a compromise among different investment strategies such as technology, training, learning, collaboration and legal requirements.

LITERATURE REVIEW

Several frameworks can be found in the literature that define a set of characteristics, stages and policies to develop and assess cyber resilience in organizations. For example, Linkov et al. (2013) defines a matrix that helps organizations to manage adverse events. This matrix combines four domains (physical, information, cognitive and social) with four stages that define the event management cycle that a system needs to follow to be resilient: plan and prepare, absorb, recover and adapt. Thus, each cell in the matrix contains policies or actions that address the question: ''How is the system's ability to [plan/prepare for, absorb, recover from and adapt to] a cyber-disruption implemented in the [physical, information, cognitive, social] domain?''.

The National Institute of Standards and Technology (NIST) develops a Framework for Improving Critical Infrastructure Cybersecurity (NIST, 2018), that defines five stages, called functions, in the cybersecurity management lifecycle: 1) identify (develop understanding of and manage risk to systems, assets, data, and capabilities), 2) protect (develop and implement appropriate safeguards to ensure delivery of critical infrastructure services), 3) detect (identify the occurrence of a cybersecurity event), 4) respond (take actions regarding a detected cybersecurity event), and 5) recover (maintain plans for resilience and to restore any capabilities or services that were impaired due to a cybersecurity event). Each of these stages or functions are subdivided in categories and subcategories, that provide aspects to consider for cyber resilience building process. This framework has 22 categories divided into 98 subcategories. For example, the category "Asset Management" is divided into subcategories like "Physical devices and systems within the organization are inventoried", "Software platforms and applications within the organization are inventoried", etc. (NIST, 2018).

On the other hand, World Economic Forum develops its own framework combining the characteristics of frameworks developed by NIST and Linkov (World Economic Forum, 2016a). This framework uses the four domains defined by Linkov and a combination of stages defined in the two previous frameworks. The stages are: 1) Plan and prepare 2) detect, 3) absorb, 4) recover and 5) adapt. Each cell of this framework includes several policies to build the cyber resilience of the organization. For example, in the physical domain, for the plan and prepare stage, there are policies such as: "Implement controls/sensors for critical assets" or "Assessment of network structure and interconnection to system components and to the environment" (World Economic Forum, 2016a).

The described frameworks suggest the implementation of dozens of policies to build cyber resilience. Investments

are needed to develop these policies but some-times it is hard to understand and measure the impact of these policies in the cyber resilience enhancement in the short, medium and long term. Simulation models can help understand the effects of different policies over time under different conditions or scenarios. Actually, simulation models can represent the real system in a mathematically reliable way simulating the behavior of complex systems over time, enabling users to understand, train and learn about how the complex a system works (Coll, Richard & Lajium, 2011).

System Dynamics (SD) is a modeling and simulation methodology that has been used in several disciplines of research such as in engineering, scientific humanitarian sciences, economy, manufacturing and management, planning and logistics, healthcare, urban planning etc. The SD uses a top-down approach that allows to manage and analyze complex adaptive systems involving interdependencies (Forrester, 1961; Sterman, 2000). This methodology is grounded in the theory of nonlinear dynamics and feed-back control, which deals with the internal feedback loops and time delays that influence the whole system (Casalicchio *et al.*, 2007).

SD methodology allows modelling effectively socio-technical systems, consisting of human, organizational and technological parts. In particular, SD is used when the individual properties are not decisive and high-level aggregation is desired or required for management purposes. This is typically the case for management strategies and long-term planning (Iturriza *et al.*, 2018; Sarriegi *et al.*, 2008).

SD's top-down approach and its high-level aggregation allow this modeling and simulation technique to include "soft" variables whose dimensions are usually unknown and their values difficult to measure exactly (Forrester, 1980; Labaka *et al.*, 2015). This is possible because SD's approach considers high level causal relationships and the general structure of the system and not the specific values of variables (Forrester, 1980). Moreover, these variables', even though they have unknown values, cannot be left out of the model since that would be to consider they have no effect, but most of the time the effect of soft variables such "morale", "awareness" or "commitment" are known to have crucial effects on many socio-technical systems (Forrester, 1980).

These characteristics are known to be part of the cyber resilience management and building processes. On the one hand, cyber resilience development involves complex and multiple relations between variables and the presence of significant delays. The process of building cyber resilience in an organization needs to consider variables that evolve quickly, like new type of cyber-attacks or software upgrades, with others that need longer times to change, such as organizational culture or individual attitudes towards security. On the other hand, building cyber resilience involves soft variables that cannot be directly measured, such as employees' awareness, cyber resilience level, etc., but that have crucial effects on the evolution of cyber resilience management. And for these reasons, we consider that SD is especially suitable to model and simulate cyber resilience management.

Besides, through the simulation of different scenarios in an SD model, managers can determine the investment strategy that best suits their objectives and needs since they can see what the results of their investment strategies would be according to the structure of the system that has been modeled. This does not mean that the model is predictive, but that a model that follows the theoretical behaviors can give managers some awareness of what the consequences of their investment decisions are.

SYSTEM DYNAMICS MODEL

In this paper we have developed a System Dynamics (SD) model that allows CIs providers (independently of whether their private or public) to reflect on the consequences of adopting different policies to improve the cyber resilience level. The developed simulation model includes what the literature identifies as key aspects and policies to build cyber resilience and models their interrelationships. This makes the model a useful tool for exploring different scenarios to see how the implementation of some policies or lack thereof can affect the impact of cyber incidents in a critical infrastructure over time.

Due to the nature of SD, the models developed with this technique can be summarized in causal loop diagrams (CLD). CLD represent causal relationships, causal loops and interactions between causal loops through variables and arrows. In a CLD an arrow represents a causal relationship, and the "polarity" of the causal relationship is depicted as a + or – sign near the head of the arrow. In this sense, the + sign represents a directly proportional relationship (i.e. when the variable near the base of the arrow increases, the variable near the head of the arrow increases as well and vice versa), and the – sign represents inversely proportional causal relationships (i.e. when the variable near the base of the arrow increases, the variable near the head of the arrow decreases and vice versa).

As said previously, cyber resilience provides a holistic approach that focuses on systems rather than individual organizations (Björk *et al.*, 2015). This means that CI's internal and external aspects should be taken into account (Labaka *et al.*, 2013). The developed model includes both aspects/contexts: internal and external that are explained in the following sub-sections.

Internal Cyber Resilience Sub-Model

The internal cyber resilience sub-model is limited to the CI boundaries. This sub-model represents policies such as investments in technology, training, systematization and learning that are influenced by the level of awareness of decision makers. All these policies can be found in different frameworks and standards in the literature (Linkov *et al.*, 2013; NIST, 2018; World Economic Forum, 2016b).

The policies included in this sub model and their behavior are described as follows:

- Awareness represents the level of knowledge the decision makers of the CI has about the vulnerabilities and risks that surround that organization. Awareness level triggers the investments in Training, Cybersecurity equipment or both. This causal relationship is represented with causal loop notation in Figure 1.

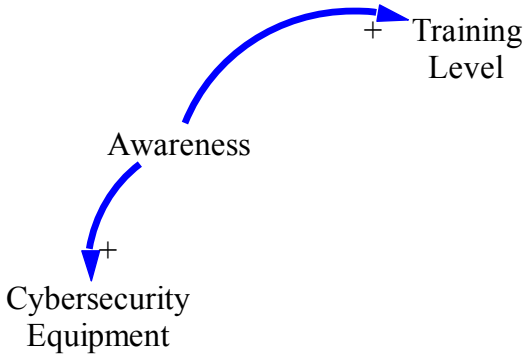

Figure 1 Relationship between Awareness, Training Level and Cybersecurity Equipment

- When the organization invests in Training the staff learns about the risks that surround the organization and the best practices currently available in order to mitigate them. Hence, the level of Training will also increase the Awareness, because as the staff gets to know more, they will be more concerned about how vulnerable the organization is because of their lack of knowledge. This added relationship can be depicted as in Figure 2.

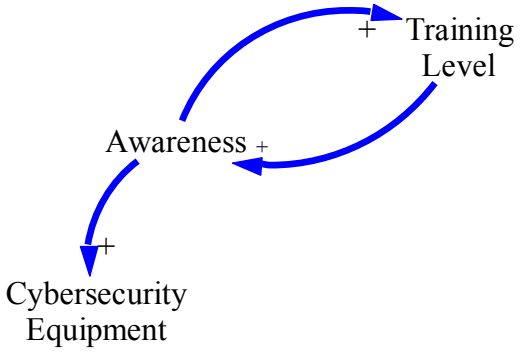

Figure 2 Training Level has a directly proportional relationship with awareness

- Systematization is the policy where internal standard processes are created to prevent incidents, mitigate them and recover from them. This policy is a direct effect of the Training policy and will only start to be applied when the staff has a certain Training level where they are able to design efficient processes. This new variable would be related to the previous ones as shown in Figure 3.

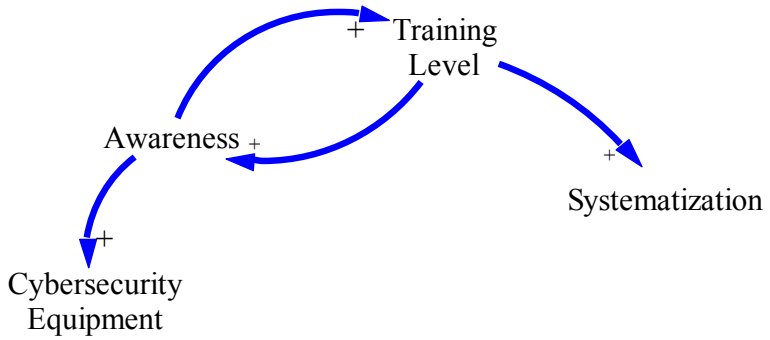

Figure 3 Trained staff can start developing systematic cyber resilience processes

- The model also takes into account the investment on Cybersecurity equipment policy. This policy represents the acquisition of software for protection against threats and detection of cybersecurity incidents.
- When the organization suffers a disruption because of an Impact event (when it has an Impact > 0) the organization's Awareness level increases. This can be represented as in Figure 4.

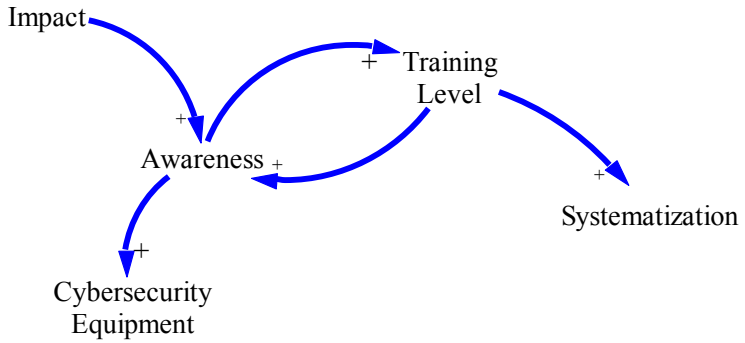

Figure 4 Impacts to the company increase awareness

In order to represent how these policies affect cyber resilience level when implemented or not implemented, they are related to the variables *Prevention capacity*, *Absorption and recovery capacity* or both. *Cybersecurity equipment* is considered to have no effect on the *Absorption and recovery*, but to have great impact on the *Prevention capacity* because most commercial software is designed to protect, and when a system is infected, protective software does not help to mitigate the crisis. On the other hand, *Training* and *Systematization* help both *Prevention* and *Absorption and recovery capacity* since knowledge of the threats, and standard processes can help the personnel recover faster from a crisis. Also, to complete the representation of the cyber resilience management, the *Internal lessons learned* variable is a representation of the adaptation stage of cyber resilience, that according to Linkov et al. is "Using knowledge from the event, alter protocol, configuration of the system, personnel training, or other aspects to become more resilient" (Linkov *et al.*, 2013). With these added relationships, the model has all the relationships shown in Figure 5.

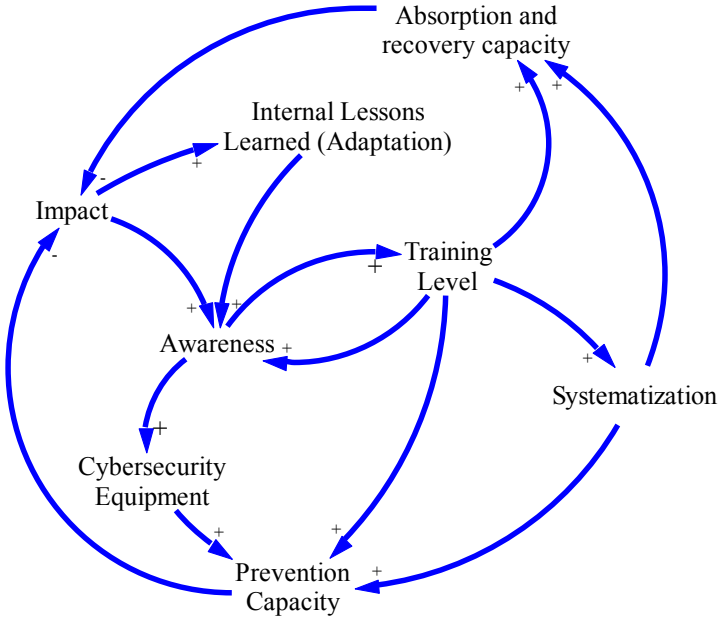

Figure 5 Relationships in the internal cyber resilience sub-model

In turn, Prevention capacity and Absorption and recovery capacity, affect the Impact inflow and outflow in the following way:

- A higher *Prevention capacity* would decrease the magnitude of the impact making the *Impact increase* be lower for any *Impact event* and as a consequence resulting in a lower value for the *Impact* stock, and vice versa.
- A higher *Absorption and recovery capacity* would decrease the recovery time making the *Impact decrease* higher, resulting in a lower value for the *Impact* stock, and vice versa.

External Cyber Resilience Sub-Model

In order to capture the effect of the external context in the cyber resilience of an organization, we have made a second sub-model that includes policies from the literature such as:

1. Collaboration: it represents how through a Collaboration policy an organization is able to learn from cybersecurity incidents that have not yet happened to them but have happened to other organizations.
2. Regulation: this sub-model represents how even if the organization does not invest in Collaboration and therefore does not learn from external cybersecurity incidents, high impact cyber events can foster the tightening of legal requirements. This tightening in legal requirements would make the organization more aware of the risks in the environment, and thus more investment on cyber resilience policies would be applied.

The behavior of this sub model is described as follows:

- External Impact is a variable that represents the incidents suffered by other organizations.
- Collaboration represents how much communication the organization has with external stakeholders and surrounding organizations. Thus, when there is no Collaboration, no matter how the External impact variable behaves, there will be no External lessons learned. On the other hand, the more Collaboration there is, the more External lessons learned increases when surrounding organizations suffer incidents. When the organization learns from what happened to other organizations, the Awareness increases as well, because the decision makers would become aware of the surrounding risks. This can be represented in CLD notation as shown in Figure 6.

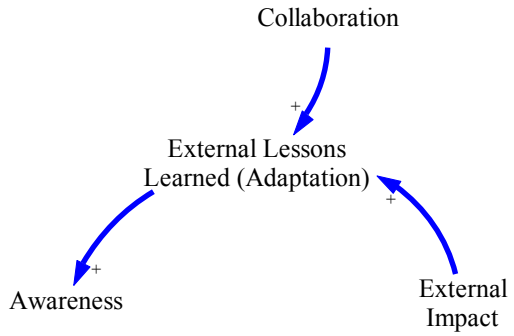

Figure 6 The lessons learned from incidents to other companies depend on the level of collaboration

- Independently of how much Collaboration there is, External Impact affects the legislation: the bigger the impact on other critical infrastructures, the more New legal requirements will appear. These New legal requirements that the organization needs to comply with, make the decision makers aware of what happens outside of the organization increasing their level of Awareness. This is the final relationship in the external cyber resilience submodel and can be represented as in Figure 7.

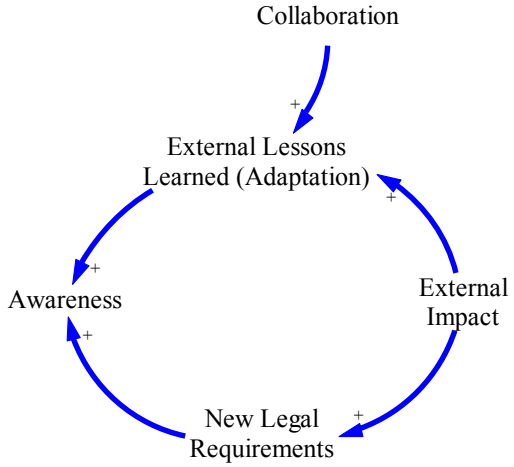

Figure 7 All the relationships in the external cyber resilience sub-model

This sub-model is connected to the internal cyber resilience sub-model because the policy of Collaboration affects the Absorption and recovery capacity, and because New legal requirements will appear when significant cybersecurity crises happen either to the organization or to external organizations. Also notice that by joining these two sub-models it is possible to model the complete cyber resilience management of a critical infrastructure.

SIMULATIONS

The effect of different policies included in the simulation model has been analyzed in the different scenarios shown in Table 1.

Table 1 Simulation Scenarios

Group	Scenario
Internal Crises	Series of internal crises Series of internal crises with no investment on training Series of internal crises with no investment on cybersecurity equipment
External crises	Series of external crises Series of external crises with no investment on collaboration
External and internal crises	Series of external and internal crises

Internal Crises Scenarios

The internal crises scenarios assume that nothing happens to external organizations and the organization being studied suffers three big crises at months 10, 50, and 90. The scenarios simulated in this model assume that there is a limited budget that can be either invested on training or on cybersecurity equipment, however, since every CI has a different budget and since when using SD the specific values of variables are not as important as the general structure of the system, this budget has been assigned through percentages. In this sense, the three internal crises scenarios that have been simulated demonstrate the behavior of the model on the following three cases:

1. A base run, where the organization invests on training and on cybersecurity equipment equally (50%-50%) according to its awareness level. This case is called Series of Internal Crises.
2. A second scenario where the organization does not invest on cybersecurity equipment, but invests 100% of its budget on training and collaboration. This case is called Series of Internal Crises with no Investment on Cybersecurity Equipment.
3. A third scenario where the organization does not invest on training, but invests 100% on cybersecurity equipment and collaboration. This case is called Series of Internal Crises with no Investment on Training.

The simulation of these scenarios shows that in the case of internal cyber resilience, investing only on training is more sustainable than investing only on cybersecurity equipment. This can be supported by comparing Impact graph on the three scenarios (see. Figure 8). On this graph, the base run shows a decreasing trend, while Series of Internal Crises with no Investment on Training run shows not only a bigger Impact with every crisis, but also with each crisis it takes longer to recover. These behaviors are due to the effect of not having Training and Systematization on the Prevention capacity and the Absorption and recovery capacity. On the other hand, not having cybersecurity equipment, makes the Impact grow at the beginning, but on the long-term the impact ends up decreasing with respect of the initial crisis.

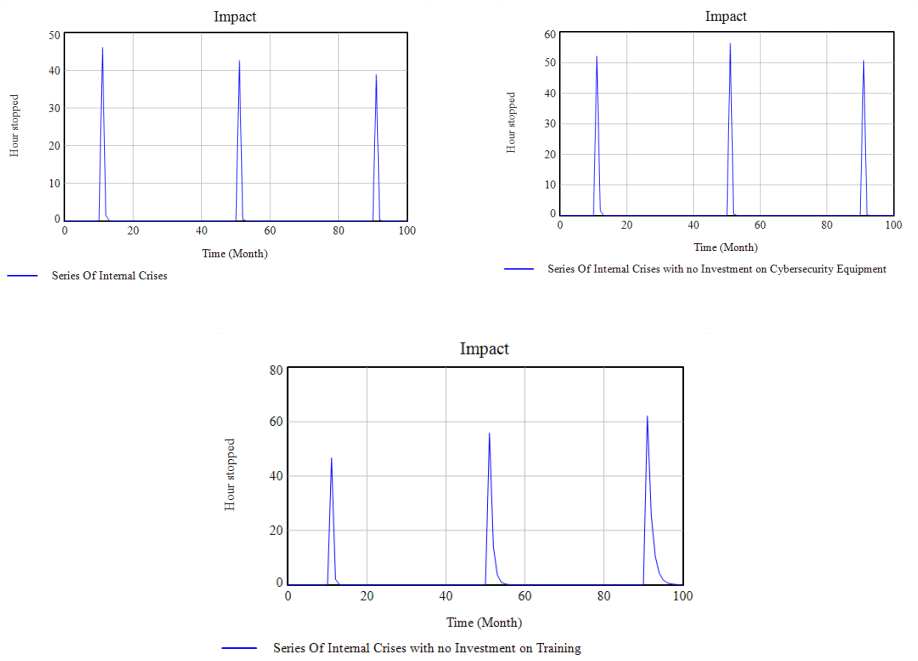

Figure 8 Impact behavior in internal crises scenarios

Another way of supporting that a training policy is of critical importance in a CI is the Awareness variable's behavior over time (see. Figure 9). This graph shows how, when not investing on training, Awareness only grows when there is a crisis and it grows because of the new legal requirements that appear and because of the lessons that are learned from the suffered impact. However, the lack awareness due to the lack of knowledge of the surrounding risks makes this kind of Awareness unsustainable, and thus the Awareness variable's trend is to decrease.

On the other hand, when there is no investment on cybersecurity equipment, due to the higher investment in training, the awareness reaches higher levels than on the base run. The reason behind this behavior is that the investment in training reinforces the management's knowledge of the risks to the CI and knowing more about the threats that the company is exposed to makes the management more aware of the problems the company may have. This behavior is also comprehensible since having more impact in the short-term would worry the

management more and thus make them more aware from the beginning.

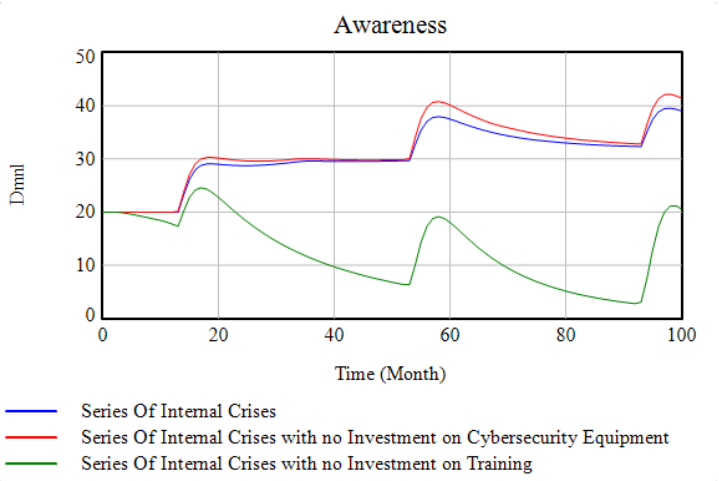

Figure 9 Awareness behavior in internal crises scenarios

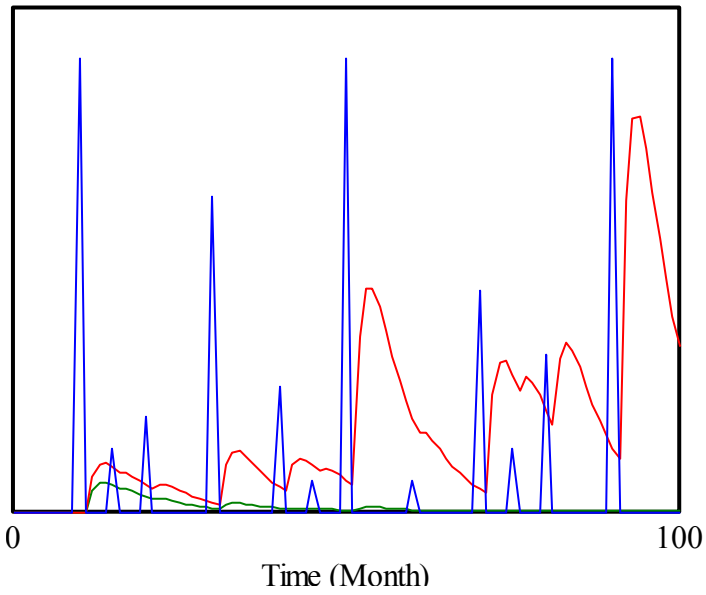
External Crises Scenarios

The external crises scenario group assumes that nothing happens inside the organization but the external organizations are suffering different-sized cyber incidents over time. The two scenarios simulated demonstrate the behavior of the model on the following two cases:

1. A base run, where the organization invests in all possible policies, including Collaboration. This scenario is called Series of External Crises.
2. A second scenario where there is no investment on Collaboration, but the organization does invest in training, and cybersecurity equipment. This scenario is called Series of External Crises with no Investment on Collaboration.

The purpose of these scenarios is to show the benefits that Collaboration has on the organization's cyber resilience. These benefits can be shown by comparing the crises that external organizations have suffered and the External lessons learned that the organization acquires from those crises (see Figure 10). On both scenarios the External impacts are the same. The graph shows that, as explained when describing the model, when there is no Collaboration, no matter how the External impact varies, the organization does not learn from what happens to others. On the graph, this behavior is shown as well as an increasing learning with each crisis on the Series of External Crises case where there is investment on Collaboration.



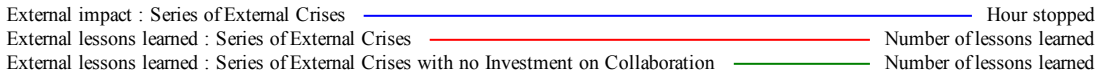


Figure 10 External impact and external lessons learned in external crises scenarios

Another result of investing on Collaboration can be observed on the behavior over time of the Awareness variable (see Figure 11). On this graph the effect of Collaboration is shown with higher values on the Awareness variable for the case where there is Collaboration. Another effect of Collaboration besides this increasing difference between the case with no Collaboration and the base case, is the increasing peaks of Awareness on crises that are a direct result of the External lessons learned that have been shown before.

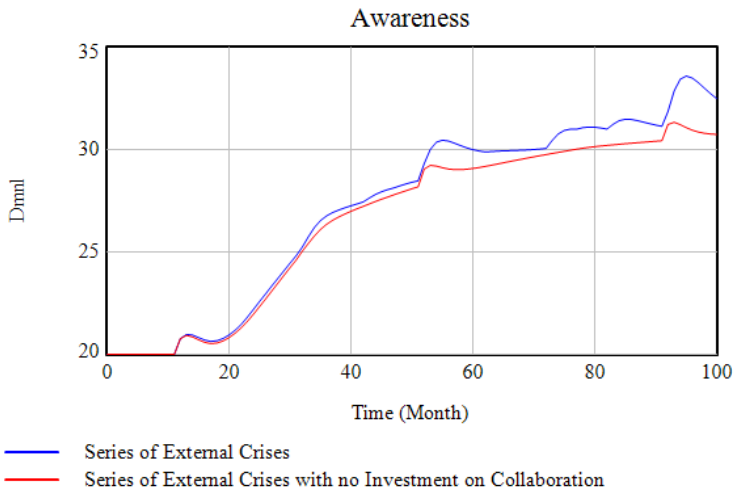

Figure 11 Awareness behavior in external crises scenarios

Internal and External Crises Scenario

Finally, the internal and external crises scenario shows how the organization would behave when there are different-sized external crises and a series of internal crises over time. To do this, the input crises for both of the previous groups have been applied. This scenario demonstrates the normal operation of the organization when it applies all of the policies that have been modelled.

As expected, the impact caused by the crises the organization suffers over time has a decreasing trend, just as it had when the *Series of Internal crises* scenario was simulated (see Figure 12). However, this time the decreasing trend is slightly steeper because of the effect of *Collaboration* on the *Awareness* of the organization. Also, in this scenario, the time to absorb and recover from the impact is also slightly smaller because of the effect of *Collaboration* on the *Absorption and recovery capacity* of the organization.

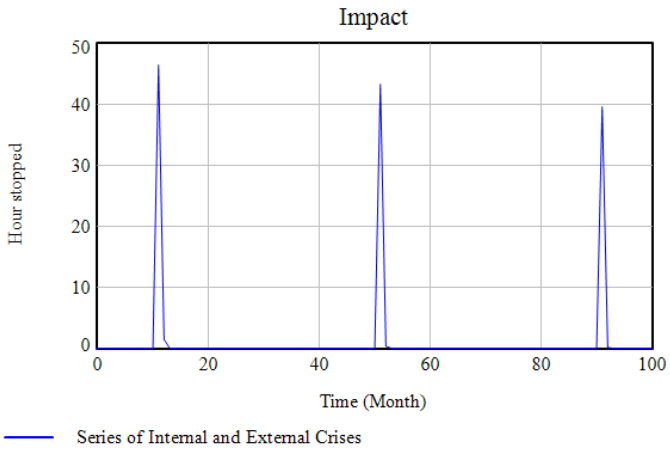

Figure 12 Impact on Internal and External crises scenario

Notice that this final scenario's behavior over time will be the sum of the base run scenarios' behaviors over time on the previous groups. This can be observed, for example, on the behavior over time graphs of the *Awareness* of

the two previous groups' base cases and the *Awareness* on the *Series of Internal and External Crises* scenario (see Figure 13). This graph shows how internal crises affect *Awareness* significantly more than external crises, and that investing on all cyber resilience policies that have been modelled when the organization is in an environment where there are internal and external crises result on more *Awareness.* This increase in Awareness, would in turn result on a better cyber resilience because of the causal relationships inside the model.

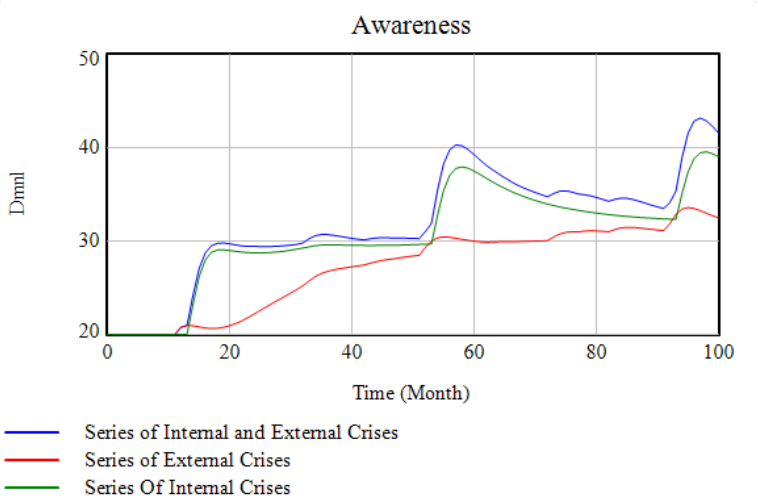

Figure 13 Awareness on the base run of the three scenario groups

CONCLUSIONS AND FUTURE RESEARCH

In this paper, we have developed an SD model that gives some insight on the management of cyber resilience on a critical infrastructure. To do this, theoretical relationships between variables related to cyber resilience have been modeled. These variables and relationships include cyber resilience domains as well as policies.

Through this model and through simulations done on it, the following conclusions have been drawn:

- When speaking about internal cyber resilience, investing only on cyber security equipment (state of the art software to protect the organization from cyber events) is a short sighted strategy that will end up having repercussion in the CI. On the other hand, investing only on training is more viable in the long term, but not ideal since it leaves the CI unprotected in the short-term.
- Collaboration with external organizations has slow results, but it adds up to help significantly to increase the Awareness as well as the Absorption and recovery capacity of the organization.
- For an optimal management of an organizations cyber resilience it is necessary to apply both, internal and external policies in the organizations resilience management plan.

The model described on this paper, however, has limitations as it is merely demonstrative and only reflects the theoretical behaviors of an organization applying these policies. Reality is much more complex and more variables are involved. This model should be validated with experts' knowledge and its limitations should be addressed in future research through the calibration of the model with real organizations' data such as a real budget and a real investment plan.

ABSTRACT

Partial or total horizontal evacuation of populations in urban areas is an important protection measure against a natural or technological risk. However, casualties during massive displacement in a context of stress and in a potentially degraded environment may be high due to non-compliance with instructions, accidents, traffic jams, incivilities, lack of preparation of civil security or increased exposure to hazards. Working in evacuation plans is therefore fundamental in avoiding casualties caused by improvisation and in promoting self-evacuation whenever possible. Since it is impossible to re-create the conditions of a crisis on the ground to assess such evacuation plans, there is a need for realistic models in order to evaluate them using simulations. In this paper, we present the ESCAPE software framework that helps in the development of such plans and testing them. In particular, ESCAPE, which uses the GAMA open-source platform as a core component, provides an agent-based simulation tool that supports simulation of the evacuation of a city's population at fine temporal and geographical scales. The framework was developed such that it works for a wide range of scenarios, both in terms of hazards, geographical configurations, individual behaviors and crisis management. In order to show its adaptability, two applications are presented, one concerning the evacuation of the city of Rouen (France) in the context of a technological hazard and the other pertaining to the evacuation of the district of Hanoi (Vietnam) in the event of floods.

Mass Evacuation, Individual Behavior, Crisis Management, Agent-Based Modelling, Geographical Information System

INTRODUCTION

High concentration of critical infrastructure and decision-making power in increasingly urbanized spaces makes risk and disaster management highly complex (Perrow 2007). Population evacuation may be the only effective response to the risk, which generally increases with urbanization rates on the coastlines and in deltas, the presence of factories in areas of high population density, and climate change. Strategy planning therefore becomes a crucial concern, however, its evaluation outside a crisis context is difficult. Indeed, while it is very important to prepare populations and organizations to face such events with the help of exercises or educational programs, there are many aspects that cannot be foreseen, *e.g.* side effects that prevent people from leaving the area or communicating, or behaviors that cannot easily be anticipated, such as people panicking or not following recommendations. Furthermore, during extreme events, new risks emerge from the actions and interactions between individuals in a potentially hostile (flood, hurricane) and degraded (closed road, broken bridge) environment. All of this can further increase the vulnerability of people who need to be evacuated and the occurrence of incidents: accidents, traffic jams, incivilities, panic situations, lack of preparation for civil security events, increased exposure to hazards... For example, the 55 deaths recorded during the Hurricane Rita in Texas were associated with the evacuation process rather than the storm itself (Knabb et al. 2006). Absence of an organization such as an emergency and crisis management authority and lack of a risk culture among the concerned population are thus important factors of territorial vulnerability.

Mitigation of risks associated with an evacuation then requires an improvement in the risk culture of populations as well as better operational knowledge among evacuation managers. This must integrate confrontation with potentially unforeseen situations, such as traffic congestion, a broken road section on an evacuation route or the dispatch of contradictory orders by different crisis management players. Drills are usually designed to deal with these requirements (Chalaris et al. 2018): these are however difficult to implement, expensive and time-consuming, and they do not allow one to re-create the actual response of individuals to stressful and potentially harmful situations. Computer simulation is taking over, as it relies on increasingly realistic models. The aim is to explore the collective impact of thousands of individual decisions taken in contexts of stress, imperfect information and potentially degraded environment.

Agent-based models (ABM) (Zucker et al. 2008) are particularly well-suited for studying how individuals with heterogeneous behaviors in mutual and environmental interaction can influence the overall dynamics of an evacuation partly controlled by an organization. This modeling makes it possible to approach realism in behaviors (capacity of displacement, perception of the environment, objectives) while differentiating the agents (motorists, pedestrians, public transport, civil security). It also makes it possible to integrate geographic data (land use maps, transport networks) and social data (number of inhabitants, road traffic) into the models with a very high level of detail (age, gender, risk culture). This approach enables the researchers to observe the dynamics of the system at various scales, that of the agent or that of the entire system, thus opening up many possibilities in terms of agent granularity. The citizen has local information of the situation, that is to say, the information, which he gets through his senses, enabling him to move or the information, which he gets through his social network, helping him to make a decision. The organization gets broader information on the situation from its sensors in the field (cameras, civil security agents, probes) and can activate its plans. This type of model is also very flexible - it is easy to change a behavior, a spatial attribute or a proportion - and can therefore be used as an artificial laboratory to test many hypotheses (Daudé 2008).

This paper presents ESCAPE, an agent-based framework dedicated to the study of mass evacuation strategies of territories under the threat of imminent events due to natural or technical hazards. A preliminary description in figure 1 shows the main components of ESCAPE: hazards, territorial issues, planning and realization of crisis management that foresees a population evacuation.

With the help of this schematic description of the field of knowledge, this paper aims to propose a conceptual framework and a software architecture (ESCAPE) for mass evacuation using an agent-based model and GIS. It is organized around four main modules:

- the **Environment** module is related to the spatial and demographic description of the simulation domain. It makes it possible to describe the territory by identifying the main issues exposed in a perimeter of potential danger. These critical issues include the population, transport networks, energy, public institutions;

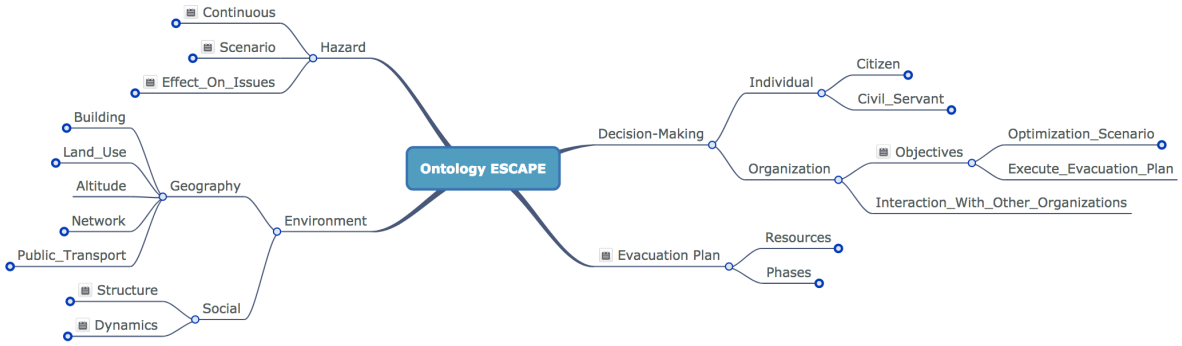

Figure 1. General diagram of ESCAPE

- the **Hazard** module makes it possible to describe all the characteristics of a hazard and provides some modeling tools. It enables the integration of various levels of spatialized hazard intensity by geographical information layers, as well as the construction of dynamic propagation models of a hazard;
- the **Crisis Management** module aims to define available resources which can be used by the organization to operationalize a plan and launch it in phases depending on various scenarios of hazard dynamics.
- the **Decision-Making** module focuses both on features related to individual mobility, including travel choices, motivations and goals that can be influenced by hazards, as well as on the disaster management authority. We will see that cognitive processes govern agent mobility behaviors as well as the behaviours of organization, whether it is strategic (plan to follow) or tactical (adjust or cope with the unexpected) behavior;

The first section gives an overview of mass evacuation models developed within an agent-based model's meta-framework. The second section presents the four core blocks of the ESCAPE framework: spatial and demographic data management, hazard dynamics, decision-making behavior and evacuation planning. The third section presents two ongoing applications of ESCAPE: traffic dynamics in Rouen (France) under the threat of industrial accidents and pedestrian evacuation of a district in Hanoi (Vietnam) during a flood event. The results of these applications are discussed in the fourth section that also leaves the door open to further developments.

MODELLING MASS EVACUATIONS

To meet the requirements of planning and crisis management adapted to specific contexts, ESCAPE proposes to develop realistic models, as well as describe the environment, the population and the mobilities in various contexts, from normal to crisis situations. On this point, ESCAPE stands out from most of the existing tools that are oriented towards simulating traffic in normal and mono-modal conditions. We propose tools for multi-modal displacement modeling taking into consideration the agents' cognitive capacity that allows them to change behavior depending on the context and the means to achieve their objectives.

While well-known traffic frameworks, like MATSim, TRANSIMS, SUMO or SimMobility, make it possible to model day-to-day urban traffic, most of them have limitations when used to study disruption induced by extreme events (Czura et al. 2015a). However, several extensions have been proposed in order to adapt these frameworks to the study of mass evacuation: MATSim provides a dedicated extension to study evacuation (Lämmel et al. 2009). Several proposals use the template (Kim et al. 2017; Zhu et al. 2018) for Tsunami and Hurricane evacuation with a simplification in the modelling: pre-computed Origin-Destination (OD) escape trips based on MATSim's iterative optimization process. Locally, simplification is also seen in terms of a first-in first-out model for micro traffic simulation. The SUMO extension called VEBEN++ has been used to study disruption in traffic due to uncommon events (Flötteröd and Erdmann 2018). Unfortunately, as for MATSim, it requires all possible pathways including the evacuation ones to be pre-computed. This is a major issue due to the fact that hazards and social dynamics during the event can have an impact on this environment. For example, one cannot predict that a major road would be blocked during evacuation not because of the flood but because of a major accident. It is this almost impossible to pre-compute all possible pathways given such uncertainties. Moreover, the pedestrians' walking model is based on dynamics that are very close to those of vehicles and does not reflect the actual people movement in crisis situations (Beck et al. 2014): pedestrians move over a network made up of virtual lanes called stripes but can neither use free walking areas nor can they cross roads outside of crossing sections. Several other platforms have been used including AIMSUN (Afzal et al. 2017), VISSIM (Harten et al. 2018), or Paramics (Chen and Zhan 2008) to study

evacuation from a regular traffic simulation platform. These are all based on the study of traffic demand and supply in specific circumstances of evacuation, for example, focusing on traffic mitigation optimization (Harten et al. 2018) or evacuation strategy comparison (Chen and Zhan 2008).

So, even if agent-based models studying traffic evacuation come in great numbers, there is no dedicated framework to the best of our knowledge (Hawe et al. 2012). Furthermore, except for traffic related platforms, agent-based evacuation models often do not incorporate complex transportation systems (Wang et al. 2016) nor a smart organization responsible for evacuation management. For the modelling platform, we choose GAMA, an agent-based development framework (Grignard et al. 2013; Taillandier et al. 2018). It has been used recently to study evacuation and traffic during a catastrophic event (Valette et al. 2018; Czura et al. 2015a; Adam and Gaudou 2017). The platform has several well-suited features such as GIS native integration and simple traffic-related primitives for car (Taillandier 2014) as well as pedestrian mobility over both network and continuous topology (Chapuis, Taillandier, Gaudou, et al. 2018). This is the framework we choose for the development of ESCAPE.

ESCAPE: AN AGENT-BASED AND GIS FRAMEWORK TO MODEL MASS EVACUATION

The ESCAPE framework is organized around a combination of geographic information systems, agent-based modeling, and simulation exploration methods. Using this framework, we produce a virtual laboratory which allows us to import layers of geographic information describing a territory and its issues with respect to a potential hazard whose intensity is scripted or described using a simulation model. This framework allows us to describe crisis plans based on hazard thresholds and actions to be initiated, as conditioned by available resources. Organizations are then in charge of executing the plan according to a scenario defined either by the user or by the dynamics of the hazard's model. The main dynamics of the ESCAPE model concern individual agents, who will react, or not, to the perceived, assessed or real dynamics of the hazard. The focus here is on a plan that provides for evacuation, with information that is then disseminated to agents and an environment, especially for evacuation routes, which can be modified accordingly. The framework provides tools for observing and diagnosing evacuation efficacy.

From the modeling of catastrophic events to traffic-related behavior and evacuation/containment plan integration, the framework aims at facilitating the modeling process by integrating modules into a single agent-based modeling solution: all tools have been integrated as one or multiple plugins to the GAMA platform. It includes primitives to manage input data for transportation support, demographics and hazards; various algorithms related to traffic modeling for vehicles, pedestrians, public transport and all the infrastructure; the ability to design evacuation/containment plans and the indicators to assess their quality or make comparisons between them; the Human Machine Interface to create, organize, manage the needed input and the generated output of these evacuation/containment plans. The following sections detail each of the components required in ESCAPE.

Environment Module

The environment module makes it possible to describe the geographical and social space as well as the daily mobility in the study area. The central concepts are depicted in Figure 2 using Unified Modeling Language (UML) class diagram: the geographical space is made of *Area* and *Transportation network*, while the demographic part comprises a description of *Human* people, including their daily mobility activity, and the *Household* they belong to.

In ESCAPE, an *Area* is a spatial object with associated geometry (point, line, polygon, etc.) where people can either walk through, like a park, or cannot cross, like water bodies (*e.g.* river, lake). Some areas have special features: for example, a building can have a certain number of floors and a capacity of reception if it is a public building. Transportation networks provide the medium for agent mobility. These are made up of edges and node intersections, and can stand for private vehicles, pedestrians or public transport. The last aspect concerns human agents and the households they belong to: Every human agent is endorsed with demographic attributes, like age and gender, and an agenda that describes the purpose and mean of its mobility expectations. Households gather humans in family groups, with an associated role (*i.e.* parent, child, other) and at least one home place location (*i.e.* a building). In the following sub-sections, we describe the concepts related to the environment module.

Human and Household: synthetic population generation

Individual characteristics (age, gender, affiliation to one or more social and / or professional networks) have a great impact on mobility behavior (Luo et al. 2016) as well as on the response to a crisis situation and evacuation (Bañgate et al. 2017). Hence, it is important to have a synthetic population of agents that represents the targeted population accurately. For this purpose, census data constitutes a crucial resource for calibrating the model of the population studied. This data is not systematically available and many countries have only sparse statistics to offer. Regarding ESCAPE, the synthetic population is generated using the Gen* (Chapuis, Taillandier, Misslin, et al. 2018) plugin

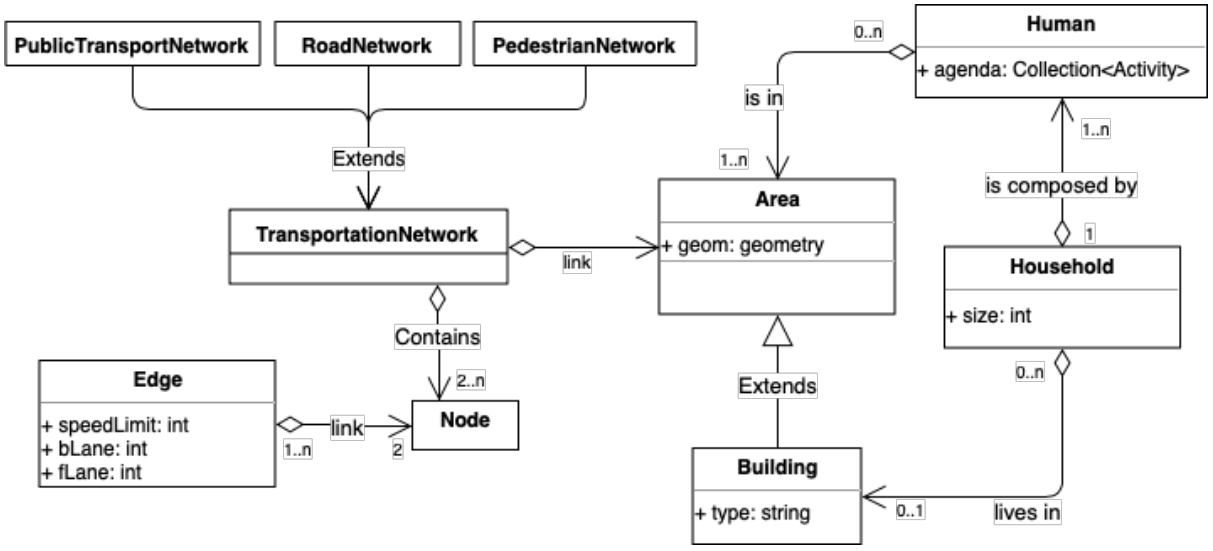

Figure 2. UML class diagram of the environment module in ESCAPE

for GAMA [1], that makes it possible to create individuals grouped into households and to give them attribute values, for example a gender and age for an individual or the number of vehicles and dwelling types for a household. The library provides several well-established algorithms, state of the art synthetic reconstruction and combinatorial optimization techniques (Müller and Axhausen 2010) respectively to create or to replicate known individuals and households according to the available data: either micro-data (sample), aggregated data or both. In addition, every household has a default home place to be linked to, *i.e.* a building as defined in the environment module (see sub–section Transportation network and Area), according to customized spatial distribution. Based on the same principle, any individual of the synthetic population can be linked to several spatial objects, like a workplace, a school or a preferred shopping center. For each agent, we can then define a list of all the places that he or she will visit at different moments of the day and on different days of the week. An individual activity space can be defined based on specific studies such as household displacement survey (Czura et al. 2015a), social networks (Cebeillac et al. 2017) or based on a rough hypothesis such as the relation between age and activity type. Another important issue in the definition of the population and its location lies in taking into account people who do not reside in the area but may be present at the time of an event: this is the case for those present because of tourism, leisure or professional activities. Another aspect which may be important is the determination of the non-autonomous population (isolated, elderly, disabled, hospitalized, imprisoned) which will imply repeated bus trips to evacuate them.

Transportation network and Area: GIS data integration in ESCAPE

Spatial data is also mainly used to set up the simulation environment. Our framework provides an input data structure, with a mandatory and optional setup to design the simulation environment (Grignard et al. 2013). It allows us to build basic blocks within the ESCAPE framework: the road network, public transport, walking areas and all the obstacles like buildings and water bodies.

Road network. The road network is the main medium for the traffic model. It can be set up using raw OSM data or custom vector shapefile. Required features include the number of lanes, direction and speed limit for the roads. The road network is composed of roads as edges, defined as polylines, and the nodes depend on OSM's nodes or the shapefile's nodes. In our proposal, the network is made up of active road and node agents: roads register users and give them information about speed limit, the number of lanes and the other connected roads. They can also handle traffic dynamics when computer efficiency is a concern, turning into a single agent aggregating all concerned vehicles, by using the same approach as the one presented in (Banos et al. 2017). The nodes can be intersections when 3 or more roads are connected to it, bus stop, evacuation or simple node. Intersections have two basic actions: give directions according to vehicle destination and manage traffic signal. The impact of road and intersection agents on traffic dynamics is detailed in section Human agent and mobility.

Public transport. The public transport plugin requires two types of information in order to operate: spatial data and time data. As for the road network, spatial data can be set up using OSM or a shapefile, and consists of a path and a

[1]Both the source codes are available on github : https://github.com/ANRGenstar

list of stops, for each transport line. The path is used to control the bus routes, by lowering the weight of roads during Dijkstra computation. Stops are merged into the road network by splitting the closest road, if required, and creating a new node. The time data constitutes the schedule sheets (one for each line), similar to those displayed at bus stops, but in the CSV format. The time data is used to simulate bus departures, and the time they are supposed to be (or wait) at each stop. Here is a sample CSV schedule file:

```
Stop 1 , 05:53 , 06:10 , 06:34 , 06:44 , 07:02 , 07:07
Stop 2 , 05:58 , |     , 06:39 , |     , 07:07 , |
Stop 3 , 06:03 , 06:15 , 06:44 , 06:49 , 07:12 , 07:12
```

In this example, the first bus will be created (or activated if a pool of buses is defined) at the cycle corresponding to 5:53, and should arrive at 5:58 at Stop 2 and at destination Stop 3 at 6:03. The following one starts at 6:10 and goes directly to Stop 3 for 6:15 (| is a skipped stop). We planned to use the GTFS[2] standard at first, but a flat file is more adapted to our case. We decided to create a script to generate a compatible set of files from a GTFS database. It is however dependent on the data quality, since GTFS is generally not respected perfectly (Kujala et al. 2018).

Walkable areas. Pedestrian agents are able to walk in specific areas, called walkable areas, following an overprinted virtual pedestrian network: the first one is constructed combining the area with the attribute *walkable* turnint it into a true and free space, that is the overall studied area minus all obstacles (buildings by default, but can be extended to any spatial object); the second one is inferred from former areas using Delaunay's triangulation. The algorithm creates nodes on the triangle's segments that are not in contact with obstacles. Then, one or two links are created between nodes of each triangle in order to create a minimum number of cross-sections, while triangles with only one segment free from obstacle are defined as dead-ends (Chapuis, Taillandier, Gaudou, et al. 2018). A combination of the virtual network and walking areas is used for pedestrian traffic movement (see section Human agent and mobility).

Non-walkable areas. Buildings are static spatial entities (polygons) that populate the geographical space of the simulation. Building attributes will be used by individuals to drive strategic goals in the traffic model: localization of the activity places such as workplace, school or home. It is possible to assign a certain number of floors and a refuge function to the building. In the first case and according to the nature of the hazard, a number of floors above a submersion wave, for example, may cause a building to become a vertical evacuation site. In the second case, the shelter is a building open to public and can be used as a confinement site inside the danger zone in the event of an industrial alert. It may also be outside the danger zone, the refuge then being a building previously identified and equipped to shelter a determined number of evacuated people. Non-walking areas also include non-building spatial entities like water bodies.

To summarize, this first *environment module* provides tools to give a detailed description of (i) the geographical area (elevation, road-network, building, walkable area, water body), and (ii) the population present on the territory at the time of the decision to evacuate, or the triggering of the hazard. Each agent can be defined on the basis of demographic characteristics, be attached to a family unit, can be autonomous or not in terms of mobility, be associated with a place of residence that can be outside the simulation zone and have a list of places he or she visits, regularly or otherwise. As this data is used to instantiate the initial population, one can define other attributes which may be of interest to simulate individual behaviors. These attributes may represent knowledge about risk and security instructions as well as emotional factors. All these attributes could be used by cognitive tools that take the thought-processes, decisions and reactions (see section Agent cognition) into account. The next paragraph presents the second module dedicated to hazard description.

Hazard Module

ESCAPE Framework features hazard modeling library tools that enable simulation of disastrous events with increasing complexity: from static spatial objects to dynamic agents. The simplest way to model such type of events is to define a static object to be triggered at a certain time and/or space during the simulation. This object can represent the possible impact zone related to a Seveso accident (see section Industrial hazard case study). Each object, whether static or dynamic, has attributes that serve to qualify its potential impact on the issues, *i.e.* the environment, the human agents and / or the organization. These attributes can be a water level and speed associated with a spatial footprint, a lethal effect for agents present in the zone or the blocking of roads in the perimeter subject to the extension zone of the hazard. It is possible to produce scenarios for the evolution of a hazard, in the form, for example, of nested zones whose transition from one to another in time and in space is based on past events (for

[2]General Transit Feed Specification

example, a flood) or a hypothetical scenario which mimics the growth of the spatial area representing the event. Modelers can provide as many extension zones describing the spatio-temporal dynamics of the hazard as necessary. These objects and the transition scenario from one to the other can then be used as indicators for triggering a warning system and a crisis management plan (see section Crisis Management).

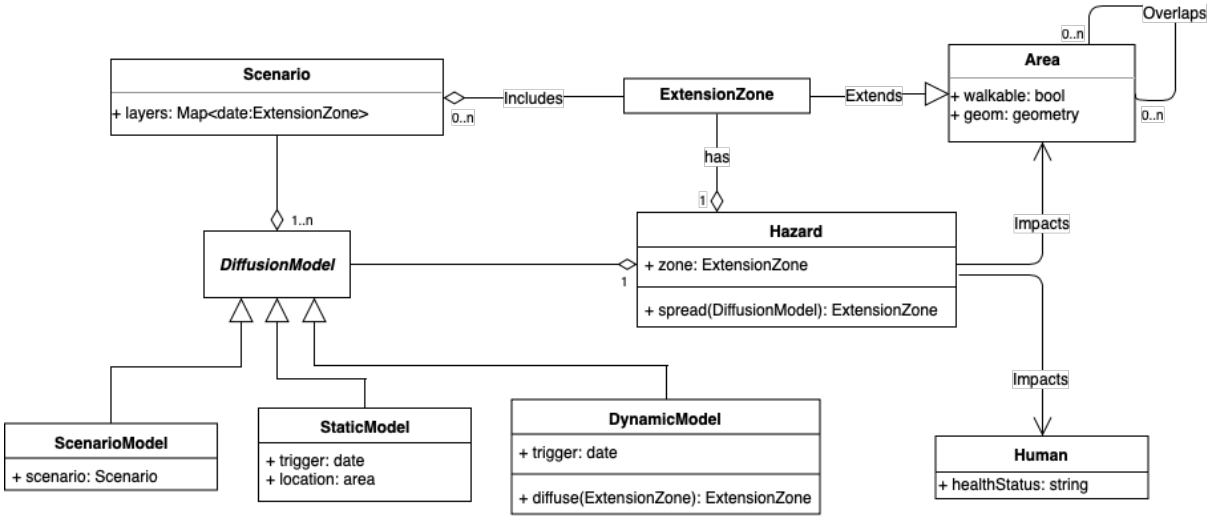

Figure 3. The UML class diagram of ESCAPE hazard module

Another way to represent the evolution of a hazard or danger consists in generating a catastrophic event using dynamic diffusion rules. We provide two methodologies to generate this kind of events: extension over cells of a cellular–automata or moving geometries over a continuous space. The first one consists in splitting the spatial area of study into cells of equal size, e.g. 20 x 20 meter square that cover the overall studied area, and mimic the evolution of the event by the diffusion of properties and values from cell to cell. For example, one cell can be on fire and diffuses fire to adjacent cells following a diffusion equation that can include any process, like direction of wind or the amount of combustible. The initial distribution of the variable to be diffused can be easily set up using GIS data. The second option is close to the scenario-based representation of a hazardous event: starting from an extension zone, e.g. shapefile of a river or the footprint of a building on fire, the spatial object representing the catastrophe can be extended using agent-based spreading rules. In this extension, each vertex of the hazard spatial object is an agent that will apply the spreading rules: for example, a flood spatial object could have vertices speed up by decreasing or slowing down with increasing elevation, stopped by obstacles such as buildings, or splitting up when reaching a threshold distance between them. Generative solutions can be useful in two cases: when data is missing or when one wants to explore several catastrophic developments from a base scenario.

To summarize, this second *Hazard module* makes it possible to develop an ESCAPE scenario in a specific zone with really crude data, for example, only one shapefile giving a specific zone to evacuate in order to define the best evacuation roads and evaluate the delay of evacuation. In this case, one can assume no interactions with the hazard, which is in many cases the aim of preventive evacuations. One can also import several layers representing the spatial and temporal dynamics of the hazard. In this case, ESCAPE provides tools to configure the delay between each layer in order to simulate the speed of the event. Finally one can choose to model the hazard dynamics with CA or moving geometry. This last possibility is interesting in case there is no information about the possible spatial extent of a hazard or if one has only its maximum extension value.

The realism of the simulations thus requires, for these two previous modules, a precise description of the territories concerned by the hazards and their stakes. The use of a geographic information system makes it possible to structure this data. This realism also involves a detailed description of the population to be evacuated. With the use of agent-based modeling, each agent is differentiated according to several criteria: gender, age, family composition ... Each agent will also have a perception and representation of his environment, and will be able to act accordingly, which we will see later in this paper. Before that, the next section presents the third most important module in ESCAPE which allows the description of means implemented by public and private actors to make the territories less vulnerable to these hazards. In particular, it insists on crisis management and its strategic and operational aspects.

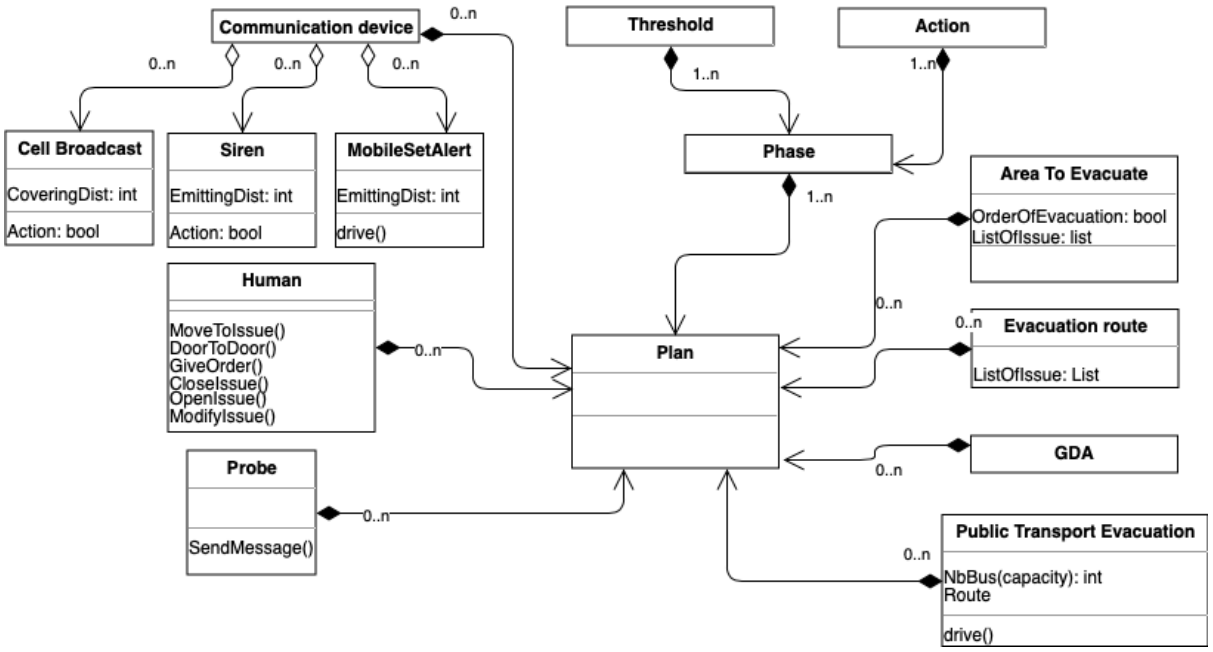

Figure 4. The UML class diagram of ESCAPE evacuation plan module

Crisis Management Module

Whenever an evacuation is required, whether it must be accomplished urgently (Tsunami) or spread over time (cyclone), the objectives are the same: How does one alert the people? By what means can we get as many people out of this geographical area as possible in the shortest possible time? How to organize bus routes so that they cover the widest possible area and collect the largest number of people? How to offset population departures in order to limit network congestion? How to deal with people who are not residents and who are not familiar with the evacuation procedures? The possibility of describing an evacuation plan or confinement strategy with ESCAPE is then a crucial issue. It must be a means to evaluate existing evacuation plans depending on factors such as the number of casualties or the time of complete evacuation.

On the basis of spatiotemporal hazard scenarios identified hereinabove, emergency planning zones can be defined and measures for the protection of the population worked out by the different authorities. Evacuation plan description can be schematically split into two categories, one related to available *resources*, both material and immaterial, and one related to the *phases*, *i.e.* the different stages of use of these resources according to the evolution of the hazard and of the plan itself (see figure 4).

Available resources

Planning involves deploying along a scale, (hazard intensity-based, time-based or alert-based) divided into a finite number of phases, a series of actions that mobilize resources to accomplish a program. Our framework provides optional setup to design available resources, *i.e.* but one can simulate self-evacuation of people to explore the overall effect of a lack of strategy. A certain number of human resources, probes, buses or shelters are all resources which can be used in a plan to conduct an evacuation.

Checkpoints and probes in the territories. Observation of an evolving hazard in a territory is an essential factor to start an action plan as soon as possible and to make it evolve during an event. Probes are agents placed in the environment to record specific attributes, such as the water level or wind speed. We can locally use these probes to follow the evolution of a hazard described from a dynamic model. We can also use these probes to follow traffic congestion, as does video surveillance, for example. This information can be provided to the organization, automatically or on demand, to trigger or to decide the type of actions to be taken.

Communication device. Evacuation implies alerting and keeping the people informed during an event. Various tools are implemented in ESCAPE to simulate information diffusion. Alerts can be transmitted through a network of sirens. In this case one can define location of these sirens and the distance covered by the microphone which is supposed to transmit the signal to the agents. Alerts and information can also be sent using radios or mobile devices, in this case the spatial dimension is less important than the individual equipment level and connection to

social networks which can be defined during the initialization process. Alerts and information can then be given to the entire population (siren, radio) or to sub-groups (cell broadcast principle).

Areas to be evacuated. The determination of the areas to be evacuated makes it possible to estimate the number of people who will have to be evacuated, independently or assisted by public transport. As for the environment definition, these areas to evacuate can be defined using a shapefile. Identification of these areas makes it possible to estimate whether it is necessary to carry out a poly-phased evacuation, by focusing at first on the evacuation of the people present in the most exposed zones. The choice between a simultaneous evacuation or an evacuation in phases can be then made on the basis of information related to hazard scenarios (differentiated levels of the hazard in the area, temporal dynamics of the hazard) or of a geographical division depending on criteria such as maximum population densities, building types, road network constraints etc. It finally helps to identify evacuation routes that minimize the risk of congestion. When an evacuation concerns many neighborhoods, care is taken, for example, to avoid the flow of vehicles crossing or converging towards the same exit point.

Gathering and orientation areas. Provisional shelters are places for hosting evacuees who do not have accommodation, such as family or friends. Each hosting site has a limited human capacity which must be known in order to allocate the population in the various shelters. For people with their own accommodation solution, orientation zones are targets that must be reached quickly during evacuation to exit the danger zone. These are most often roundabouts, motorway entrances or commercial areas that the most important roads converge to, thus facilitating the evacuation. From there, the vehicles disperse to reach various destinations outside the danger zone. The existence of these assembly points is generally accompanied by evacuation routes, a sub-section of the road network that the motorists will have to use, depending on their location, in order to leave the zone. These routes may be more or less adapted to the evacuation, with certain routes closed to traffic or traffic direction changed on others.

Public Transport Evacuation Plan. Public transportation is a resource deployed to collect non-autonomous people (children, elderly) and more generally anyone who does not have a means of transport to take them to the shelter or the orientation zone. We need to define pick-up points (bus stop) inside the zone for evacuation to shelters outside the area. Resources involved in terms of buses required and pick-up points depend on the proportion of non-autonomous population as defined in section Human and Household and their residence place. During the evacuation, the schedule file and normal routes are no longer adapted. Instead, we use evacuation routes (Noria), with pick-up and evacuation points and a pool of buses.

Human resource. Execution of a plan involves deploying human resources on the ground which will be able to secure danger-prone areas, install signposts on the ground, inform and help people during the evacuation process. ESCAPE provides two different methods to take such resources into account. The first one is to create agents in order to perform specific actions. These actions will then be limited by the number of agents available and their capacities to carry them out. Methods such as door-to-door information dissemination or road closure are available to these agents. The other option is to declare a value of available agents per hour and to compute, for every action taken in a given place, the necessary time to accomplish it and counting down the credit time.

After quoting the various resources available to the crisis manager, the following section details the use of these resources before and during the crisis.

Phase specification

The perception of an event (rising water level) can lead to an action (close) on a target (a road). Planning is about connecting perceptions with actions and targets in order to achieve a set of goals. These sets perception-action-targets can be broken down into various phases, from a vigilance phase to an alert one. A plan can then be described with the help of general semantics allowing each alert level to define perceptions that will trigger actions to be executed on a set of targets during the simulation. The overall plan is then supervised by one or more organizations that will be able to allocate resources for its execution.

Steps or phases of a plan. The phases of a plan relate to the pre-crisis, crisis and post-crisis periods. ESCAPE offers tools to model the first two phases, only the first one (preventive evacuation) or the second one (emergency evacuation). The procedures that allow the continuation of certain activities even in a degraded situation and the planning of the return of the populations are for the moment outside the scope of ESCAPE. From a time scale or threshold scale, the user can define as many phases that exist in a specific plan or create a new plan from scratch. It is possible to associate the time or threshold scale to a series of objects which will be used to both describe the hazard dynamics as well as engage in new protocols. The position of each object along the axis defines the time (or threshold) of its activation. These objects can represent probes (level of water), polygons (spread of flood), time (before event) or information (weather warning). The user, by changing the slider position on the scale, can decide the moment or the intensity at which the phase is switched on or off. Objects on this scale will then define the

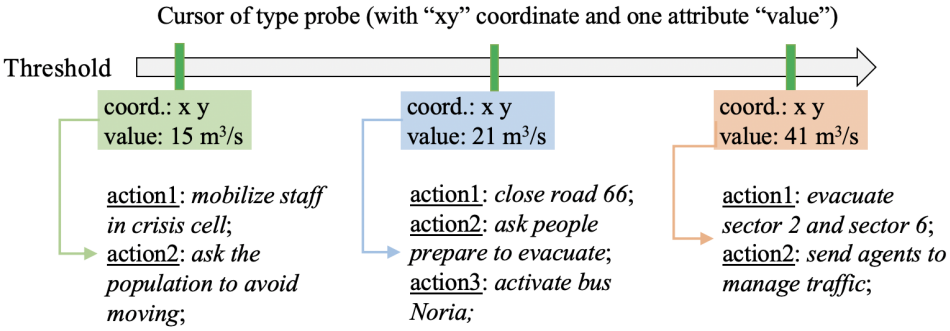

Figure 5. an example of scale of evolution of the hazard allowing to graduate the actions to lead

phases, such as *vigilance*, *pre-alert* and *alert* phases. Once the various phases are defined, it is necessary to define actions that can be taken for each of them (5).

Actions in a plan. An action, for example the closing of a bridge, is triggered by an organization either through direct access to the object concerned (here a link of the road network) or performed by an agent which must then have capabilities (perception, mobility, cognition etc.) to act on this object. An action can have a limited life, which must be defined in terms of phase, time or threshold. It can also have an unlimited life, which implies that once a phase is triggered, the initiated actions continue to be realized even if the thresholds progress and engage additional actions related to the subsequent phases. Many actions can be performed following the triggering of a phase. If initially these actions concern essentially the diffusion of information to the population and the agents involved in the plan, concrete actions such as closing of the schools or activation of Noria buses can follow. Gathering information on the evolution of a hazard or population dynamics is an action that can be performed throughout the simulation. Information can be collected either locally via probes or agents or globally via counters. Information here represents the mediated perception of an event. The second type of flow of information is related to information transmission. Resources such as communication devices can be used to transmit information to agents or other organizations. This information coming from the organization are inputs for other agents, whether it is individual agents of the population or organization agents (civil servants). The semantic content of sent messages is important because it will act on the action performed by the receiver. But a plan is not just about information flow but also about concrete actions. The main actions to be carried out in the implementation of an evacuation plan are possible here. Sending personnel to a specific area, closing / opening an object (e.g. a road section), modifying the attributes of an object (e.g. traffic light), triggering the dispatch of messages. The execution of most of these actions involves the use of the agents' elementary behaviors as described in figure 6.

After defining the risks in a given territory, the resources available and the strategies that can be implemented to protect populations, the last section describes the intelligence of the ESCAPE system.

Decision-Making Module

This cognitive module deals with individual aspects for perception, displacement, decision making or emotions related to citizens or civil servants and with organizational aspects for operationalization of the plans, adaptation to event dynamics and for optimization scenarios.

Agent cognition toward mobility behavior

Individual and collective response to unpredictable and potentially threatening circumstances due to a hazard event are difficult to observe and reproduce. However, there is a broad consensus on the complexity of human behavior during such an episode (Toledo et al. 2018). Hence, we want the agents of our framework to be able to mimic those responses and exhibit complex decision-making processes and behaviors. Our proposal extends the BDI model of cognition (Bratman 1987) to include emotional response and social attachment to better apprehend individual and collective dynamics during evacuation.

Enhanced Belief-Desire-Intentions architecture. In order to enable such complex human behaviors, ESCAPE allows the use of BEN (Behavior with Emotions and Norms) agent architecture (Bourgais et al. 2017). BEN is based on the BDI model of cognition that features modules for adding emotions, emotional contagion, personality, social relations and norms to agent behavior. It was already used to model human behaviors in two evacuation contexts: bush fire evacuation in Australia (Adam, Taillandier, et al. 2017) and the evacuation of the Station Night Club in the US (Valette et al. 2018). The use of BEN for ESCAPE enables not only taking into account the capacity of the

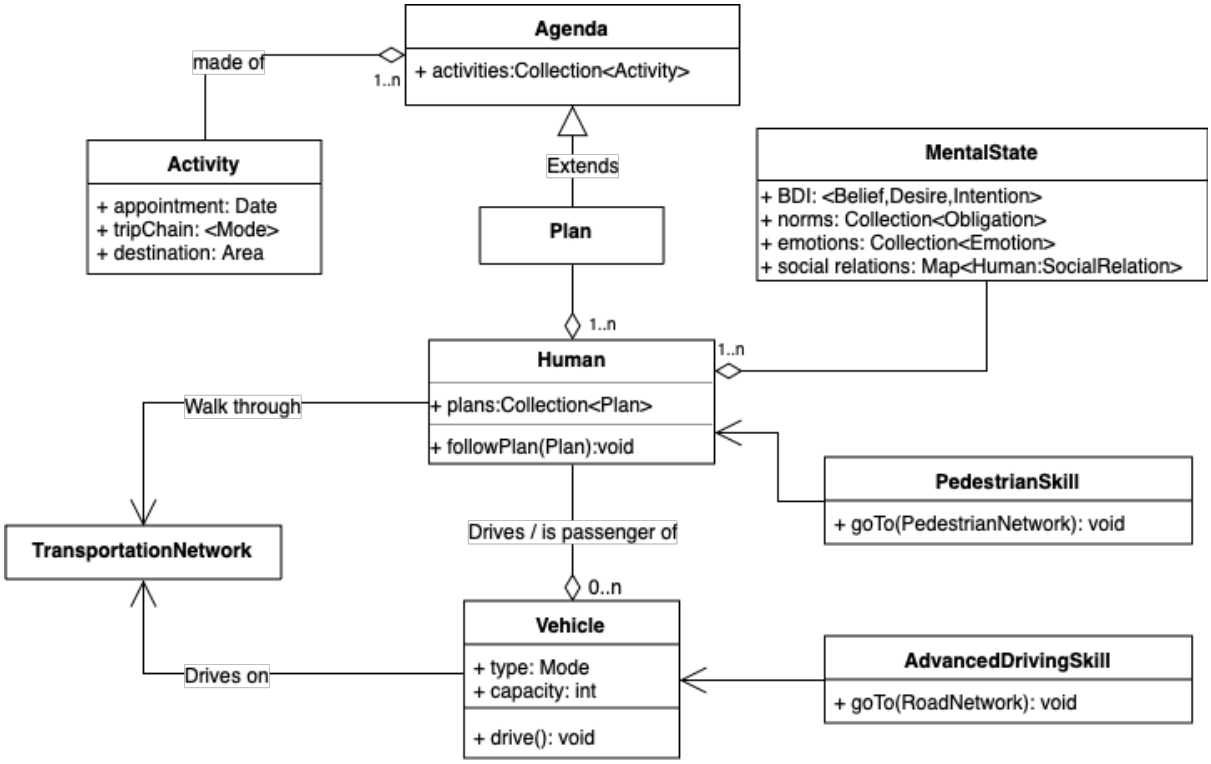

Figure 6. The UML class diagram of ESCAPE Human agent module

agents to carry out complex plans (*e.g.* choosing sub-objectives from a set of antagonist desires such as going to school to pick up their children and going as far as possible from the hazard area), but also the impact of emotions (and their contagion) and norms (laws, social norms) on the agent behavior. Not only can BEN be used to model the transition between normal behavior and evacuation behavior, using the knowledge of the disaster or danger signal, but the addition of norms, emotions and social relations also makes it possible to specify heterogeneous responses: for example, will drivers follow driving rules while feeling in danger or will parents go to the designated shelter while their children are at school? Moreover, the architecture is flexible enough to endorse normal as well as crisis behavior and decision-making circumstances. In addition to these cognitive aspects, the agent has skills related to its mobility.

Strategical, Tactical and Operational level. ESCAPE promotes an activity-based macro traffic dynamics using data-driven synthetic agenda to cope with the strategic level. Each individual of the synthetic population is generated with a scheduled set of activities according to its demographic attributes and optional data about mobility activities (see section Human and Household). Thus, the overall traffic demand is generated from the bottom-up, emerging from the agenda of individual users. The tactical level is more concerned with how the agent will cope with the direct environment in order to reach its destination. Using the BDI architecture coupled with emotions and social constraints (*i.e.* norms and social relationships) makes it possible to respond in a credible manner to unexpected traffic-related circumstances: for example, will they follow driving rules or will emotions and desires lead them to disregard them. The operational level is agentified using multi–modal algorithms to handle traffic related micro, *e.g.* lane change or collision avoidance, to nano dynamics, *e.g.* time frame speed regulations and continuous pedestrian walking direction. In the subsequent paragraphs, we will give details of the tactical and operational levels of pedestrian and motorized mobility behavior.

Human agent and mobility

Agent mobility includes pedestrian and motorized trips using private or public transport vehicles 6. Agents mostly follow a synthetic activity agenda as the main plan which is supposed to replicate daily mobility. In an emergency situation, depending on its perception by agents and the knowledge about safety measures, they can switch off more or less rapidly their synthetic agenda - they change their plans - to follow other targets: go back home, pick up children at school, reach an evacuation center ... and implement new means to achieve them: new trip, new modes of transport, all of this with a more or less strong emotional charge.

Pedestrian mobility model. Pedestrian mobility is a mix between free movement in a continuous space and a constrained path defined on a specific pedestrian network (Chapuis, Taillandier, Gaudou, et al. 2018). These interlacing dynamics make it possible to define the shortest path on a dedicated network and micro dynamics of continuous movement. On the tactical level, agents estimate the shortest path on the dedicated pedestrian virtual network, and, on the operational level, move over a continuous space following a series of nodes as intermediary goals. Each edge is then considered as a segment that occupied all the available space defined in the walking area, pedestrians going in and out as is the case in 1D road networks. Agents will avoid collision with other agents inside segments following a repulsion mechanism inspired by the social force model (SFM) (Helbing and Molnar 1995). Enhancements from the classical physical inspired model include behavioral and collective adaptation: the probability of agents getting back to a previous position when its current move inside a segment is blocked by other pedestrians and the collective speed adaptation negatively correlated (with threshold values) to the number of other users within the segment.

Vehicle mobility model. This model basically concerns motorized modes of transport, from individual to collective ones. The main idea is to dedicate a tactical level for *i.e.* path finding, re-routing and response to environmental change and to dedicate an operational level to *e.g.* lane change, speed or collision avoidance. The main processes of vehicle micro and nano dynamics are comprised within a *skill*, a set of methods (behavior) and variables (attributes) automatically associated to a kind of agent within the GAMA platform. This skill makes it possible for any vehicle (private car, bus) in ESCAPE to: manage moving speed, lane change, overtaking and distance from other users according to driving rules, road attributes and willingness of the driver. For more details on algorithms and processes involved in vehicle behavior, see Taillandier 2014 and Czura et al. 2015a. Note that both the use of personal vehicles and moving buses on a dedicated network as described in Transportation network and Area use the same library.

Evacuation behavior. While an agent will follow the agenda for day–to–day trips, *e.g.* go to work or go shopping, any hazard related event (siren, SMS, rumor etc.) can disrupt this normal course of action. In this transition stage, humans rarely remain fixed in one type of behavior but instead have a series of behavioral reactions, according a continuum between instinctive reactions such as stupefaction, panic, automaton behavior or instinctive struggle (Goya 2014) to reasoned reactions such as following the rules (confinement, evacuation), following the social norms (altruism) or individual rationality (pick the children up from school, fight against the potential impact of the danger). Deviant behaviors such as looting and curiosity can be ranked in this latter category (Cantin et al. 2016). In Escape, we then consider evacuation behavior as a different version of the agent's normal mobility behavior. The normal mobility behavior is then written in each agenda and each agent uses strategies and tactical behavior to follow this agenda. With hazard dynamics and / or the evacuation signal, agents may trigger another strategy. So, despite the danger, a certain part of the population will temporarily follow their every day life: this happens frequently in flood risk territory where, despite an alert level asking people to stay at home, the residents do not trust these authority signals and continue their normal activity, thus potentially endangering themselves (Ruin et al. 2017). On the contrary, others can react automatically to the event and the signal but do not follow any rule or advice given by the competent authorities: they will stay locked up at home instead of evacuating for example, or the opposite. Finally a proportion of people will both react in a timely manner to their own safety and follow the instructions that are given. It is the spatio-temporal conjunction of these three types of behavior that makes evacuation complex and which requires that it be organized and controlled.

Organization agent

Evacuation of hundreds of thousands of people is often based on an organization controlled by only a few dozen experts and guided on the ground by hundreds of agents. Human issues are therefore essential for the success of an evacuation, because people are expected to follow actions planned by experts, and organizations must be ready to adapt to people reactions and behaviors if dynamics fall outside the framework it has set. We make a distinction between and individual, as depicted previously with the citizens, and an organization. In the first category we also add those responsible for evacuation (civil servants: police, firefighters, civil defense, etc.). The second category represents an entity which aims to use resources in order to execute an evacuation plan as defined in Crisis Management. It is possible that an evacuation concerns several organizations if several plans exist. This may be so in the case of a major crisis spreading over a very large geographical area that involves several municipalities. In this case, one main organization can control the others with a specific plan and can collect and diffuse information about possible contradictions between actions taken by these different organizations. The behavior of an organization is then to use the information collected on the "ground" through control points and from other organizations to coordinate the evacuation plan. One can say that evacuation from the organization's point of view is a top-down approach.

The last section presents two case studies still undergoing active development. The aim of these two examples is to give some details about data processing, methods implemented and model evaluation.

ESCAPE CASE STUDIES

The first example shows the use of the driving skill in the context of the evacuation of a city with automobiles, the second one focuses on the evacuation of a district by pedestrians, access to motorized vehicles being impossible. Geographic data of these two case studies is loaded to define graphs from polyline geometries and polygons with related attributes (i.e. building, park, school ...).

Industrial accident in the French city of Rouen

Rouen is a Norman city (France) built across the river Seine, with six bridges over it. This topology makes its road network vulnerable to events that would damage or more generally reduce access to the bridges. Many SEVESO plants are installed along the banks of the river, most in reach of at least one bridge: industrial hazards are a preeminent risk for the city. The official instructions in the case of an industrial accident is the confinement of people, at home or in the nearest building. But if an event occurs during the day, tens of thousands of motorists or people on public transport may have to leave the dangerous area as quickly as possible due to lack of available shelter. How long can it take at best? Are the bridges that divide the city into two a real challenge for spontaneous evacuation? We built Rouen's road network with OSM data and chose to define as orientation zones all the nodes located at the border of the simulation space. These orientation zones represent targets that must be reached by drivers to evacuate the zone at risk. Bus lines and bus stop times are taken directly from the public site of the agglomeration's transport authority. Each stop is thus associated with a node in the graph and whenever necessary, in particular for the exclusive use of bus lanes, certain sections have been identified as being authorized for the buses only.

Figure 7. ESCAPE Rouen. Road network and buildings from OSM, with car (in green) and buses (in red)

Localization of the population is an important issue for this type of unpredictable hazard because it greatly affects its vulnerability. We have chosen as the initial condition the worst situation, that is to say, during the peak traffic time in the morning on a weekday. The volume of cars in circulation and their location on the network was estimated from the city's traffic count data. The driver's agenda was defined from the household and displacement survey, which indicates all the movements of a population sample for a typical day. Each agent localized in the network has an agenda indicating the places he must successively go to. Being in one place, he will implement different behaviors (tactical, strategical and operational as described in (Czura et al. 2015b)) to reach his next destination. The definition of the plan has only two phases here, since it goes from a normal circulation phase (Tranouez et al. 2009) to an accident phase (Daudé et al. 2009). In this case, all the agents receive the alert signal at the same time

and change their destination whatever be their agenda. For each of them, the new destination becomes the closest exit point of the network in terms of reaching time. Figure 7 shows a part of the simulation space. We can clearly see, in the center of the image, the 6 bridges that connect the right and the left banks of the city. Unsurprisingly, the city center with its 5 bridges is the longest to evacuate. According to initial conditions and parameters used (Czura et al. 2015b), it takes almost an hour and a half to evacuate most of the 42 000 vehicles present initially.

In these simulations, buses had the exclusive use of their dedicated lines and we did not simulate traffic accidents. The constraints on the use of the network can easily be relaxed by introducing in the plan, the use of a new network layer adapted to the evacuation, in which the bus lanes can be used by all vehicles, with possibly a change in the direction of circulation to promote centrifugal movements. The capacity of the model to allow integration or emergence of accident-prone situations is more complicated because of the several factors that may be involved in a traffic accident. For the moment, the mobility model corresponds to that of an autonomous car, capable of making rational decisions concerning its own objective (to reach a point as quickly as possible) while adapting itself to the behaviors of the other cars present in its environment. One might be tempted to use accident statistics on the territory to inject accident probabilities at certain accident-prone points. But we cannot be certain that it would be the same areas concerned and the same behaviors that would cause accidents during a crisis and evacuation situation.

Flood risk in a small quarter of Hanoi city

According to the world risk index, Vietnam is one of the 20 most vulnerable countries around the world with respect to natural disasters. The country's long coastline (covering more than 3400 km), the two major deltas (Red river and Mekong) and low altitude (only 20% of level land cover) make recurrent storm and typhoons deadly. On November 2017, Ho Chi Minh City authorities decided to evacuate by anticipation 2 million people because of the typhoon Damrey, nonetheless, causing at least 30 deaths. Management and control of such extreme and large events are a priority challenge for Vietnam's authorities.

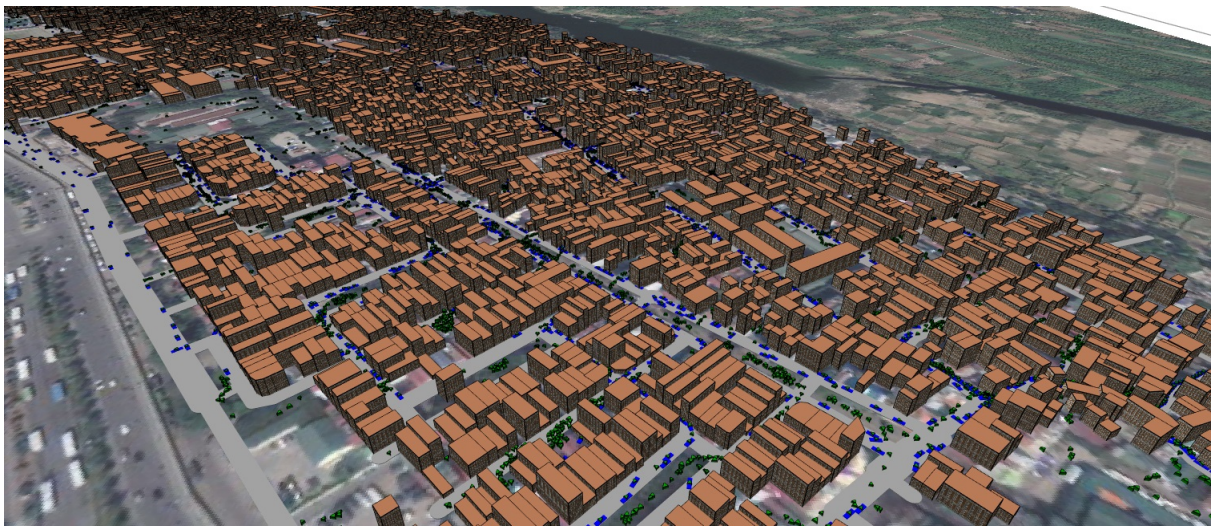

Figure 8. ESCAPE in Phuc Xa quarter in Hanoi. Evacuation model (Chapuis, Taillandier, Gaudou, et al. 2018) with both vehicle (in blue) and pedestrian (in green)

A previous study applied our framework to the small ward of Phuc Xa in Hanoi, the capital city of Vietnam (Chapuis, Taillandier, Gaudou, et al. 2018). It covers 1km^2 between the Old Quarter of Hanoi separated by a Dike and the Red River. The simulated scenario has been built in anticipation of a possible failure of the Hoa Binh dam, situated more than 80km upstream of Hanoi. The failure would cause a wave of water to submerge a large portion of the city, including Phuc Xa neighbourhood. Because of the lack of data, the hazard was not directly implemented into the simulation model. Rather, we chose to trigger dispatch of an evacuation signal to all the individuals of the studied population, urging them to evacuate the area towards the closest exit. Regarding the synthetic population of agents, we recreated the record population from available census of 2009: 15767 people with known age and gender.

Regarding mobility behavior, we implemented a basic every-day-life synthetic agenda as a proof of concept. Agents leave their home place to go to another building in the area at any random time between 8 and 10am. The target building represents either a known localized workplace and school for an active adult agent and under-18 agents respectively. A third kind of mobility, which mostly consists in wandering around, was implemented for retired

people. For mobility modes, we emphasize two-wheel vehicles and pedestrian mobility behavior. Agents will choose to use one or the other depending on the estimated travel time, without any consideration on whether they are moving towards everyday objectives or evacuation exits.

Much attention has been given to the micro-level mobility model: pedestrian movement is explicitly represented with avoidance of collision and walking over a continuous space, while two-wheel vehicles follow the rules defined in the previous study in the city of Rouen (see sections Human agent and mobility and Industrial hazard case study). For the former, the initial setup was defined using shapefiles of buildings and free walking areas. We applied Delaunay's triangulation algorithm to divide the whole space into small sections that allows pedestrian agents to find their way through the entire ward, while walking towards intermediary target points as is the case in a network.

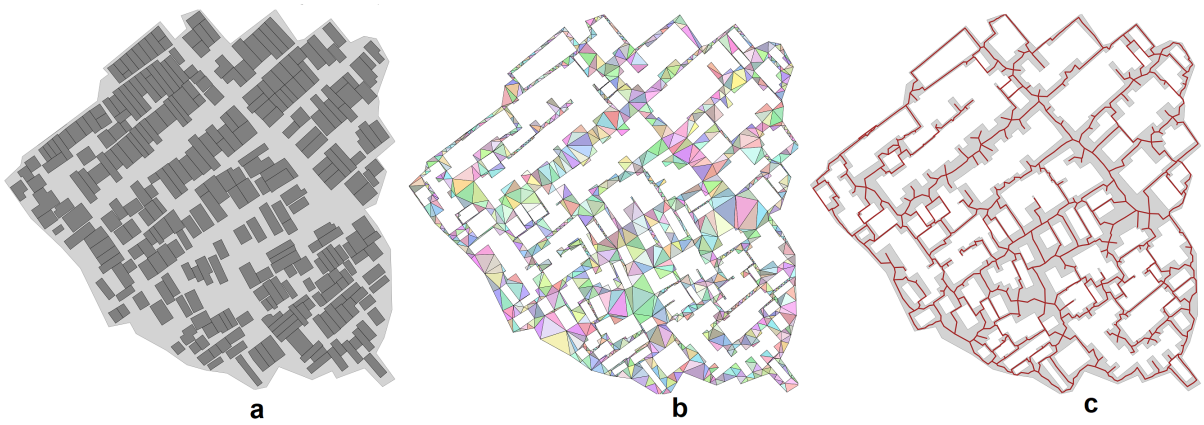

Figure 9. Small section of the ward with (a) walking area detection using buildings (b) Delaunay's triangulation process resulting in a scattered walking area (c) the final pedestrian virtual network to guide people walking through the area

As depicted in figures 9, defining the virtual network, in which the agents find their way to walk towards the destination, is a three-step process: (a) defining the walking area using any obstacle, in our case all the buildings (b) dividing the whole area into small sections to be used (c) eliciting the virtual network. Like vehicles, the agent will then be able to search for the shortest path from the starting point to the pedestrian destination using the network.

The evacuation signal is sent early in the morning at 8.00 am, with mobility behavior starting at 7.30 am. This means that some agents will be at home and others moving towards their goals as they walk or drive to their workplace, school or just wandering around. Thus, the evacuation starts while people are already in the middle of their daily activities. Considering this basic setup, we have been able to estimate the time of evacuation for the overall area to be about 1 hour 37 minutes. However, because of lack of data, we have not been able to apply any kind of mitigation strategy, nor different scenarios considering the impact of the hazard on the evacuation process.

CONCLUSION AND FUTURE WORKS

This paper is about a new multi agent-based simulation framework named ESCAPE, which aims to support a wide range of population evacuations in urbanized territories. As such, ESCAPE can clearly be categorized as a decision-making tool. It can take into account both the fine geographic scale, *e.g.* nano-scale traffic and continuous movement as well as the fine time scale, *e.g.* second-to second speed regulation. It is built upon the GAMA environment and organized around four main modules:

- the **Environment** module deals with the spatial and demographic description of the simulation domain;
- the **Hazard** module describes all the characteristics of catastrophic events and the associated impact on human agents and infrastructures;
- the **Decision-Making** module focuses on the behavior and cognitive processes of people affected by the hazards and organizations attempting to manage the evacuation;
- the **Crisis management** module provides available resources and plan to guide and coordinate human and organizational agent responses;

The framework already integrates dedicated tools to provide modelers an easy-to-use environment to simulate evacuation in urbanized areas. However, the integration process is still a work-in-progress and we plan to release the first beta version in 2019. As shown in previous case studies, at the current stage, the framework makes it possible to simulate the evacuation of a city using multi–modal traffic model. The next phase will be to implement evacuation plans and organization to manage them, in order to simulate evacuation strategies. This will take the form of *how-to* and *what-if* scenario. Indeed, one essential aspect of studying evacuation through simulation is the possibility of testing several strategies and assess how they succeed and compare the output. To this end, we propose several default indicators like time of evacuation and the number of exposed agents. But our perspective is to give modelers tools to build their own indicators, so that they can adapt what success is and how they can asses it to the type of hazard (and exposure), the kind of safe area or any other evacuation circumstances. A typical *What-if?* scenario in ESCAPE is to replay the same simulation and then to disrupt an element, either of the plan (no activation of an action) or of the environment (faulty probe or blocking of a section). An optimization scenario *How-to?* in ESCAPE can calculate routes that minimize the evacuation time of a group of people located in different areas to gathering and regrouping areas. The classical Dijkstra algorithm can be used as a preliminary approximation in order to build an evacuation plan, which will then be evaluated through simulations.

ABSTRACT

In developed countries, small and medium-sized enterprises (SMEs) represent the majority of all businesses, e.g. 99.9% in the UK. Given this significant proportion, any disruption to the operation of SMEs will have a negative impact on a nation's economy. In the context of flooding, this paper reports on the use of agent-based modelling and simulation (ABMS) to assess SMEs immediate response and short-term recovery. In particular, it focuses on the interactions between manufacturing SMEs and mutual aid partners, and retail SMEs and companies specializing in refurbishing premises. Results show that a manufacturing SME with a mutual aid partner can reduce loss in production by approximately 6% over a 7 working day period. In relation to retail SMEs, those with employees able to be allocated to refurbish its premises recovered faster than SMEs employing a refurbishment company, potentially one day earlier.

Keywords

SMEs; agent-based modelling and simulation; flooding; short-term recovery; manufacturing and retail.

INTRODUCTION

Disruption caused by flooding to small and medium-sized enterprises (SMEs) can result in a significant impact on a nation's economy (Coates et al., 2014). For instance, the UK's 2007 summer floods had an estimated 2.3 billion of total economic costs (Chatterton et al., 2010). A considerable portion of these losses affected SMEs which they represent 99.9% of all UK businesses (Rhodes, 2015). The term SME indicates a business with a given number of employees that differs based on the country of origin (Hallberg, 1999). The upper limit is 250 employees in the UK (Lukács, 2005) while the number increases to 500 employees in the United States (Ayyagari et al., 2003).

SMEs are often at high risk of flooding and other natural hazards (Crichton, 2008; Wedawatta et al., 2010). Also, SMEs usually have limited resources in terms of manpower and finance (Omar & Fraser, 2010; Sullivan-Taylor & Branicki, 2011; Van Gils, 2005), and tend to lack organisational disaster mitigation plans (Jones & Ingirige, 2008; Li et al., 2015). Thus, due to the importance of this proportion of businesses to a developed nation's economy, this paper aims to assess small manufacturing and retail businesses immediate response and short-term recovery from flooding. More specifically, the paper examines mutual aid partner's effect on manufacturing SMEs recovery and the effect of refurbishment companies' on the recovery of retail SMEs. According to Stier and Goodman (2007), mutual aid is defined as the sharing of suppliers, equipment, personal information, or other resources between two parties. Also, it is indicated that mutual aid is useful when local resources are insufficient to meet a business needs due to the disaster that has occurred (Sutton & Tierney, 2006). Furthermore, businesses are encouraged to improve their disaster response through contracts and mutual aid agreements. However, mutual aid agreements can be limited in scope, in which it is impossible to anticipate every eventuality (British Columbia, 2014).

Simulation models, such as agent-based models (ABM), have become a common tool in many disciplines for solving complex systems created of autonomous entities (Grimm et al., 2006). Agent-based modelling and simulation (ABMS) represents a powerful analytical research tool that can be used to investigate complex

processes (Shim et al., 2017). ABMS is commonly recognized as an effective tool for solving complex problems in business and social science (Dignum & Tick, 2007; Gilbert & Terna, 2000; North & Macal, 2007; Prasad & Chartier, 1999). Agents can be defined as an entity acting within a virtual environment that act based on predefined rules (Labarthe et al., 2007; Macal & North, 2010). Autonomous agents can be modelled to represent individuals or organisations with a set of attributes to personalize them, and rules to regulate their interactions with the other agents within their environment (Macal & North, 2010). In relation to ABMs' specifications, Helbing (2012) stated that the interaction network must be defined. Also, the initial values of all variable and the boundary conditions should be determined in advanced.

ABMS is used in this research in order to represent the large number of SMEs, each with a set of attributes and behaviours, which interact with related organisations. The approach involves interactions between SMEs and related organisations such as suppliers, customers, electrical contractors, plumbing contractors, IT service providers, refurbishment companies, mutual aid partners, Environment Agency, cleaning service providers, and insurance companies. Each of these types of related organisations provides SMEs with assistance or a service to support their post-flood recovery.

Contribution of this paper

The agent-based modelling and simulation reported in this paper focuses on the recovery of manufacturing and retail SMEs from a severe flood event in Tewkesbury, UK. Further, it reports on the interactions between SMEs and ten different SME-related organisations (suppliers, customers, electrical contractors, plumber contractors, IT service contractors, cleaning service providers, Environment Agency, mutual aid partners, refurbishment companies, insurance companies). However, the paper focuses on presenting only the interactions between (a) manufacturing SMEs and mutual aid partners, and (b) retail SMEs and companies specializing in refurbishing premises; although other SME-related organisations are modelled. Also, for manufacturing SMEs, their recovery has been assessed by making use of the trapezoidal rule to establish the level of production loss due to the flood event.

AGENT-BASED MODELLING AND SIMULATION APPROACH

An agent-based model has been developed and used in simulations to assess the potential effects on SMEs' immediate response to, and short-term recovery from, flooding of a range of precautionary measures deployed in the manufacturing and retail sectors. In this research, the ABMS approach is made up of three main components as indicated in Figure 1: (i) flood-event simulation; (ii) a modelled geographical environment (MGE); (iii) agent-based modelling and simulation. Firstly, flood event simulation represents the input data (e.g. inundation data) that feeds into the MGE component. Next, the MGE combines Ordnance Survey (OS) data (e.g. Topography, Integrated Transport Network (ITN), and AddressBase Plus layers) with the input from the flood event simulation to enable the identification of the flooded and non-flooded organisations. Consequently, the identified organisations, including flooded and non-flooded SMEs in addition to related organisations, are modelled as autonomous agents and simulated over three time frames: pre-flood, during flood, and post-flood.

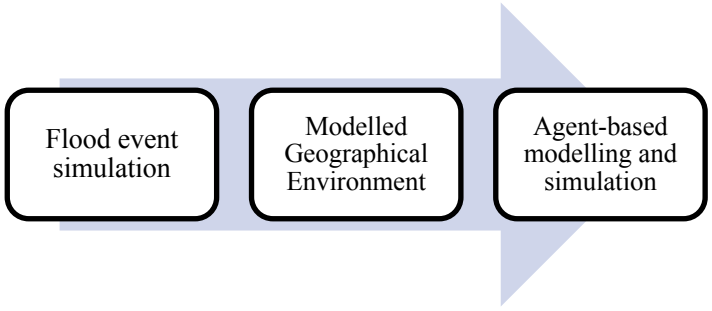

Figure 1. ABMS Approach Overview

MODELLING SMES FROM THE MANUFACTURING AND RETAIL SECTORS

Overview

Manufacturing and retail SMEs are modelled as autonomous agents with a different set of attributes, behaviours, and predefined precautionary measures. Behaviours, along with their typical durations, attributes and precautionary measures were established from various sources: (i) semi-structured interview transcripts with

SMEs having experience of flooding or being at risk of flooding; (ii) EA guidance; (iii) academic literature.

Attributes can be static (e.g. business name, size, and location) or dynamic (e.g. power available and the number of employees at a premises). SMEs' behaviours can be carried out in the pre- and/or post-flood period as discussed in (Alharbi & Coates, 2017, 2018). These behaviours are classified in terms of their type (e.g. generic or specific), priority execution order, required number of employees (e.g. single or multiple) required to enact them; pre-flood behaviours are as indicated in Figure 2. Further, each of these behaviours has a duration range obtained from transcripts of semi-structured interviews with SMEs, which introduces a degree of stochasticity into the model.

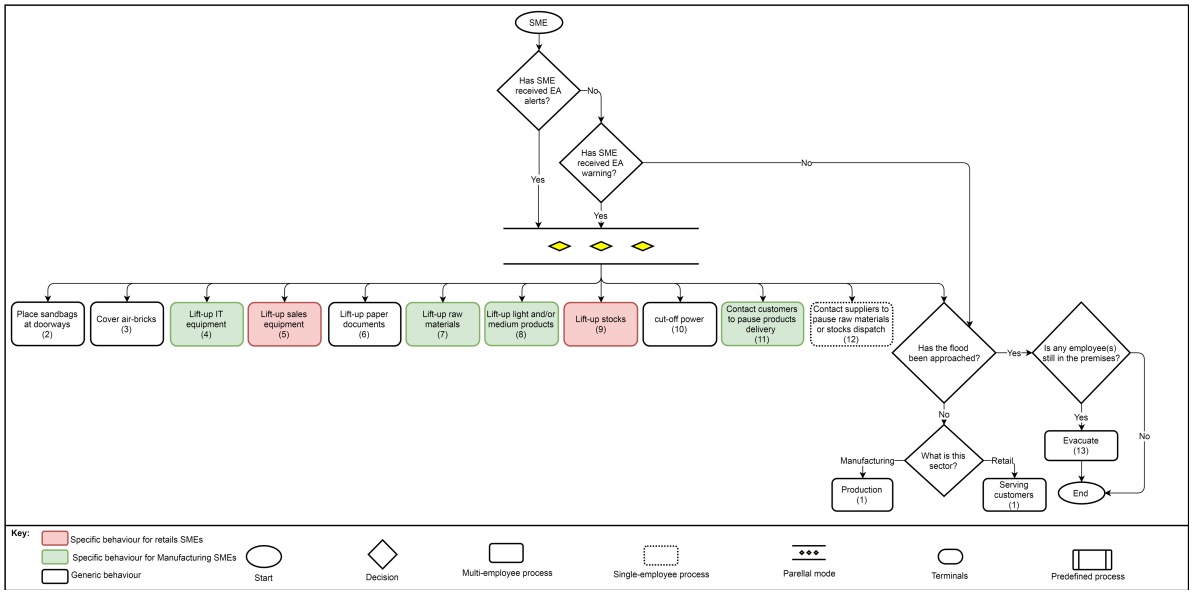

Figure 2. Pre-Flood Behaviours

In Figure 2, all the possible SMEs' pre-flood behaviours for both sectors are presented along with their associated priority execution order. Also, as shown in Figure 2, the colour used to represent pre-flood behaviours signifies the type of SME sector: green for the manufacturing sector; red for the retail sector; white for both sectors.

In relation to SMEs' precautionary measures, these are implemented by businesses prior to a flood event taking place and are intended to: (i) prevent or reduce water entering an SME's premises (e.g. build bund wall) or (ii) remove the need for, or reduce the duration of, some behaviours (e.g. raise the location at which raw materials/stock are stored).

Manufacturing SMEs

Manufacturing businesses represent a key component of developed countries' economies (Haraguchi et al., 2017). In the UK, manufacturing SMEs account for 5% of businesses, 10% of employment, and 15% of economic turnover (Rhodes, 2015). Manufacturing SMEs are modelled with the following dynamic attributes: raw materials (*RM*), production machines (*M*), employees (*E*) and power (*P*). These attributes vary during the course of a simulation and contribute directly to the SMEs' performance, i.e. production level *(PL)*. At each simulation tick, (a) production level and (b) raw materials available at the next simulation tick are both determined. If the amount of raw materials available at the current tick $\mathrm{RM_t} \geq \min\{\mathrm{E_p}, \mathrm{M}\}$, then both (a) and (b) are determined as follows:

$$\mathrm{PL} = \min\{\mathrm{E_p}, \mathrm{M}\} \times 100 \quad (1)$$

$$\mathrm{RM_{t+1}} = \mathrm{RM_t} - \min\{\mathrm{E_p}, \mathrm{M}\} \quad (2)$$

In equations (1) and (2), both (a) and (b) are determined according to the relationship between (i) the ratio of production employees working on production, $\mathrm{E_p^p}$, to total number of production employees, $\mathrm{E_t^p}$, and (ii) the ratio of machines available, $\mathrm{M_a}$, to total number of machines, $\mathrm{M_t}$. However, if the amount of raw materials available at the current tick $\mathrm{RM_t} < \min\{\mathrm{E_p}, \mathrm{M}\}$, then the production level is determined according to the amount of raw materials available at the current tick as follows:

$$\mathrm{PL} = \mathrm{RM_t} < \min\left\{\mathrm{E_p}, \mathrm{M}\right\} \quad (3)$$

$$\mathrm{RM_{t+1}} = 0 \quad (4)$$

In addition to these attributes, manufacturing SMEs are modelled with a different set of generic and manufacturer specific behaviours along with a set of precautionary measures (e.g. raise the location at which machines are placed), which may be implemented by an SME prior to a flood event occurring. These behaviours and attributes have been identified from a series of semi-structured interviews with SMEs involved in flood-related events and/or are located in flood-prone areas. Details of the attributes and behaviours of manufacturing SMEs are provided in (Alharbi & Coates, 2017, 2018).

Retail SMEs

The retail sector refers to the wholesale and retail sale of any type of goods or their associated services (United Nations, 2008). In the UK, retail businesses account for 33% of turnover and 19% of employment (Rhodes, 2015). Furthermore, it has been reported that the retail sector is among the largest job creators in the UK (Omar & Fraser, 2010). In this research, retail SMEs are modelled as agents along with their pre-defined static attributes (e.g. name and size) and dynamic attributes - power (*P*), stock (*S*), sales equipment (*SE*), and employees (*E*), and environment condition (*EC*) - along with a different set of precautionary measures.

In terms of the dynamic attributes, the relationship between them is presented in Figure 3, demonstrating that the availability of each is necessary for service capability, i.e. the capability to offer a service to customers.

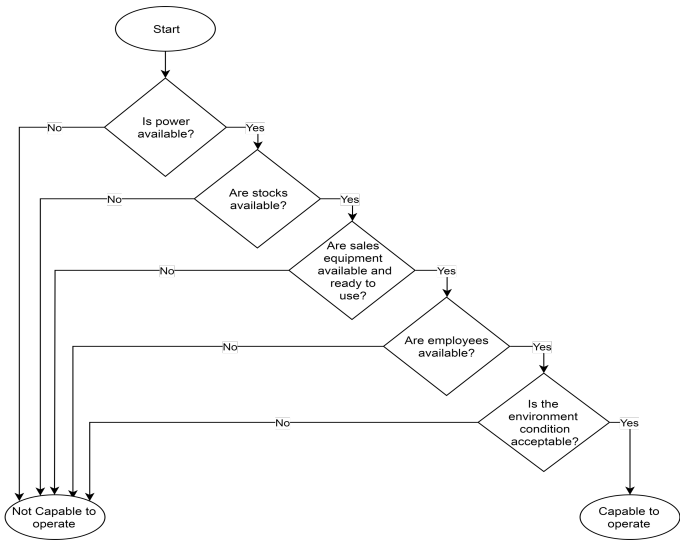

Figure 3. Retail Dynamic Attributes Relationships

As mentioned previously, these dynamic attributes may change during a simulation and contribute directly to a retail SMEs' performance, which is measured as the service capability level (*SC*). The flood event is simulated at 30-minute intervals, each of which corresponds to 1 simulation time step or tick (t_s); the service capability is determined at each half hour interval (or tick) throughout the simulated period. Post-flood, a flood-affected retail SME's service capability can be resumed if:

(a) the power supply is restored to the premises, i.e. $P = 1$ ($P = 0$ indicates that a retail SME's premises has no power and thus it is unable to operate), and
(b) stock is available, $S > 0$, where S is the percentage of stock available in its premises, and
(c) sales equipment is available, $SE > 0$, where SE is the percentage of an SME's available sales equipment, and
(d) employees are available, $E > 0$, where E is the percentage of an SME's employees available to work, and
(e) environment conditions are acceptable, $EC > 80\%$, where EC is the percentage of the work environment conditions are in a state suitable for the SME to operate.

In relation to (c), sales equipment is replaced if damaged. Replacing damaged equipment affects the recovery profile, prompting retail SMEs' status to be either in recovery, i.e. $SC = 0\%$, or fully recovered, i.e. $SC = 100\%$, providing the other dynamic attributes are greater than zero. For the environment conditions (EC), a value of

80% was selected signifying that if 80% of the premises was refurbished to an acceptable state making it possible for customers to visit the premises then the retail SME could operate, if the other dynamic attributes are greater than zero.

SME RELATED-ORGANISATIONS

SME related-organisations, which may include other businesses, can interact with SMEs to provide assistance or a service, such as electricity repairs, to support their recovery. These organisations include electrical contractors, plumbing contactors, cleaning service providers, and IT service contractors; these are modelled as either regional or national. On request, regional organisations arrive quickly at an SME's premises, but are limited in terms of numbers. In contrast, national organisations are likely to arrive later than the regional service providers, but are greater in number. For cleaning service providers, they could have a pre-defined contract with insurance companies to provide such a service to insured SMEs if required. Thus, a cleaning service could be interrupted while working for a non-contracted SME at any time when it is contacted by an insurance company with which it has a pre-defined contract. In this case, the affected non-contracted SME would need to contact another service provider; otherwise its employees may need to be allocated to clean up. In terms of suppliers and customers, a supplier provides manufacturing and retail SMEs with raw materials and stock respectively, at regular intervals, e.g., daily, every three days, weekly, or every two weeks. For manufacturing SMEs, customers take delivery on a daily or weekly basis based on the type of products, daily if light products whereas medium and heavy products are delivered weekly.

As shown in Figure 4, manufacturing and retail SMEs can interact with electrical contractors, plumbing contractors, the Environment Agency (EA), suppliers, customers, cleaning service providers, and insurance companies. In addition, manufacturing SMEs can interact with IT service contractors and mutual aid partners, whereas retail SMEs can interact with refurbishment companies. While a cleaning service can be provided to both manufacturing and retail SMEs, refurbishment occurs only in retail SMEs. This refurbishment behaviour refers mainly to renovation and redecoration of retail SMEs' premises

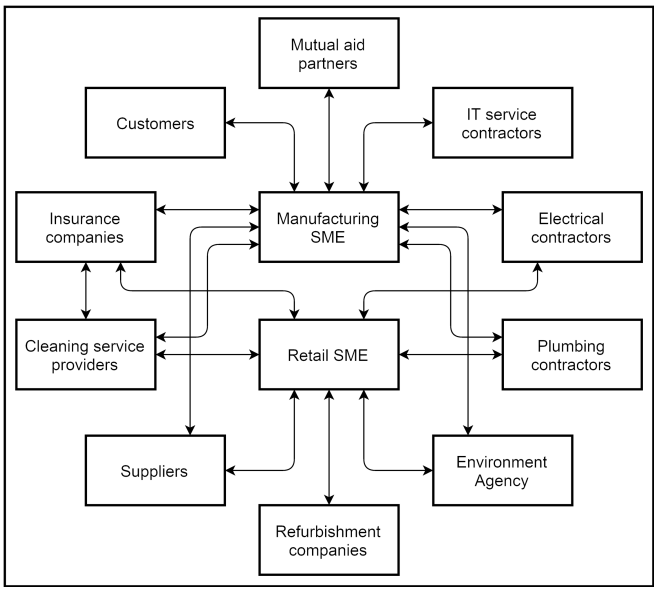

Figure 4. Interactions between SMEs and Related-Organisations

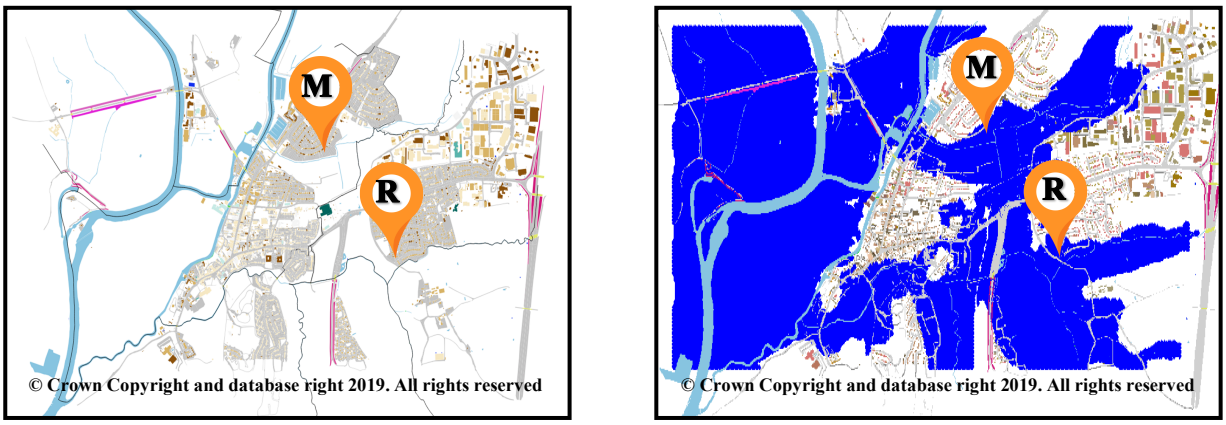
AGENT-BASED SIMULATIONS

Case Study

The case study presented in this paper is related to the 2007 severe flood event in Tewkesbury, UK. This geographical area was considered due to the high water levels reached, which significantly impacted homes and businesses. According to Tewkesbury Borough Council, more than 1800 houses and 300 businesses were flooded (Tewkesbury Borough Council, 2018). In Figure 5, the locations of two micro-sized businesses of the 349 modelled, labelled 'M' and 'R' for an SME from the manufacturing and retails sector respectively, are identified in (a) before the flood occurs and (b) after 3 days of rainfall.



(a) Tewkesbury Before Flood **(b) Tewkesbury After 3 Days of Rainfall**

Figure 5. Case study area: Tewkesbury

The flood event simulation generated inundation data representing the water depth throughout the area selected modelled at 30-minute intervals over a 318.5-hour period. After coupling the OS data, including the AddressBase Plus layer, with the inundation data, a total of 920 organisations were identified in the area under consideration with 207 of them flooded at some point during the 318.5 hours simulated. Table 1 presents a breakdown of these organisations according to the International Standard Industrial Classification of all Economic Activities (ISIC) (United Nations, 2008).

Table 1. Organisations in Tewkesbury

ISIC	Organisations		
	Flooded	Not flooded	Total
Administrative services	10	39	49
Accommodation services	8	30	38
Agriculture/forestry/fishing	1	2	3
Arts and entertainment	5	11	16
Education	0	5	5
Electricity/gas/steam	1	2	3
Finance	0	6	6
Construction	1	3	4
Human health / social work	7	100	107
Information/communication	0	8	8
Manufacturing	16	107	123
Mining and quarrying	0	3	3
Other service activities	4	29	33
Professional services	0	3	3
Public administration	8	16	24
Retail	4	222	226
Transportation and storage	92	118	210
Water	50	9	59
Total	**207**	**713**	**920**

According to statistical data related to businesses in the UK, 99.9% of all businesses are SMEs with 96%, 3.3% and 0.6% being categorised as micro-, small- and medium-sized respectively (White, 2016). Thus, the flooded manufacturing and retail businesses are modelled (see Figure 6) in these proportions given a random number of employees generated for every SME corresponding to their respective size. That is, a micro-sized business has 1 to 9 employees, a small business has 10 to 49, and a medium-sized business has 50 to 249 (White, 2016).

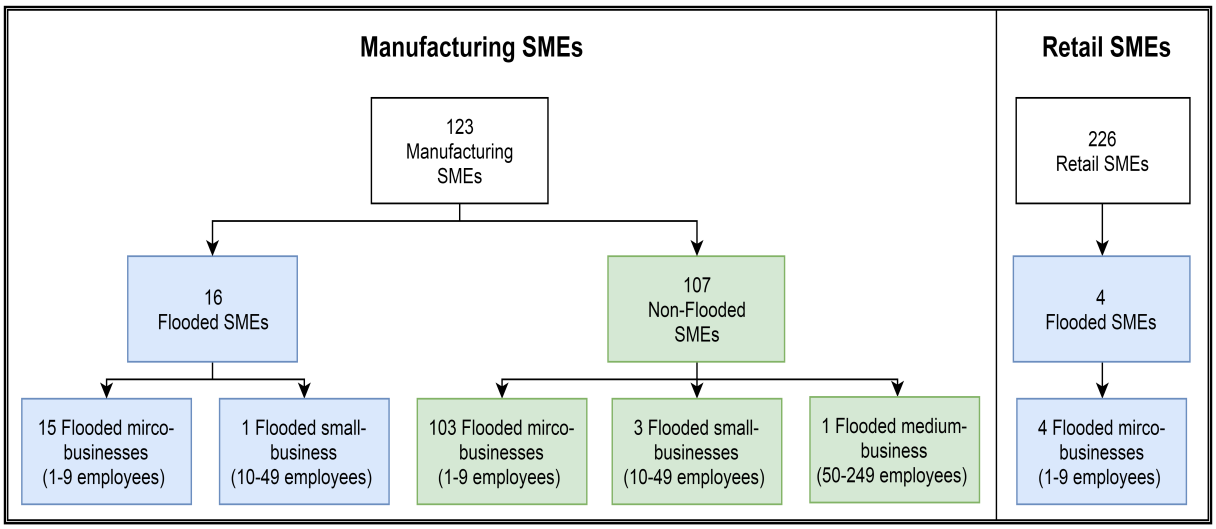


Figure 6. Manufacturing and Retail SMEs Modelled as Agents

Simulation Experiments

Four simulation experiments have been carried out with each representing different collections of precautionary measures implemented by a micro-sized manufacturing and retail SME referred to as 'M' and 'R' in Figure 5. This size of businesses was chosen due to its prevalence within SMEs. In Table 2, these four simulation experiments are defined with a focus on an SME's interaction with related-organisations.

Table 2. Simulation Experiments

Experiment	SME sector	Mutual-aid	Refurbishment by
S1	Manufacturing (M)	Yes	Not applicable
S2		No	Not applicable
S3	Retail (R)	Not applicable	Employees
S4		Not applicable	Refurbishment company

PRELIMINARY RESULTS

For the SMEs located in Tewkesbury, Environment Agency (EA) alerts were received on day 2 at clock time ($t_c = 8{:}00$) and simulation tick ($t_s = 48$), i.e. 36 hours before the flood commenced. Subsequently, EA warnings were received on day 3 ($t_c = 8{:}00$ and $t_s = 104$), that is 3 hours prior to the expected flood commencing. According to SEPA (2019), EA alerts can arrive 36 hours prior to the expected flood commencing whereas warnings may be received approximately 3 hours in advance. After receiving an EA alert ($t_s = 48$), SMEs' employees were allocated to prepare for the potential event and thus the pre-event production level fluctuated between 0% and 100% (see $t_s < 226$ in Figure 7). Specifically, employees were allocated to place sandbags at doorways, cover airbricks, lift-up paper documents, and contact suppliers to pause raw materials/stock dispatch. For the manufacturing SME, employees were additionally prompted to lift-up IT equipment, raw materials, light and medium products, and contact customers to pause product delivery. However, the retail SME's employees were allocated to lift-up sales equipment and lift-up stock.

Manufacturing SME Simulation Experiments

In the two simulation experiments undertaken S1 and S2, for the micro-sized manufacturing SME, the flood commenced at $t_s = 226$ ($t_c = 13{:}00$ on day 6) and receded at $t_s = 742$ ($t_c = 19{:}00$ on day 16), reaching a depth of 0.403m in the premises, as indicated in Figure 7. The flood duration of 516 ticks (i.e. 258 hours), coupled with the depth of water reached, led to 100% of machines and raw materials stored at ground level being damaged. Furthermore, this SME had a total of seven production employees ($E_t^p = 7$) but only six

available ($E_a^p = 6$) in the first day after the flood water receded, then all seven available thereafter.

In Figure 7, two simulation experiments are presented: (i) the red line refers to simulation experiment S1 in which the manufacturing SME has a pre-defined mutual aid partner; (ii) the green line represents simulation experiment S2 in which the manufacturing SME does not have a mutual aid partnership. Note that in the part of Figure 7 labelled (a), for S1 and S2 in the period $t_s = 0$ to 816, the production level is the same thus the red line is hidden by the green line.

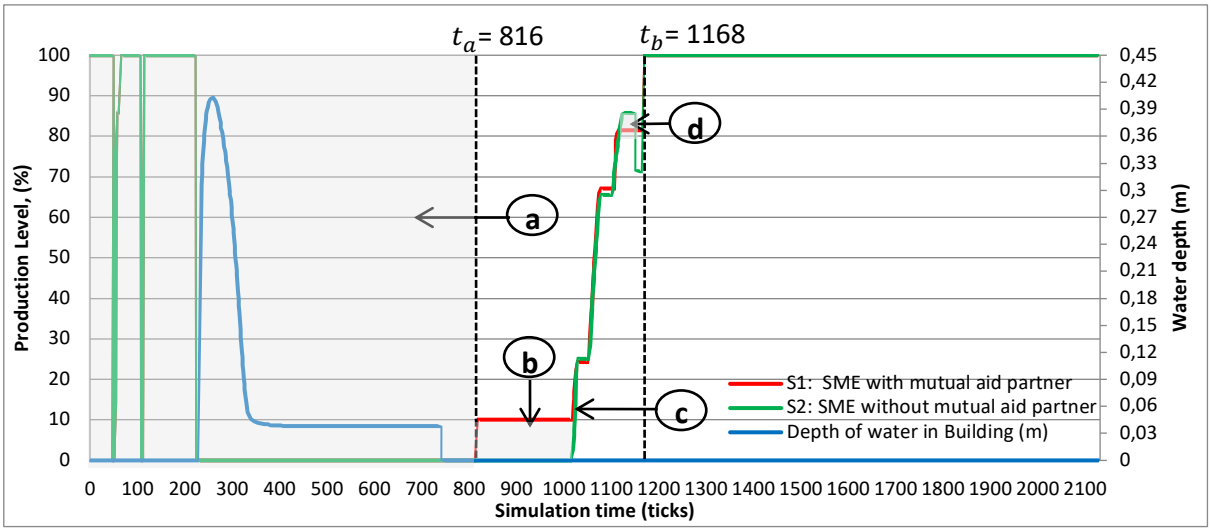

Figure 7. Simulation of Manufacturing SME – Production Level and Flood Water Depth in Premises

In relation to the manufacturing SMEs recovery, given the flood receded outside working hours, ($t_c = 19{:}30$ on day 16), the SME was unable to immediately commence actions that would start the process of recovery. However, at simulation tick $t_s = 768$ ($t_c = 8{:}00$ on day 17), employees in the SME simulated in S1 were allocated to contact their insurance company and their mutual aid partner simultaneously, whereas employees in the SME simulated in S2 were only allocated to do the former.

For S1, during the next day at simulation tick $t_s = 816$ ($t_c = 8{:}00$ on day 18), one production employee (E_p^p=1) was allocated to work on the allocated machines (M_m=10%) at the mutual aid partner's site and thus the production level was restored to PL=10%. Meanwhile, employees of the SME at the flood-affected premises were assigned to drying machines while waiting for compensation to be paid by their insurance company, which would, in turn, enable them to hire electricians and plumbers to carry out repairs (assuming that the SME selected did not have sufficient funds available). At tick $t_s = 962$ ($t_c = 9{:}00$ on day 21), the compensation was paid, enabling employees in the SME simulated in S1 to contact electricians and plumbers, who arrived at tick $t_s = 1011$ ($t_c = 9{:}30$ on day 22). At the same tick, the cleaning service provided by the insurance company arrived and carried out cleaning for 26 hours. Furthermore, at $t_s = 1019$ ($t_c = 13{:}30$ on day 22), with electricity restored, a proportion of production employees were allocated to repair machines, enabling a significant increase in production level (see Figure 7 (c)). At simulation tick $t_s = 1168$ ($t_c = 16{:}00$ on day 25), the employee allocated to work at the mutual aid site returned and started working at the affected SME's site, restoring production level to *PL*=100%.

In relation to simulation experiment S2, compensation was paid at $t_s = 962$ ($t_c = 9{:}00$ on day 21) enabling employees in the SMEs to contact electricians and plumbers who arrived at $t_s = 1011$ ($t_c = 9{:}30$ on day 22) as in S1. At tick $t_s = 1019$ ($t_c = 13{:}30$ on day 22), a proportion of employees were allocated to repair production machines and to work on production, resuming the production level to 2.5%; this was 203 simulation ticks later than the SME simulated in S1 (see Figure 7 (b)). At $t_s = 1121$ ($t_c = 16{:}30$ on day 24), it can be seen that the production level presented in the SME simulated in S2 ($PL \approx 85\%$) is greater than that simulated in S1 ($PL \approx 81\%$). This is due to the percentage of machines repaired in the SME simulated in S2 being greater than those repaired in S1 (see Figure 7 (d)), which had fewer employees in its premises; recall, one employee of the SME simulated in S1 was allocated to work at its mutual aid partner's site. Finally, the production level of the SME simulated in S2 was restored to *PL*=100% at $t_s = 1168$ ($t_c = 16{:}00$ on day 25), exactly the same as in S1.

The average production level loss (PL_{loss}) over a certain time frame ($t_a - t_b$) as shown in Figure 7, is defined in equation (5):

$$PL_{loss} = \frac{\left(100 \times (t_b - t_a)\right) - \left(\sum_{i=t_a}^{i=t_b} h \frac{(f(x_i) + f(x_{i+1}))}{2}\right)}{\left(100 \times (t_b - t_a)\right)} \times 100 \quad (5)$$

where x_i is the simulation tick and $f(x_i)$ is the corresponding production level. This method, which employs the trapezoidal rule (Kreider et al., 2005; Smyth, 2014; Trefethen & Weideman, 2014), subdivides the given interval $[t_a, t_b]$ which refers to the time period post-flood at what the production level is resumed (t_a) and the time at which production level is restored to 100% (t_b). This interval is divided into n sub-intervals of equal width $h = \frac{t_b - t_a}{n}$. In this research, $h = 1$ since $n = t_b - t_a$. Based on the method outlined, the production level associated with each experiment was used to determine the approximate average of production level loss (PL_{loss}). Based on Figure 7, the production level loss of the SME simulated in S1 is $PL_{loss} = 69\%$ whereas the production level of the SME simulated in S2 is $PL_{loss} = 75\%$, i.e. 6% greater than S1.

Retail SME Simulation Experiments

To investigate response and recovery from flooding, the retails SME referred to as 'R' in Figure 5 is simulated with and without a refurbishment company being called to attend its flood-affected premises. As shown in Figure 8, in the two simulation experiments for the micro-sized retail SME, the flood commenced at $t_s = 223$ ($t_c = 23{:}00$ on day 5) and receded at $t_s = 752$ ($t_c = 23{:}30$ on day 16), lasting for 529 ticks (i.e. 264.5 hours) and reaching a depth of 0.901m in the premises. This SME had a total of seven employees ($E_t = 7$) but only six were available ($E_a^p = 6$) in the first day after the flood water receded, then all seven were available thereafter. The recovery profile of service capability is relatively similar for both simulation experiments S3 and S4. Recall, replacing the damaged sales equipment with new equipment prompts the retail SME to restore their sales capability to 100% in a single tick.

For the retail SMEs recovery, a proportion of employees of the SME simulated in S3 and S4 were initially allocated to contact their insurer to (i) enable the flood damage to be assessed, (ii) organise a cleaning service to attend the premises, and (iii) provide financial compensation. After receiving the latter, a proportion of employees were allocated to contact electricians and plumbers to request they attend to carry out the necessary repairs. Furthermore, once electricians and the plumbers arrived at the flood-affected premises, a proportion of employees were allocated to supervise these repairs, along with the cleaning service provider organised by the insurance company. Finally, employees of the SME simulated in S3 and S4 contacted their suppliers to resume delivery of stock, and also to return the lifted-up sales equipment and documents to normal locations. For the SME simulated in S4, employees were additionally allocated to contact a refurbishment company and to supervise them when they arrived.

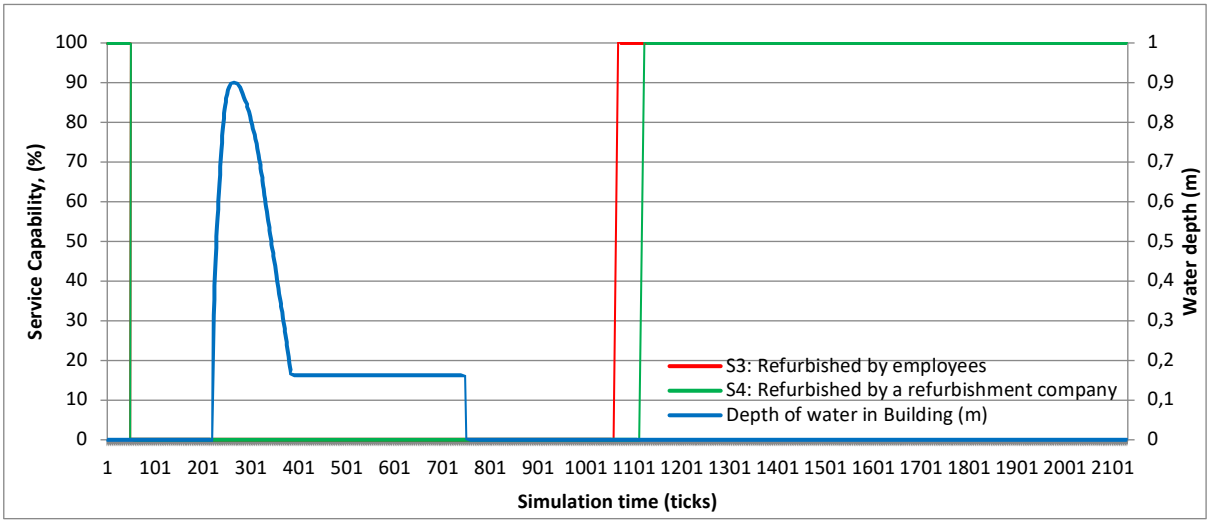

Figure 8. Simulation of Retail SME – Service Capability and Flood Water Depth in Premises

In simulation experiment S3, the service capability was restored to 100% for the retail SME at $t_s = 1065$ ($t_c = 12{:}30$ on day 23), whereas in S4 this was restored to 100% at $t_s = 1119$ ($t_c = 15{:}30$ on day 24), i.e. 54 simulation ticks later than in S3 (see Figure 8). This difference was due to the process undertaken in the retail SME simulated in S4, i.e. contacting a refurbishment company and waiting for them to arrive at the SME's premises (as opposed to allocating their own employees, if able, to carry out refurbishment).

CONCLUSION AND FUTURE WORK

In this paper, an agent based modelling and simulation approach has been presented to assess mutual aid and refurbishment on manufacturing and retails SMEs' recovery from flooding respectively. Within the ABM, a set of pre- and post-flood behaviours have been implemented and examined along with a set of precautionary measures. Two micro-sized SMEs have been selected in the case study presented due to their prevalence in the geographical area in which the flood event was considered, namely Tewkesbury in the UK. This geographical area was selected due to the severe impact of flooding experienced by businesses in 2007.

Four simulation experiments have been defined with each representing a different scenario for the SMEs under consideration. Results show that the manufacturing SME with a pre-defined mutual aid lost 69% of its production over 7 working days whereas the same SME without a mutual aid partnership lost 75% of its production in the same period of time, i.e. a difference of 6%. This significant difference allows a manufacturing SME to maintain production over a period that it would otherwise be non-operational. This provides a motivation for manufacturing SMEs to establish mutual aid partnerships as a way of assisting short-term recovery from a flood event. For retail SMEs, results show that the SME with employees allocated to refurbish its flood-affected premises regained its service capability faster than by employing a refurbishment company, i.e. 27 hours sooner. This difference motivates retail SMEs to allocate employees to refurbish premises, if possible, although it is understandable that not all SMEs' employees are skilled or capable to refurbish. This research will be developed further to involve a larger set of behaviours and precautionary measures and to develop the level of interaction between SMEs and their related-organisations, such as suppliers and customers.

ABSTRACT

Constructing shelters in suitable quantities, with adequate capacities and at the right locations is essential for evacuees under earthquake disasters. As one of the disaster management methods, constructing shelters can help to significantly reduce disruption and devastation to affected population. Mathematical models have been used to solve this problem allied with a heuristic optimization algorithm. The optimization of evacuation efficiency, as one of the most important objectives, has many expressive forms, such as minimizing evacuation distance and evacuation time. This paper proposes a new model that aims to minimize evacuation time with a new calculation method and to maximize total evacuees' comfort level. The modified particle swarm optimization (MPSO) algorithm is employed to solve the model and the result is compared with a model that calculated evacuation time differently and a model without distance constraint, respectively.

Keywords

Earthquake shelter, location-allocation, evacuation time minimization, comfort level maximization, MPSO.

INTRODUCTION

Natural disasters have caused serious economic losses and casualties (Bilham, 2010; Norio et al., 2011; Yuan, 2008). Many engineering methods have been implemented to protect buildings and infrastructures against damages (Chen and Scawthorn, 2003). However, in some cases, these methods cannot protect people after an earthquake disaster that leaves many people homeless. Therefore, constructing emergency shelters with reasonable locations, sufficient assets and supplies is important to provide safe places to affected people at different phases of a disaster.

In this paper, a new bi-objective model is developed for determining locations of earthquake disaster emergency shelters as well as allocating affected population to specific shelters. Both evacuation time and comfort level of evacuees are considered. The evacuation time is obtained with consideration of evacuation route's width and the number of evacuees of each community. Also, an optimization approach named modified PSO (MPSO) algorithm derived from the work of Zhao et al. (2015) is used to solve the model. The MPSO algorithm incorporates simulated annealing (SA), thus allowing better solutions to be obtained for the earthquake shelter location-allocation problem. Furthermore, Chaoyang District, Beijing, China is selected for the case study and the presented results provide the local government with a solution to the earthquake shelter location-allocation problem.

RELATED WORK

In order to facilitate decision-making, many research have been carried out to help determine shelters' locations and population allocation. The methods used mostly includes spatial analysis of geographical information systems (Gall, 2004; Sanyal & Lu, 2009) and location-allocation mathematical models (Bayram, Tansel and Yaman, 2015; Gama, Scaparra and Santos, 2013; Kilci, Kara, & Bozkaya, 2015; Sherali, Carter, & Hobeika, 1991) that are derived from site selection models. The site selection models includes P-median model (Hakimi, 1964), P-center model (Hakimi, 1965), and covering model (Toregas, Swain, ReVelle, & Bergman, 1970) that have been modified to solve the disaster shelter location-allocation problem. According to the characteristics of the disaster shelter location-allocation problem that the evacuees should be evacuated to assigned shelters as soon as possible, the objective derived from P-median model is most commonly adopted. For example, the work of Sherali et al. (1991), one of the first research applied P-median model in solving disaster shelter location-allocation problem. This work developed a shelter location-allocation model with an objective to minimize the total evacuation time of all affected people to their assigned hurricane shelters. Based on these single-objective models, multi-objective models (Alçada-Almeida, Tralhão, Santos, & Coutinho-Rodrigues, 2009; Barzinpour & Esmaeili, 2014; Doerner, Gutjahr, & Nolz, 2009; Hu, Xu, & Li, 2012; Hu, Yang, & Xu, 2014; Zhao, Xu, Ma, & Hu, 2015) and hierarchical models have been proposed (Z. Chen, Chen, Li, & Chen, 2013; Ng, Park, & Waller, 2010; Widener & Horner, 2011). Multi-objective model is more popular as it can satisfy different requirements simultaneously, such as the objectives to minimise evacuation distance or time, to minimise construction cost and to minimise disaster risks. Among these objectives, the objective of evacuation time minimization is also widely used. Hu et al. (2014) proposed an earthquake shelter location-allocation model with two objectives for solving evacuees' allocation problem, i.e. to minimize total cost and to minimize total distance from communities to their assigned shelters. Similarly, Zhao et al. (2017; 2015), Xu et al. (2017) and Kongsomsaksakul et al. (2005) also developed their models with the objectives to minimize distance or time for evacuees to reach their assigned shelters, respectively. However, the definitions of evacuation time vary in these research. For flood and hurricane disasters, the evacuees are assumed to travel in vehicles and the evacuation time is defined with network model (Bayram et al., 2015; Sherali et al., 1991). Also, some researchers used evacuation distance to represent evacuation time (Alçada-Almeida et al., 2009; Doerner et al., 2009; Rodríguez-Espíndola & Gaytán, 2015). However, evacuees are expected to walk during and after earthquake disasters that cannot be calculated using the method of evacuation time calculation for hurricane and flood disasters. Although Zhao et al.(Zhao et al., 2017, 2015) proposed an earthquake shelter location-allocation model with an objective to minimize evacuation time, it is weighted evacuation time rather than real travel time for all members of a given community to reach their designated shelter. Furthermore, after a severe earthquake disaster, the evacuees may need to stay in shelters for prolonged periods of time. Thus, their comfort should be an important factor. However, the comfort level of evacuees is still not taken into account in current works.

With respect to problem solving methods, geographical information system is employed to solve simple models (Kilci et al., 2015; Ye, Wang, Huang, Xu, & Chen, 2012) while complex models with different objectives and constraints are typically solved using heuristic optimization algorithms such as ant colony optimization (Colorni, Dorigo, & Maniezzo, 1991), genetic algorithms (GAs) (Goldberg, 1989), particle swarm optimization (PSO) (Kennedy & Eberhart, 1995) and simulated annealing (Kirkpatrick, Gelatt, & Vecchi, 1983). Compared with other heuristic optimization algorithms, PSO algorithm exhibits properties including straightforward calculation process, simple parameters, and fast convergence. Also, it has been modified with simulated annealing (SA) to avoid premature convergence (Hu et al., 2012; Zhao et al., 2015).

MATHEMATICAL MODEL, OPTIMIZATION METHODS AND CASE STUDY

In this section, a mathematical model for the earthquake shelter location-allocation problem is developed. Also, MPSO, the optimization heuristic algorithm employed to solve the location-allocation model is described. Furthermore, an overview of the case study designed to demonstrate the results of the model solved with the MPSO algorithm is presented.

This work makes four assumptions as described below:

1) All residents of a community will be allocated to the same shelter;

2) The residents queue to evacuate and each evacuee occupies 1 square meter;

3) Residents will go to their assigned shelters along the shortest route from their locations;

4) The residents of a given community will be assigned to only one shelter.

Shelter location-allocation model

The objective to minimize the total evacuation time is used widely to ensure the affected people can arrive to their shelters as soon as possible. Also, the comfort level is important as the evacuees would live in their shelters for a long time after a severe earthquake disaster. Non-utilized area of a shelter for each evacuees is one of the import factors to affect their comfort level. Thus in the preliminary study reported in this paper, a model with two objectives to minimize the total evacuation time and to maximize total comfort level are proposed with a distance constraint and a capacity constraint. In this paper, the comfort level is simplified to non-utilized area before a community coming.

The notation used in this paper is shown as below.

i: Index of objective, equal to 1, 2, …,I

j: Index of community equal to 1, 2, …, M

k: Index of candidate shelter, equal to 1, 2, …, N

t_{kj}: Travel time from community j to shelter k

B_{kj}: Whether or not community j is assigned to shelter k, equal to 1 or 0

L_{kj}: Non-utilized capacity of shelter k before community j coming

d_{kj}: Shortest evacuation route's distance from community j to shelter k

D_j: The maximum evacuation distance that community j can travel

P_j: The number of people within community j

C_k: Capacity of candidate shelter k

X_k: Whether or not candidate shelter k is selected, equal to 1 or 0

w_p: Path width of an evacuation occupies

W_{kj}: The weighted mean width of the evacuation paths that form the entire route taken by community j to candidate shelter k i

v_j: Evacuation speed of the people in community j

a_i: Weight of objective i

$$\min f_1 = \sum_{j=1}^{M}\sum_{k=1}^{N}\left(t_{kj} \times B_{kj}\right) \tag{1}$$

$$\min f_2 = \sum_{j=1}^{M}\sum_{k=1}^{N}\left(L_{kj} \times B_{kj}\right) \tag{2}$$

$$d_{kj} \times B_{kj} - D_j \le 0 \qquad \forall k = 1,2,...,N; \forall j = 1,2,...,M \tag{3}$$

$$\sum_{j=1}^{M}\left(P_j \times B_{kj} - C_k \times X_k\right) \le 0 \qquad \forall k = 1,2,...,N \tag{4}$$

$$\sum_{k=1}^{N}\left(B_{kj} \times X_k\right) = 1 \qquad \forall j = 1,2,...,M \tag{5}$$

Equation (1) is the objective to minimize total evacuation time of all communities where t_{kj} is the minimum evacuation time from community j to candidate shelter k that can be obtained using Equation (6).

$$t_{kj} = \frac{d_{kj} + \dfrac{P_j}{w_P \times W_{kj}}}{v_j} \tag{6}$$

In Equation (6), the evacuation time of a community is the time required for all residents of the community to reach their shelter. Here, the distance for the final evacuee of a community is adjusted by the number of evacuees of this community, the occupied width of an evacuee and the width of the evacuation route as shown in Figure 1.

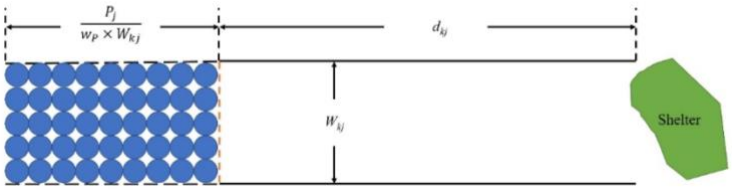

Figure 1 Evacuation distance adjustment

Parameter d_{kj} in Equation (6) is the shortest distance obtained using Dijkstra algorithm, P_j is the number of evacuees in community j, w_p indicates the width that an evacuee needs which in this paper is assumed to be 1 meter. W_{kj} is the average width of the shortest route from community j to shelter k and v_j is the average evacuation speed of community j calculated as:

$$v_j = (2 \times p_c \times v_c + (p_a - p_c) \times v_a + p_o \times v_o) \times \rho \tag{7}$$

where v_c, v_a and v_o represent the speed of a community's children, adults and elderly people that is defined by Gates et al. (2006), and p_c, p_a, and p_o are the proportions of these three categories of people respectively. The parameter ρ is an adjustment parameter of the evacuation speed relative to the ordinary speed that is set as 1 in this paper.

In Equation (1), B_{kj} is a decision variable that indicates if the community j will be allocated to shelter k (1 allocated, 0 otherwise). Equation (2) is the objective to maximize the comfort level of all evacuees in their allocated shelters. The parameter L_{kj} indicates the non-utilized capacity of shelter k before community j coming. Equation (3) represents the distance constraint that a candidate shelter cannot be selected by a given community if the distance is greater than D_j, the farthest this community can reach. Equation (4) indicates the capacity constraint that the number of evacuees allocated to a shelter cannot exceed the capacity of the shelter. Here, C_k is the capacity of shelter k that can be obtained by total area of shelter k divided by smallest refuge area per person, i.e., 1 m^2 (Beijing Municipal Institute of City Planning & Design, 2007). X_k is a decision variable that indicates whether the candidate shelter k will be selected (1 selected, 0 otherwise). Equation (5) ensures that a community can only be allocated to one shelter.

Modified particle swarm optimization algorithm

The model proposed in this paper involves different two objectives. There are different approaches can be taken to solve models involving multiple objectives such as Pareto-based approach and converting the multi-objective problem to a single objective problem. This conversion can be achieved by summing the weighted values of each of the multiple objectives to be an average assessment index as shown in Equation (8). I is the number of objectives and a_i is the weighted value of objective function f_i. The weight assigned to each objective function can be determined according to the prior information on the relative importance of each one. Here, it should be noted that the units should keep consistent.

$$\min f = \sum_{i=1}^{I} (a_i \times f_i) \tag{8}$$

In the preliminary work reported in this paper, the weighted-based approach is used and the two objectives can be converted to a single one, to minimize average assessment index, as shown in Equation (9). In the preliminary work presented in this paper, both the two weights, a_1 and a_2 are set as 0.5. To eliminate the effect of the units, a normalization approach is employed as shown in Equation (9). $f_{1,\min}$ and $f_{2,\min}$ are the minimum values of function 1 and 2 respectively that are solved individually neglecting the other function. Similarly, $f_{1,\max}$ and $f_{2,\max}$ are the maximum values of function 1 and 2 respectively that are solved individually neglecting the other function.

$$\min f = \left(a_1 \times \frac{f_1 - f_{1,\min}}{f_{1,\max} - f_{1,\max}} \right) + \left(a_2 \times \frac{f_{2,\max} - f_2}{f_{2,\max} - f_{2,\min}} \right) \tag{9}$$

To solve the model proposed in this paper, MPSO algorithm is introduced by adding SA to PSO algorithm. The pseudo code for the MPSO algorithm is presented in Algorithm 1. MPSO algorithm begins with a population of size 100 that is generated randomly via the INITIALIZE function. The particle of swarm P is named u. After the first 100 iterations, the solution of each subsequent iteration will be compared with previous 100 solutions. If there is no difference between them, then a new particle swarm is generated using INITIALIZE function. The MPSO process executes until the convergence is met, i.e., the solution remains the same for 1,000 iterations.

Algorithm 1 MPSO

```
1:  P ← INITIALIZE(popSize)
2:  While (MPSO not converged) do
3:    COMPUTEOV(P)
4:      for each particle in P
5:       if von Neumann topology then
6:         v ← UPDATE_v(p, v, p_best, n_best)        ▷ Update particle's velocity
7:      else
8:         v ← UPDATE_v(p, v, p_best, g_best)        ▷ Update particle's velocity
9:      p ← UPDATE_p(p, v)                           ▷ Update particle's position
10:     if p_current > p_best
11:       p_best ← p_current
12:     else
13:       p_best ← apply SA(p_current)               ▷ Apply SA
14:     if von Neumann topology then
15:       for each particle in P
16:         n_best ← UPDATE_n(p_n, n_best)           ▷ Update best of neighbours
17:     else
18:         g_best ← UPDATE_g(p_g, g_best)           ▷ Update global best
19:     if PREMATURE(P) then
20:       P ← INITIALIZE(popSize)
```

In algorithm 1, both von Neumann topology and global topology are used. More specifically, if using the von Neumann topology, each particle's velocity and position in iteration t+1, v_u^{t+1} and p_u^{t+1}, are updated using Equations (10) and (13) respectively. If using the global topology, each particle's velocity and position in iteration t+1, v_u^{t+1} and p_u^{t+1}, are updated using Equations (11) and (13) respectively.

$$v_u^{t+1} = \varphi(v_u^t + c_1 r_1 (p_{best,u}^t - p_u^t) + c_2 r_2 (g_{best}^t - p_u^t)) \quad (10)$$

$$v_u^{t+1} = \varphi(v_u^t + c_1 r_1 (p_{best,u}^t - p_u^t) + c_2 r_2 (g_{best}^t - p_u^t)) \quad (11)$$

$$\varphi = \frac{2}{|2 - (c_1 + c_2) - \sqrt{(c_1 + c_2)^2 - 4(c_1 + c_2)}|} \quad (12)$$

$$p_u^{t+1} = p_u^t + v_u^{t+1} \quad (13)$$

where φ is the constriction coefficient introduced by Clerc and Kennedy (2002) to guarantee convergence by avoiding the explosion of the particle swarm. It is a function of c_1 and c_2 as shown in Equation (10) that are the cognitive and social acceleration coefficients respectively where $c1$=2.8 and $c2$=1.3 leading to a value of φ=0.7298. In Equation (8) and (9), r_1 and r_2 are generated randomly in the range [0, 1]. For each particle, the fitness value of each particle can be calculated using COMPUTEOV function that is Equation (1). For each particle, its best position so far, $p_{best,}$ can be replaced by its current position, $p_{current}$, if $p_{current}$ is better. However, if $p_{current}$ is worse than $p_{best,}$ SA is applied such that a worse position can be accepted with a lower probability. When von Neumann topology is used, the best position among neighbouring particles, n_{best} is updated via the UPDATE_n function that compares the positions of neighbours of a particle, p_n. When using global topology, the best position among all particles, g_{best} is updated by comparing it with all other particles.

Case study

Figure 2 illustrates the location of the geographical area for case study in this paper, namely Chaoyang District,

Beijing, China. More specifically, Figure 2(a) shows the location of Beijing in China and Figure 2(b) shows the location of Chaoyang in Beijing.

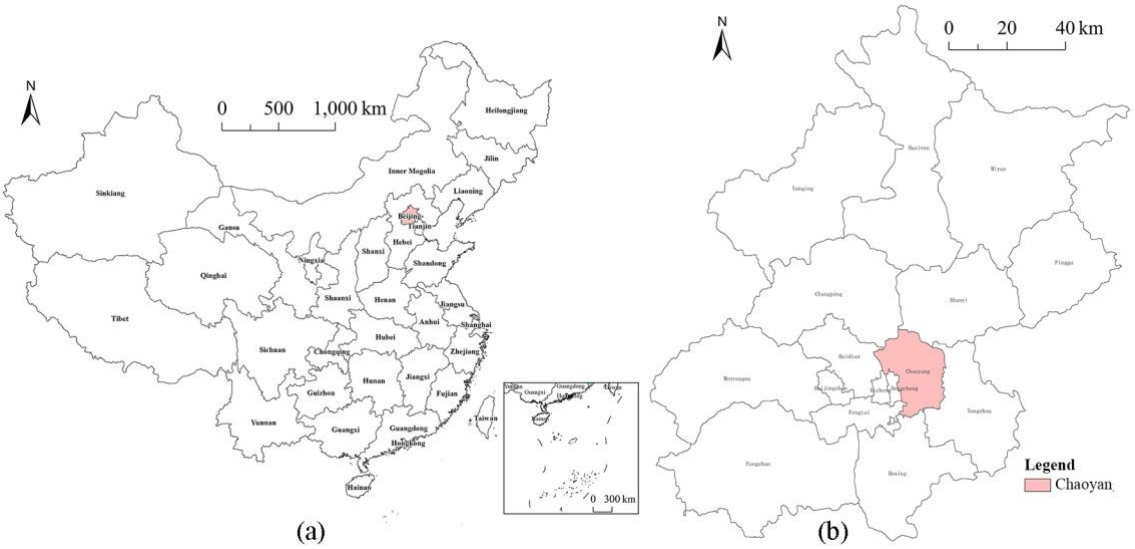

Figure 2. Location of Jinzhan, Chaoyang, Beijing, China

Figure 3(a) presents a map of communities, shelters and evacuation path network, which was provided by the Key Laboratory of Environmental Change and Natural Disaster of Ministry of Education, Beijing Normal University. Figure 3(a) indicates the locations of 72 candidate shelters and 463 communities that need to be allocated to the designated shelters. All these 72 candidate shelters are more than 500m from the earthquake faults, have slopes less than 20°, and covered by basic facilities in consideration of the safety requirement (Hu et al., 2014). The area of these 72 candidate shelters are shown in Table 1. The 463 communities in Chaoyang District are shown in Figure 3(b) that is provided by the Beijing Bureau of Civil Affairs. It shows that the population of Chaoyang is mainly concentrated in the central part of the district while the northwest and southeast look to be the most sparsely populated areas.

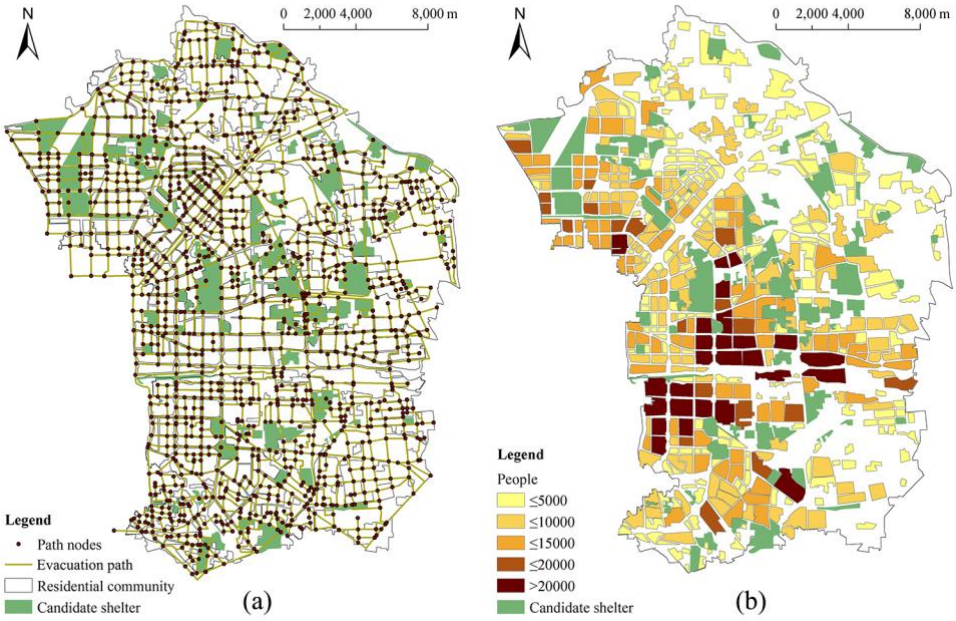

Figure 3. Location of communities, shelters, evacuation paths and distribution of population

Table 1. Area of candidate shelters

PRELIMINARY RESULTS AND DISCUSSION

As the location-allocation problem involves a large number of communities and candidate shelters, and different constraints, the aforementioned MPSO algorithm was adopted. The program executes 9 times in a laptop with 16GB memory and 2.2 Hz Intel Core i7. It needs average 5 minutes to obtain the result for each execution. In this section, the shelter selection and community allocation to the selected shelters are shown at first. Also, the average assessment index of each community is analyzed. Then, the result is compared with the result of the model with objective to minimize total evacuation time and the model without the distance constraint.

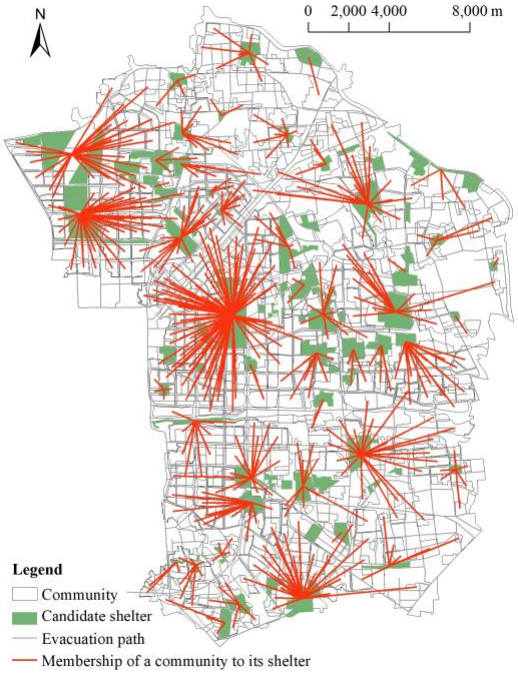

Figure 4. Location-allocation result

Figure 4 presents the result of shelter selection and how the 463 communities are allocated to them. A total of 47 shelters are being selected. The value of f , f_1, and f_2 are 0.2116, 5.47×10^5 and 2.83×10^8 respectively. It can be seen that shelters with larger capacity exhibit higher attractiveness that many relatively distant communities are allocated to them. In comparison, smaller shelters mainly serve communities more closely located.

Figure 5(a1) and (b1) shows the value of evacuation time of each community and non-utilized capacity before

each community coming respectively. Also, the value ranges of them are shown in Figure 5(a2) and (b2) respectively. It illustrates that the value of evacuation time, for each community is less than 4,500 seconds, among which, even some of them are less than 500 seconds. The evacuation time for community 161 is the most that is 4,274 seconds while that for community 64 is the least. Most of the value for non-utilized capacity before a community coming is less than 4.2×10^6 m^2 and more than 4.3×10^4 m^2. Also, it can be seen that the value of evacuation time is more concentrated than the value of non-utilized capacity before communities coming.

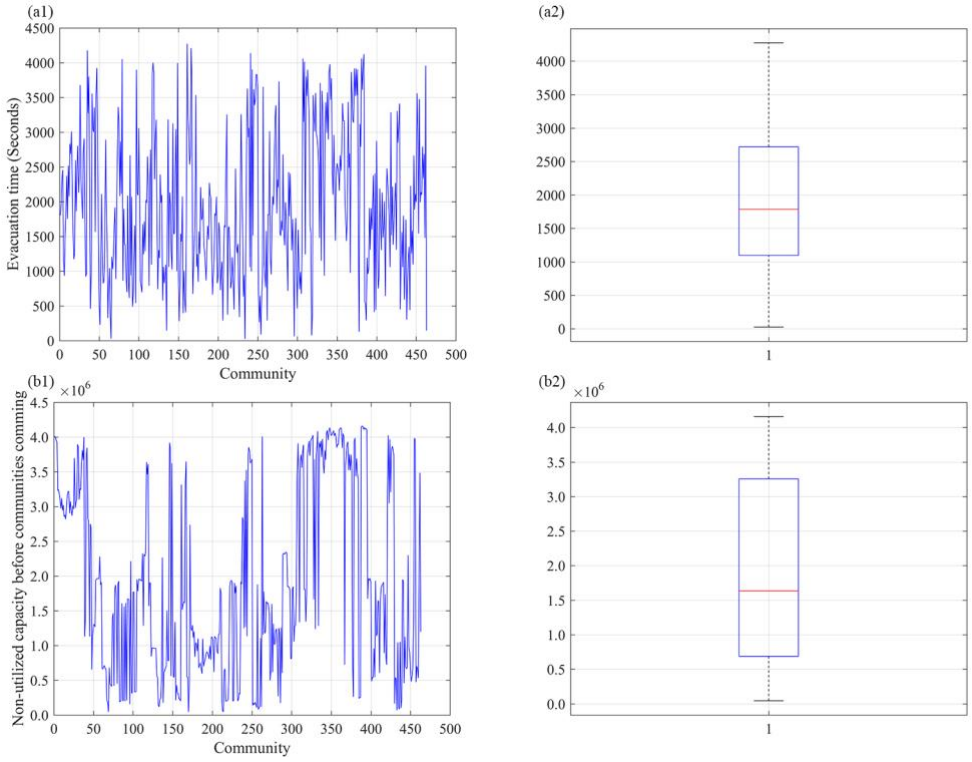

Figure 5 Evacuation time of each community and non-utilized shelter capacity before each community coming

The proportion of utilized and non-utilized area of 47 selected shelters are visualized in Figure 6. It presents that the utilized area is obviously less than the non-utilized area for all selected shelters. For shelter 43, the proportion of utilized area is the largest amongst all of 47 shelters with the value of 0.269. Thus, as the proportion of non-utilized area for all selected shelters is more than 0.5, each selected shelter has sufficient room to house relief workers and volunteers. Also, there is enough room for relief assets storage and movement of evacuees.

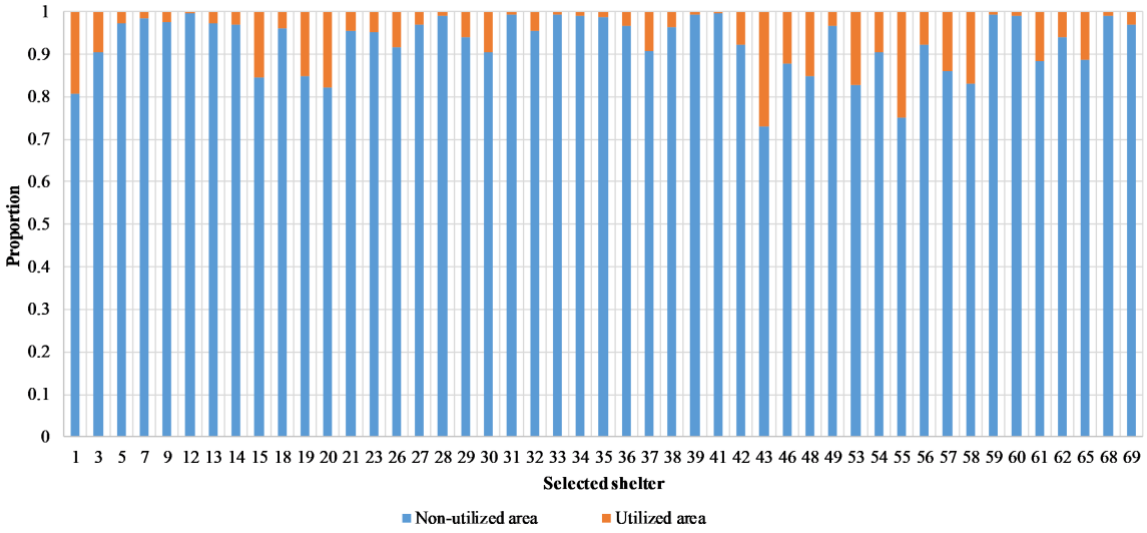

Figure 6 Proportion of utilized area and non-utilized area of each selected shelter

The result aforementioned is derived from solving the model with distance constraint described in subsection 'Shelter location-allocation model'. However, if the evacuees are not sensitive to long distance, the result will be different. Also, if the evacuees only pay attention to evacuation time neglecting the comfor level, the objective will be the mere minimization of total evacuation time. To compare with the model proposed in this paper, a model without distance constraint and a model with the objective to minimize total weighted evacuation time as shown in Equation (14) are also solved using MPSO algorithm.

$$\min f_3 = \sum_{j=1}^{M}\sum_{k=1}^{N} \frac{d_{kj}}{v_j} \times \frac{P_j}{W_{kj}} \times B_{kj} \qquad \forall k = 1, 2, \ldots\ldots, N \quad \forall j = 1, 2, \ldots\ldots, M \tag{14}$$

The location of the candidate shelters selected and how the 463 communities are allocated to them obtained using the aforementioned two models are shown in Figure 7(a) and Figure 7(b) respectively. In Figure 7(a), it can be seen that there are 46 shelters being selected. It is less than 47 shelters obtained using the model with distance constraint as shown in Figure 4. However, some communities would be allocated to shelters that the distances are too long. Figure 7(b) presents locations of 65 selected shelters and the allocation of communities to them. It indicates that the number of shelters needed is more than that of the models with the two objectives proposed in this paper and the values of both f_1 and f_2 for this solution is more than those of the solution obtained by the bi-objective model.

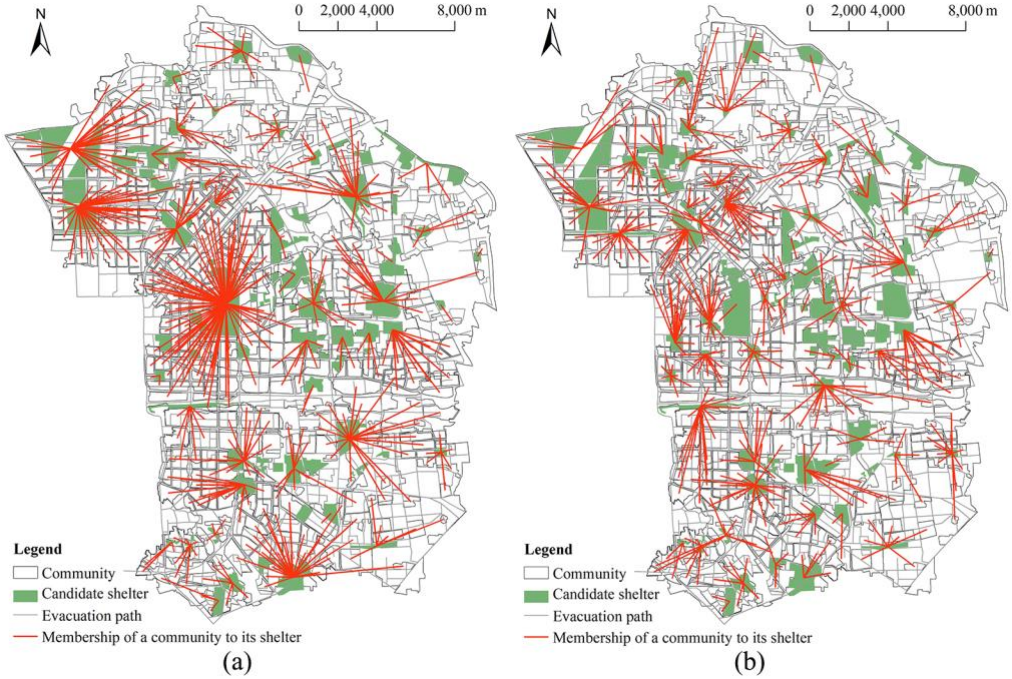

Figure 7 Location-allocation results of the model without distance constraint and the model to minimize total evacuation time

CONCLUSION

The aim of this paper is to present preliminary work in solving the proposed earthquake disaster shelter location-allocation problem. Findings in this work will facilitate future efforts for developing a more realistic mathematical model.

In this paper, a mathematical model with two objectives is proposed with capacity and distance constraints. The result obtained using this model is compared with a model without distance constraint and a model with objective to minimize total evacuation time, respectively. It is observed that the model proposed in this paper enables the balance between evacuation time and comfort level. In terms of further work, a number of improvements will be made to the mathematical model. For example, comfort level will be calculated dynamically rather than statically as in this paper. Also, other objectives can be considered in terms of the specifications of earthquake shelters such

as construction cost and damage risk. Also, the changing situations of volume of evacuees and damages to road networks caused by an earthquake will be considered. Moreover, improvement of the heuristic optimization algorithm will be carried out for more rapid and accurate problem solving.

ABSTRACT

The emergency procedures contain a set of actions responsible for providing the necessary corrective measures to address an emergency. The relevance of contextual knowledge during emergency responses is of utmost importance since many decisions are made from the information gathered in real time that sometimes conflicts with the formal knowledge specified in the emergency plan. Consequently, tools that support the emergency plan mentioned must be sensitive to context and allow decision making at the time an emergency takes place. We demonstrate how Case Management Modeling Notation (CMMN) along with Decision Model and Notation (DMN) are very suitable approaches to obtain a flexible model adapted to the context-driven response processes.

Keywords

Emergency response, Knowledge-intensive business, Business Process Model and Notation, Case Management Model and Notation, Decision Model and Notation.

1.- INTRODUCTION

Emergency plans are a set of actions and measures aimed at preventing and controlling risks to people and their property in order to respond appropriately to the possible emergency situations to which an organization is exposed. Response procedures within self-protection plans, are actions told in natural language that are carried out immediately in light of the event of a disaster with the aim of preventing the loss of life, safeguarding goods and normalizing the situation as soon as possible (Sánchez et al., 2015); however, due to its nature and the variants that may occur, the self-protection plan must be executable, scalable, adaptable and, flexible.

The problems of nature classified as knowledge-intensive business models should be addressed with notation based on Adaptive Case Management (ACM) (Di Ciccio et al., 2014; Hofmann et al., 2015). Due to the increase in natural disasters that have occurred in the last decade, one of the fields of application with greater interest at present is emergency management. However, at the time of modeling solely with traditional process notations (e.g., Business Process Model and Notation (BPMN)) it is difficult to define beforehand possible scenarios (Van der Aalst et al., 2005). In addition, critical factors such as time, excessive information from the environment, poor structuring the unrepeatable and unpredictable flow must be considered (Jul, 2007; Kushnareva et al., 2015).

In May 2014, the Object Management Group (OMG) formalized the case management language (Case Management Model and Notation (CMMN)) in its version 1.0 (OMG, 2014), which allows to graphically represent flexible response procedures based on cases to respond to the emergencies. Even though in December 2016, OMG presented version 1.1 of CMMN (OMG, 2016) where it attended the technical details of the original version, some case workers consider it still immature and doubt that it is appropriate to apply it for critical domains in real-world such as the emergency management (Kurz, 2015). Although CMMN allows the ACM, not all response procedures keep the same classification during all stages. Therefore, there are tasks that can be automated to facilitate decision-making with DMN and give continuity to the flow of response with BPMN. This paper aims to integrate the BPMN, CMMN, and DMN specifications to build what we call the **ACM hybrid model**, which allows us to adequately represent the different characteristics of emergency response procedures and when executed, adequately manage the needs of the environment.

This paper is organized as follows: section 2 describes the related works that use modeling notations to provide attention to emergencies. Section 3 explains how the BPMN, CMMN, and DMN specifications can be integrated to represent a response process named the ACM hybrid model. Section 4, as a case study, analyzes the proposal to build an ACM hybrid model based on the fire response management procedure of the Hospital Universitario y Politécnico de La Fe in the city of Valencia, Spain. Section 5 shows the execution of the ACM hybrid model using the Camunda BPM environment. Finally, section 6 presents the key findings and possible future work.

2.- RELATED WORK

In the literature, there are several studies that consider the methodology of process modeling a viable alternative to represent the emergency response processes and provide adequate responsiveness. Hofmann et al. conducted a broad structured review of the literature to identify the different existing approaches that apply methods and tools of business process management (BPM) to the domain of Disaster Response Management (DRM), concluding that it is a promising approach because of the similarity between the general structure and the aims of both business processes and disaster response processes. In addition, as a result of the research work, they obtained an adequate classification of the requirements necessary for the development of business process solutions oriented to DRM (Hofmann et al., 2015).

In 2005, Van der Aalst et al. proposed an approach in which case management was used to support flexible business processes. They identified and classified the main entities of the system and built a meta-model as part of their conclusions and found that case management offered a balance between support and flexibility, however, this paradigm alone did not solve all the problems related to changes (Van der Aalst et al., 2005).

Zensen and Küster conducted a comparison between the BPMN language with an ad-hoc subprocess approach and the CMMN notation to represent the same case study. They aimed to identify advantages and disadvantages of each language and help choose which standard to use to model processes or part of processes that require flexible parts. They concluded that the BPMN ad hoc subprocess offered a certain degree of flexibility but that arbitrary jumps were difficult to model. Likewise, they recommend that in knowledge-intensive business problems, the data should be restricted to individual tasks that should not be shared with all participants of the process. CMMN offered a greater degree of work flexibility where tasks could be grouped in stages that had semantic similarity in execution and support a declarative approach. The disadvantage was the lack of outgoing communication events. In their conclusions, they suggested a combination of both to model highly structured and flexible processes (Zensen and Küster, 2018).

Nešković and Kirchner discussed in their work the main benefits of CMMN over BPMN when modeling knowledge-intensive business problems that require using context information to allow flexibility in runtime. The technical proposal was illustrated with an example in health domain. They concluded that CMMN was designed to model only a high level of business logic, while other details remain to be specified and developed at the level of specific applications. Therefore, they recommend developing an extension for CMMN that provides this support (Nešković and Kirchner, 2016).

Recently, Shahrah and Al-Mashari have shown how CMMN can be used to model an emergency response process. They used CMMN to build a template model for a generic emergency response process and indicated that the generic model can be easily expanded or exchanged between different modeling tools or existing execution platforms. Also, they presented a case study of a flood management process as an example of the use of CMMN in the modeling of the emergency response process. Finally, they concluded that the CMMN has great potential to model case-based processes such as emergency response (Shahrah and Al-Mashari, 2017).

As can be seen from the literature review described above, and as far as we know, we did not find a case study using hybrid ACM modeling, integrating the notations of BPMN, CMMN, and DMN to represent emergency response processes. Therefore, this paper attempts to help explain the implementation of a hybrid ACM model in the emergency response domain.

3.- AN INTRODUCTION TO CMMN AND DMN

Case management (CM) was introduced as a new paradigm for business process support systems (Van der Aalst et al., 2005) focusing on the data-centered process, knowledge-intensive, flexible and adaptable processes. As opposed to traditional business process management (BPM), based on control flow, where the order of execution of activities is determined by the execution of previous activities, CM allows the execution of weakly structured process, where the dynamic selection of activities to accomplish a business goal is based upon case worker skills and the evolution of case data. CM supports the ad-hoc, dynamic and unpredictable interactions between people, process fragments, data and, documents.

Emergency response procedures are typical examples of case management: interactions between different roles or independent agencies such as fire department, police, public transportation, etc. Also fragments of unstructured response activities ready to change their behavior at runtime.

The language CMMN (Case Management Modeling Notation) is a new standard for case management published by the OMG in 2014 (OMG, 2014). The case is the main concept, which lists all possible case roles and references the Case File Model and the Case Plan Model. The Case File holds all the data used in the case; the members of the Case File are Case File Items which can be any type of information ranging from a plain file (typically encoded in XML) to a folder hierarchy. Figure 1 shows the graphic representation of CMMN elements.

The Plan Model contains the behavioral aspects of the Case Model: events, tasks, stages, and milestones, called Plan Items. The events can be activated either manually by users (user event listener), by the system after an elapsed period of time (timer event listener) or by changes detected in the Case File model (anonymous event listener). Note that the Case File implicitly includes the context for throwing events to the Case Plan Model. A human task is a unit of work performed by a user of the Case. There are two types of human tasks: blocking task (tracked by the system) and non-blocking task (manual task). Additionally, there are two more task types: process task and case task. A process task calls an external process passing parameters as required. In the same way, a case task calls an external case, providing the necessary information when necessary.

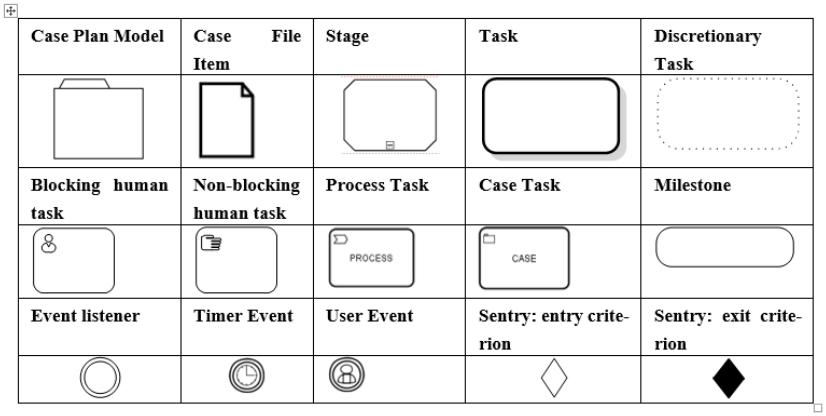

Figure 1. Elements of CMMN

A milestone represents a state reached during the case execution, which enables evaluation of case progress. The dependencies between elements of the case are modeled using event-condition pairs called Sentry, which can be of two types: entry criterion and exit criterion. The Sentry with entry criterion can be attached to case items as stages, tasks, and milestones. When the event of the Sentry occurs, and the conditions are evaluated as true the corresponding attached elements are enabled. Similarly, an exit criterion can be attached to tasks and stages. Upon task or stage completion the exit criterion terminates the attached plan item. A stage contains Plan Items and Sentry elements, to achieve one (or more) of the milestones owned by that stage.

Within the context of CMMN, a case has two distinct phases: design and execution. During the design phase, business analysts are engaged in modeling the case, which includes defining stages or tasks. During the execution phase, the case workers create and execute the plan, particularly by performing tasks as planned, while the plan may continuously evolve, due to the same or other case workers being engaged in planning and execution, i.e., adding so-called 'discretionary plan-items' (tasks and stages) to the plan of the case instance at run-time. This fundamental characteristic of case management, supported by CMMN, is referred to as 'runtime flexibility'. It allows process participants to respond to challenges or new requirements that were not considered at the time of planning the business processes. This run-time planning is based on information that has become available to the case. Changing the case behavior means changing a case process.

Decision Modeling and Notation (DMN) is a new standard from OMG. The DMN notation has been designed to work alongside BPMN, providing a mechanism for modeling the decision-making represented in a task within a process model. DMN does not need to be used with BPMN but it is highly compatible. The DMN standard allows to model and describe decisions in a declarative way on two levels, the requirements level, and the decision logic level. The first level employs Decision Requirements Diagrams (DRD). These diagrams can contain several types of elements, decisions, input data, business knowledge models, and knowledge sources. A DRD diagram shows where the information required for the evaluation of decisions comes from. The second level uses a declarative language called Friendly Enough Expression Language (FEEL) to describe the decision logic or decision tables.

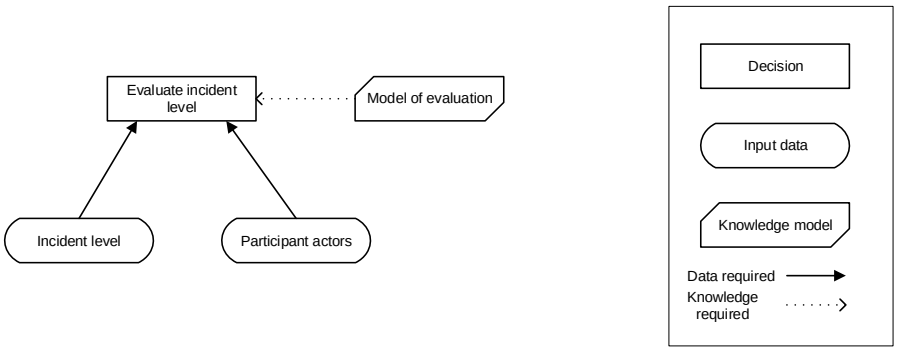

Figure 2. DRD diagram.

Figure 2 shows a decision requirement diagram with a top decision, two inputs data, and a knowledge model. The decision logic is implemented in Figure 5 using a decision table.

4.- CASE STUDY

In this section, we describe a case study of a specific emergency response process example. This case study aims to demonstrate how hybrid ACM modeling can be used appropriately to represent real situations in emergency management. The example of the case study to be used is the emergency response procedure of thin case of fire developed for the Hospital Universitario y Politécnico de La Fe located in the city of Valencia, Spain. This process was extracted from the self-protection plan that the institution provided us with and aims to define the sequence of actions to be developed for the initial control of a possible fire-type emergency, planning of the human performance, and the means available to the hospital. In essence, the hospital aims to avoid the partial or total evacuation of the center. If an evacuation in the hospital is needed, it will define the necessary guidelines so that it is carried out in the orderly, organized and easy way possible.

It is advisable that before reading the response procedures of the self-protection plan, the actors involved are identified. Likewise, they should be aware of its abbreviations, missions, functions to play and the activities to be carried out in each of the phases of the emergency. To facilitate the understanding of the emergency response procedure of the case study, Figure 3 shows the Action Diagram, which summarizes the possible sequences of action by each of the actors in the response procedure of the fire-type incident.

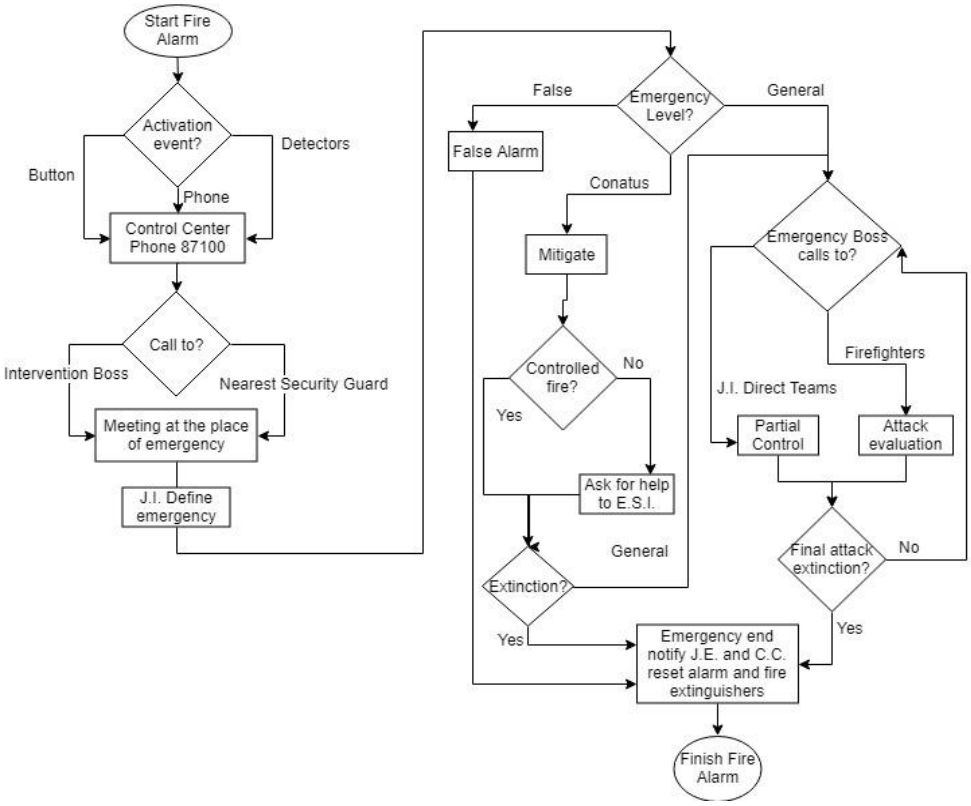

Figure 3. Action diagram of the fire-type incident response procedure.

The previous Action Diagram, facilitates the understanding of the emergency response procedure, However, there are activities that lack a clear sequence and the moment in which they must be performed, thus, this representation of the response procedure creates ambiguities and therefore, the sequence in the control flow is very unreliable when trying to make the response procedure executable in real time.

Once known and understood the content of the emergency response procedure, it is advisable to identify the key business elements and the relationship between them to facilitate the design of the hybrid ACM model.

Following the recommendations provided by the OMG standard to integrate the BPMN, DMN, and CMMN specifications as well as the content of the emergency response procedure of the case study, it is defined that the diagram in BPMN will be chosen as a base in order to potentiate the automation of the sequence. Therefore, the lanes of the pool will be the **Control Center**, **Security Guard,** and the **Emergency Boss**. With the help of the Camunda Modeler tool (Camunda Modeler, 2018), models and decision tables will be designed. It is important to note that in addition to the diagram, the digital object of each model contains in XML format the description of it, allowing the core of the BPM Camunda platform to interpret and execute the models (Camunda Engine, 2018).

Next, in Figure 4 is presented the model M0. Fire Management in BPMN, as a result of the fire-type emergency response process that was summarized in the Action Diagram of the Figure 3.

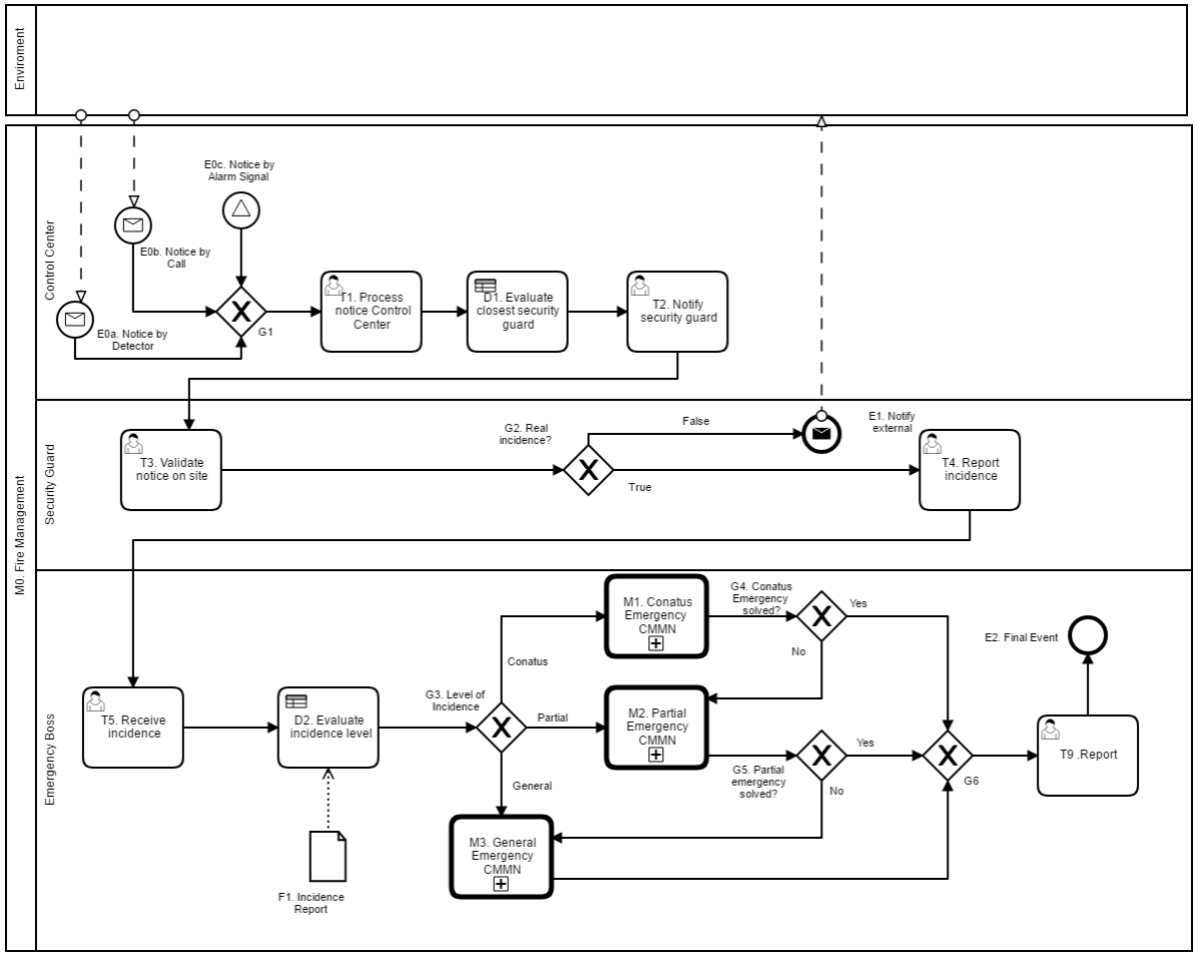

Figure 4. Model M0. Fire Management in BPMN of the Fire-type Incident

To start building the model in BPMN, it is identified in Figure 3 that the fire alarm can be activated by a telephone call, alarm signal or smoke detector, therefore, it is established that the initial events that can create an emergency instance will come from the Environment and are represented by circles. This is an example of how, based on the Action Diagram of Figure 3, the BPMN model of Figure 4 was built. Subsequently, the exclusive gateway G1 will be activated, and the information detailing the initial message will be notified in user task **T1. Process notice Control Center** and using the decision table task in DMN named **D1. Evaluate the closest security guard**, the security guard assigned to go to the incident area will be assigned to validate the emergency.

If the incidence is not real, the Environment is notified through the final event **E1. Notify externaly**; if the incidence is real, the security guard complements the **F1. Incidence Report** through task **T4. Report incidence**, this information allows the emergency boss to determine, through decision table **D2. Evaluate incidence level** in DMN, the incidence level and activate one of the ad-hoc sub-processes **M1. Conatus Emergency**, **M2. Partial Emergency,** or **M3. General Emergency** (ISGF, 2017); which are a call to the models that are in CMMN notation. Based on the output information of each of the ad-hoc sub-processes, the exclusive gateways G4, G5, and G6 bifurcate the workflow to activate another ad-hoc sub-process or reach the **T9. Report** task that when is completed, ends instance using the **E2. Final Event**.

Figure 5 shows the decision table **D2. Evaluate incidence level** in DMN to facilitate the emergency boss to evaluate which actors are going to intervene and the level of the incidence.

Model of Evaluation

DecisionIncidenceLevel

U	Input +		Output +
	Incident Level incidenceLevel	Actors Intervention actors	incidence
	string	string	string
1	"Simple"	"Local Staff"	Conatus
2	"Simple"	"Second Intervention"	Partial
3	"Simple","Limited"	"Local Staff","Second Intervention"	Partial
4	"Potential"	"Personal Local","Segunda Intervención","Pùblic Service"	General
+	-	-	-

Figure 5. Decision table: D2. Evaluate incidence level.

The Case Plan Model **M1. Conatus** in notation CMMN is illustrated in Figure 6, where the stage **M1S1. Mitigate Conatus Emergency** contains the user task **M1T1. Notify the intervention Chief** of manual activation, the task **M1T2. Mitigate Conatus Emergency** indicates to the hospital security personnel mitigate the fire with local resources. Last, through the task **M1T3. Evaluate the emergency** the user validates if the fire has been extinguished. The exit of the stage connects with the gateway **G4. Conatus Emergency Solved?** of general model **M0. Fire Management** in BPMN.

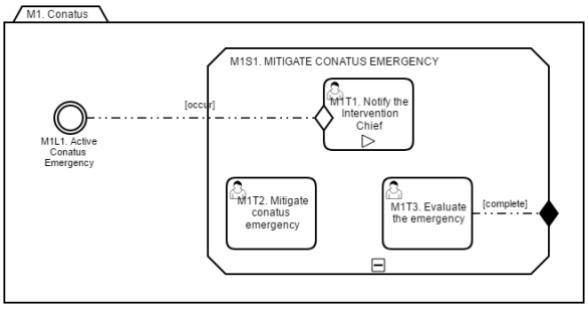

Figure 6. M1. Conatus Emergency Model in CMMN

In Figure 7, we represent the CMMN model **M2. Partial Emergency** where the stage **M2S1. Mitigate Partial Emergency** contains tasks such as **M2T1. Notify the Intervention Chief**, **M2T2. Active partial alarm signal**, **M2T3. Notify second intervention teams**, **M2T4. Evacuate visits from the area**, **M2T5. Evacuate area**, **M2T6. Mitigate fire,** and **M2T7. Evaluate partial situation**; likewise, a milestone **M2H1. Partial Emergency**. The exit in this stage connects with the gateway **G5. Partial Emergency Solved?** of general model **M0. Fire Management**.

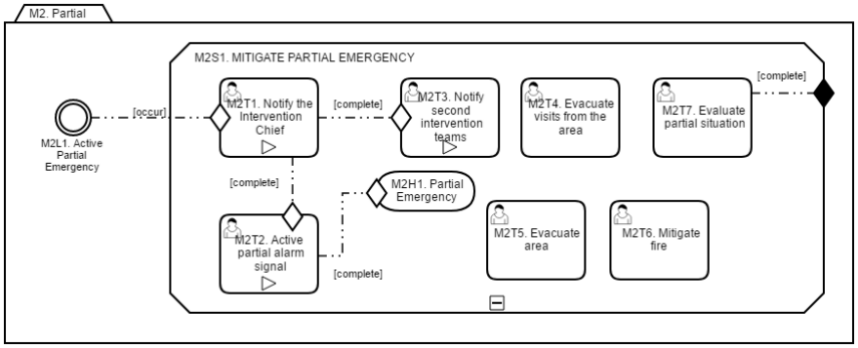

Figure 7. M2. Partial Emergency Model in CMMN

Finally, the model **M3. General Emergency** in CMMN notation (shown in Figure 8) includes the stage **M3S1. Pre-Evacuation** in which we have the tasks **M3T1. Notify firefighters**, **M3T2. Pre-evacuation procedure**, **M3T4. Receive external information** and the decision table **M3D1. Evaluate evacuation**. Furthermore, we have included the stage **M3S2. Evacuation** that connects the tasks **M3T5 Evacuation procedure**, **M3T6. Receive external information** and **M3T7. Evaluate general situation**. The exit of the model is linked with gateway **G6** of general model **M0. Fire Management**.

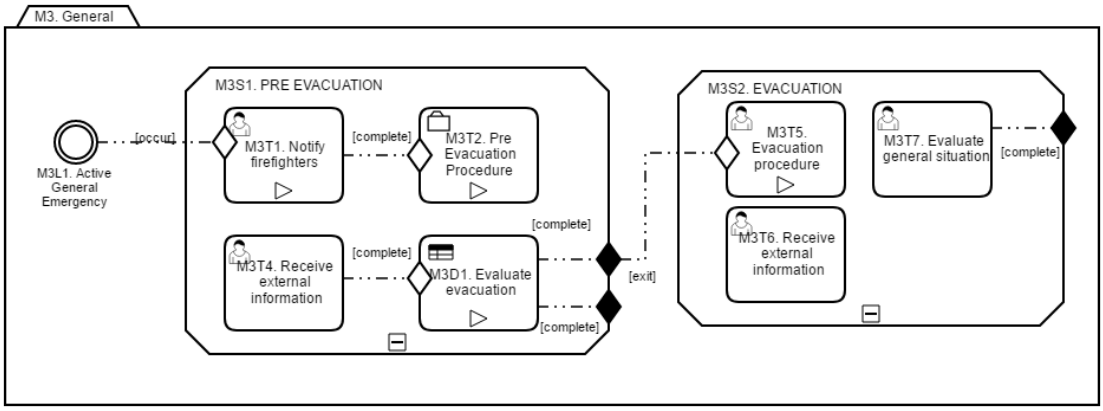

Figure 8. M3. General Emergency Model in CMMN

5.- EXECUTION ENVIRONMENT

Once we built the ACM hybrid model in the Camunda Modeler tool, we should use the BPM Camunda platform, which must be installed and configured together with the Eclipse Maven environment (Camunda Services, 2016). These settings allow one to execute the models and be able to perform simulations of various environments validating the behavior of the models with respect to variants and unrepeatable situations typical of emergency management. One of the benefits of Camunda BPM is the interoperability with other environments through web requests based on the Hypertext Transfer Protocol (HTTP), so it can be consumed through the Application Programming Interface service of the Representational State Transfer type known as the API REST. With the help of the Postman tool, we send a POST request method to simulate the activation of the fire alarm signal with the data shown in Figure 9 and with this create an execution instance.

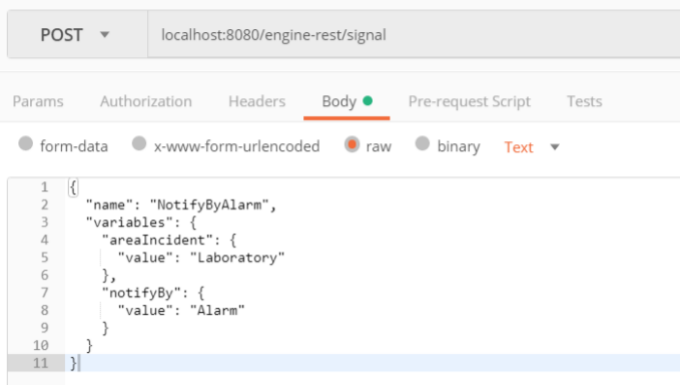

Figure 9. Activation of fire alarm signal via Postman

After this, we run the BPM Camunda platform and enter the TaskList application, finding in the option "My Task" the list of tasks of model **M0. Fire Management**. When we choose task **T1. Process notice Control Center**, we observe the data received from Postman.

On this occasion, to simplify the presentation of the paper, the fire at the **Conatus Emergency** level has been chosen as a sample, in order to validate one of the possible scenarios that may occur during the fire-type emergency in the hospital. In Figure 10, we represent the scenario of the conatus emergency using the orange color to indicate the instantiated items and in red the order of the workflow sequence in the model **M0. Fire Management**. In step 7 of the workflow, when the **T4. Report Incidence** task is activated, the security guard can complement the information for the **F1. Incidence Report** that is loaded in the **D2. Evaluate Incidence Level** and provides to the Emergency Boss, the decision making of the actors that will participate in the mitigation of the incident and establishes the level of the incident.

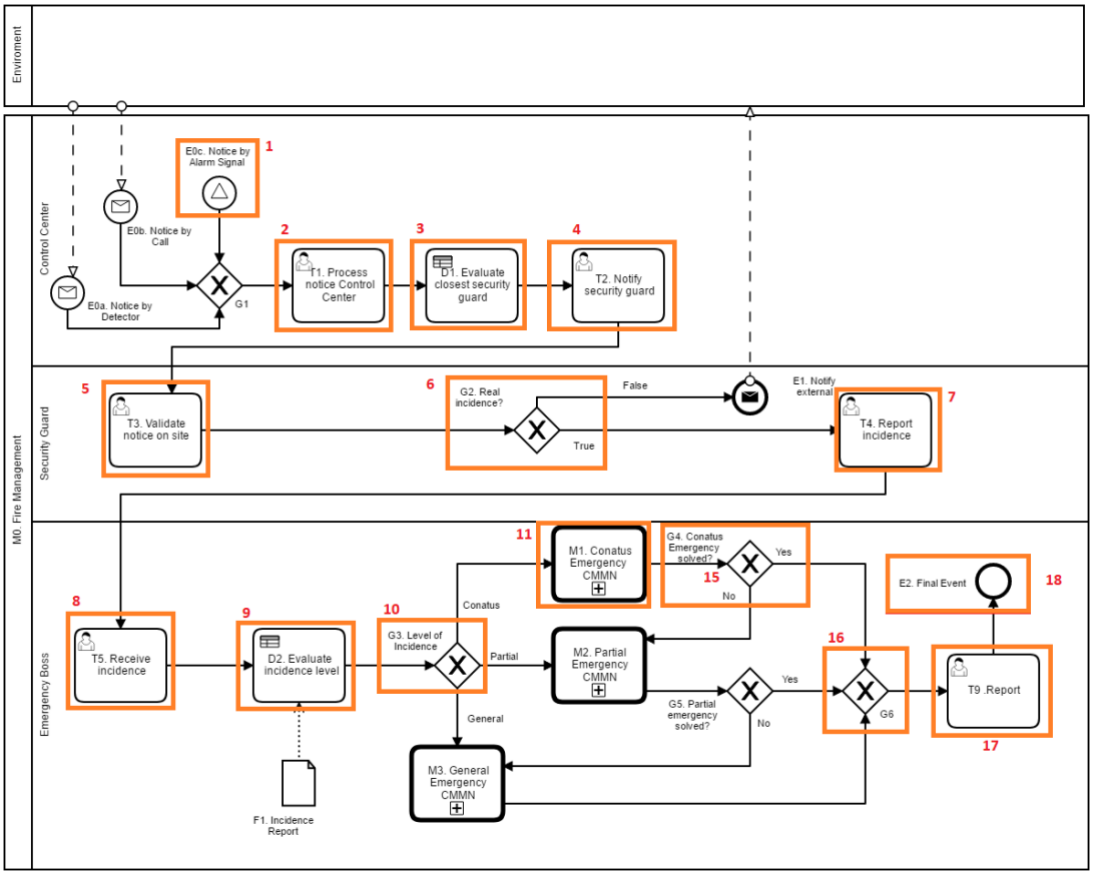

Figure 10. Representation of conatus emergency in model M0. Fire Management.

When the workflow in the simulation reaches **M1. Conatus Emergency**, a call is made to the model in CMMN notation, in Figure 11 we represent the continuation of the execution flow where the case worker intervenes to choose the tasks that will be activated.

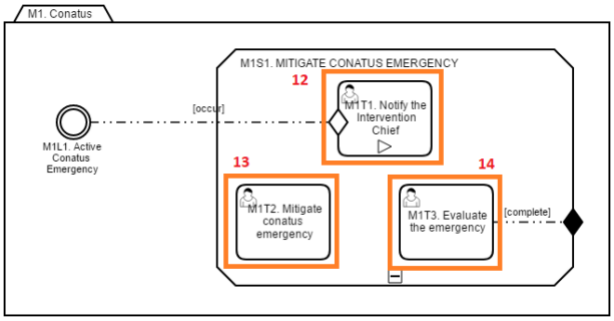

Figure 11. Representation of conatus emergency in model M1. Conatus Emergency.

With the help of the BPM Camunda platform and entering the variables of the environment via Postman for the activation of the instance, the emergency response procedure of fire type represented with the proposed ACM hybrid model has been implemented in a promising way for different scenarios.

However, we found that the web interface of the TaskList application of the BPM Camunda platform is not adequate for the interaction of the case worker during the emergency management. This was mainly because the tasks are presented as a list, which could lead to confusion when choosing the right element to instantiate. Although the Camunda BPM platform is a tool capable of executing models in BPMN, CMMN, and DMN, and its core can be consumed by API REST, the interface for a case worker is not adequate in emergency situations. Therefore, it is necessary to build a tool that maximizes the execution core's potential allowing to strengthen interoperability with other external systems and designing an appropriate interface to the case worker for emergency management. Likewise, the hybrid ACM model by integrating the BPMN, CMMN and DMN specifications would allow to create a library of processes, case definitions and business rules that facilitate the validation of new case studies.

6.- CONCLUSION AND FUTURE WORK

Emergency response procedures are characterized by being dynamic, highly knowledgeable and unstructured; therefore, they are classified as knowledge-intensive processes. Dealing with unrepeatable and unpredictable flows implies that the model must be flexible and adaptable. The Adapted Case Management appears as one of the most attractive and viable innovations in this context, thus, it has been decided to apply to the domain of emergency management. However, in most of the proposals, it is offered to choose between the modeling approach oriented to traditional processes such as BPMN or in case management as CMMN. With BPMN we find that its main benefit lies in the autonomy and agility of the execution because the pre-established conditions are the ones that guide the tasks that should be carried out in the workflow. With CMMN we obtain more flexibility, it relapses the direction of the flow in the events and the decisions taken by the case worker, the latter based on the experience of the case worker. As we can see, the greater the autonomy, the less flexibility.

Although CMMN allows attending for the adaptive case management, in emergency response procedures it is not possible to generalize that at all times the intervention of the case worker is required and to depend entirely on their experience for decision making. There are stages in which the execution can be accelerated by relying on traditional modeling approaches such as BPMN and DMN. By integrating the different approaches, we can obtain a flexible and agile model.

This document briefly presented the characteristics of the different process modeling approaches, including BPMN, DMN, and CMMN; it was demonstrated with the case study based on the of fire type incident of the Hospital Universitario y Politécnico de La Fe in the city of Valencia, Spain, how a hybrid ACM model can be built, where the BPMN, DMN and CMMN standards are integrated to represent artifacts and how they will interact with each other when a dynamic, unrepeatable and unpredictable scenario occurs. Likewise, it was shown, how the different standards converge.

ACM hybrid modeling is a promising proposal to provide support for emergency response processes and there are some modeling tools and execution platforms. Although this is the case, modeling and execution tools are still required to facilitate integration and interaction of different languages, to be adapted to an interface that provides the adequate support for emergency management.

Our future work will focus on implementing the proposal of the hybrid ACM modeling in other emergency response procedures to contrast with other cases of study. We will also focus on the development of a tool that facilitates the implementation of the proposed ACM hybrid models in an appropriate environment to the emergency management and the interoperability with external systems.

ABSTRACT

Human beings have been facing numerous emergencies which could threaten their property or even their lives in all ages. In order to learn how people respond to the emergencies like earthquakes and fire disasters, a two-stage simulation considering people's rational thinking and irrational thinking was conducted. Results show that people's irrational thinking, like the herd effect, could exaggerate people's behavior of conformity, and it changes the spatial features that stronger herd effect leads to higher cohesion level. It is also worth mentioning that crowd response of condition of smaller population is harder to predict because of its instability, and the response of the very first part of people who make decisions could make great changes to the whole crowd's response. These results could give some enlightenment on the evacuation instruction during emergencies and future research works.

Keywords

Crowd response, evacuation, expected utility theory, herd effect.

INTRODUCTION

Emergencies, like sudden natural hazards, fire disasters, explosions and terrorist attacks, have been one of the major threats for human being's survival in history. By means of effective warnings people could reduce loss to a minimum extent before the scientists find ways to predict them earlier. While the final effectiveness of the warnings does not only depend on the development of science and technology, but also rests with people's rapid and correct responses.

The whole response process mainly includes warning receiving, decision-making and action taking. The warning receiving is a relatively objective process. It is closely related with the warning dissemination process,

including source, emitter, channel, receiver and sink according to Shannon and Weaver Model (Shannon, 1949). The decision-making process starts from people receiving the warning information and ends with their making up minds to take actions or decide not to take any action. In emergent cases, like fire disasters, this process decides whether people evacuate or not, when to evacuate, how to evacuate, where to evacuate, and with whom to evacuate. The action taking is a process making the decision made in the last stage come true. It's worth mentioning that these three stages are mutual fusion and integrated that in many cases people also keep receiving new warning or information, making or changing their decisions in the meanwhile when they are taking actions. In this research, the decision-making process is the main point of study.

The behavioral decision theory is one of the applicable method to explain people's decision making in theoretical way. It has been largely applied in financial problems, government decision-making, consumer behaviour, individual choices, emergency response, and many other fields (Prather and Middleton, 2006; O'Hare and Smitheram, 1995; Stahl and Harrell, 1981; Maguire and Albright, 2005; Fischhoff, 2010). The brought up of Expected Utility Theory by Von Neumann and Morgenstern has settled down the development direction of behavioral decision making theory under uncertain conditions (Neumann and Morgenstern, 1944), but it was challenged by several paradoxes because of its assumption of rational actor. Recent years the non-expected utility theory, among which the Prospect Theory is the most popular one, becomes prevailing in related research fields (Tversky, 1979). Until now many researchers are still making efforts to bring up new theories and methods within the framework of expected utility theory to describe people's decision-making process and fix the paradoxes that the expected utility theory could not solve. For example, introducing the uncertain theory to expected utility theory (Yao and Ji, 2014; Chen and Park, 2017); introducing extra parameters to achieve equivalent predictions as cumulative prospect theory (Charles-Cadogan, 2016); and proposing a construction-specific utility framework based on expected utility theory (Alozn and Galadari, 2017).

Some researches attempted to validate these theories by methods of experiments, and results showed that measures based on expected utility model obtained some degree of convergent validity and could be good predictors of actual market behavior (Smidts, 2000). While some doubted that expected utility theory failed to effectively predict people's behaviors and that the prospect theory was more consistent with the experiment results (Friedman, et al., 2014; Baillon and Bleichrodt, 2015). However, different voices were raised that the expected utility theory was revealed to be insignificantly different from other models and could satisfy all of the preferences the other theories could do (Hu, et al., 2012; Pettigrew, 2016). Abellan-Perpinan looked into the consistency of these theories in health area and found that the prospect theory was more consistent with rankings and choices but not not with intertemporal decisions compared with the expected utility theory (Abellan-Perpinan, et al., 2009). As concluded by Ivan Moscati, who reconstructed the trajectory of experimental researches of expected utility theory between 1950 and 1985, the flaws of EUT-based utility measurement do not undermine the utility measurement in general (Moscati, 2016).

Compared with the behavioral decision making theory which applies to individual decision making, crowd decision making seems more complex and unpredictable. Crowd behavior is one of the most popular research topics both in sociology and psychology fields, and by now there has been a number of representative findings that promote the researches' development. An important research about crowd behavior is Sherif's experiment of autokinetic phenomenon, demonstrating that individuals are easy to get affected by other people's suggestive influence (Sherif, 1936). Another typical research is Asch's conformity experiment revealing that social pressure from the majority of the group could exert influence on people's conformation behavior (Asch and Solomon, 1956). After that, researches related to crowd conformity behavior sprang up, especially in the field of financial behavior researches. A mass of researches investigated the stock markets around the world and proved the existence of herding behaviors, including the U.S.A., Japan, Germany, China,Turkish, and some other countries (Demirer, et al., 2014; Ashiya and Doi, 1999; Cakan and Balagyozyan, 2014; Babalos, et al., 2015; Yao, et al., 2014; Cajueiro and Tabak, 2009; Kremer and Nautz, 2013).

Researches specific to emergent occasions are much less in quantity compared with the researches of crowd behavior defined in common occasions,. There are several prominent theories should be mentioned, including Emergent Norm Theory, Inter-group perspective brought up by Reicher and Potter (Reicher and Potter, 1985), Model of Disorder brought up by Waddington (Waddington, 2010), Social Identity Theory brought up by Turner, Oakes, Haslam and McGarty (Turner et al., 1994), and Elaborated Social Identity Theory brought up by Reicher and Drury (Drury and Reicher, 1999). These theories provided frameworks for related researches to look further into crowd behaviors during emergencies. Empirical experiments also proved the existence of herding behavior during emergencies (Altshuler, et al., 2005; Wei, et al., 2014).

Recent researches also started to make efforts to discover the secrets hidden under people's herd behaviors. It was found that people's herd behavior depends on both environmental and personal factors, like the knowledge about the alternatives options, and that only under condition of certain level of uncertainty would the herd effect occur (Lovreglio, et al., 2016). Another perspective insists that the herd behavior does not applicable to all

emergencies, for example, people prefer not to follow the majority's escape route under crowded and no choice uncertainty conditions (Haghani and Sarvi, 2017). Some found that the herd behavior occurred when the individual interactions were strong (Chang, 2014). Based on these findings, researchers tried to establish qualitative and quantitative models to explain and analyze the herd behavior, like the sequential decision model (Banerjee, 1992; Morone, 2012), informational herding model (Cipriani and Guarino, 2014), and an asymmetric information and Baysian learning model (Hott, 2009).

The researches mentioned above are mostly qualitative and empirical studies. Based on these theories, many researchers have built up various quantitative models to simulate people's behaviour during emergencies, mostly focusing on people's evacuation process, such as pedestrian behaviour, evacuation time, jamming phenomenon, bottleneck effect and so on. Some prominent researches include Helbing's research integrating panic behaviour and quantitative theories published in Nature (Helbing et al., 2002), Burstedde's simulation of pedestrian dynamics using a two-dimensional cellular automaton (Burstedde et al., 2001), Kirchner's simulation of pedestrian dynamics using a bionics-inspired cellular automaton model (Kirchner and Schadschneider, 2002), and some other related researches (Luo et al., 2008; Zaharia, 2009; Wu, 2014; Wagner, 2014).

In summary, to describe people's individual decision-making under rational thinking, the expected utility theory could be a relatively effective method in spite of its defects in explaining some paradoxes. On the other hand, the influence of surrounding people was proved to be existing, which makes the crowd to show a tendency of irrational herding behavior, and eventually make great differences on people's evacuation results. However, the quantitative researches of people's response during emergency are not many, among which mostly focusing on the evacuation process, but not much on the decision-making process before people take actions of evacuation. In this research a two-stage simulation was conducted integrating people's rational thinking of individual risk perception based on expected utility theory and irrational thinking affected by herd effect using method of cellular automaton in order to study people's possible response under different conditions, and some meaningful findings were put forward.

MODEL AND SIMULATION DESIGN

From the angle of complex adaptive system, cellular automaton (CA) could simulate the emergent feature of systems by constructing cellulars at the microcosm level and designing rules for the cellulars to interact. Now it has been widely used to simulate the social system, especially people's evacuation processes during emergencies. A cellular automaton model could be defined by a quadruple form, donated by $CA = (S, X, V, f)$, where S is cellular space, X for cellular states, V for cellular neighborhood, and *f* for transition rules of cellular states. It is suitable for simulating people's decision-making process because of the following reasons:

1. The limited cellular space in CA model is consistent with the indoor environment where the decision-making processes usually happen in real world.

2. Cellular states could reflect each individuals properties during decision-making, like decision intention, decided or not and evacuate or not.

3. Cellular neighborhood explains who exert an influence on the cellular's decision and the transition rule explains how they make the influence happen.

While the normal cellular automaton could only simulate homogeneous properties and distribution that all cellulars obey the same rule and are located orderly, which do not fit in the real social system. By integrating the method of Agent-based Model (ABM) it could well solved these problems for its feature of heterogeneity. So here we use the CA settings to simulate people's decision-making but use the ABM method to realize the simulation processes with heterogeneity.

Assume that there are people amount of N regularly located in an indoor environment, like a classroom, an office or a concert hall. The whole simulation includes two stages, corresponding to people's decision intention and interaction processes.

1. Decision intention (rational process).

Once the emergency alarm rings, for example, the fire alarm or an earthquake early warning, individuals first form their decision intention, to make it simple, of evacuate or not, and basically it is a relatively rational process. In financial researches, the expected utility theory was widely used to describe how people make choices based on potential gains and losses, which could also be utilized to calculate people's decision-making intention under emergency conditions. The following table describes the payoff matrix of each individual choosing to evacuate and not evacuate under the circumstances of true alarm and false alarm.

Table 1. Payoff Matrix of Evacuation Intention

Payoff	True	False
Evacuate	a_i	b_i
Not evacuate	c_i	d_i

According to the expected utility theory, the expected utility is given by

$$U = p_1 u(x_1) + p_2 u(x_2) \tag{1}$$

Let $p_i (0 \le p_i \le 1)$ be the perceived probability of emergency happening of individual *i*. So the value function of each individual *i* is given by

$$U_i(evacuate) = p_i a_i + (1 - p_i) b_i \tag{2}$$

$$U_i(not - evacuate) = p_i c_i + (1 - p_i) d_i \tag{3}$$

Assume that the evacuation intention was entirely decided by the expected utility. Let

$$U_i = U_i(evacuate) - U_i(not - evacuate) \tag{4}$$

then

$$y_i = \begin{cases} 1(evacuate) & U_i > 0 \\ 0(not - evacute) & U_i \le 0 \end{cases} \tag{5}$$

2. Interaction (irrational process).

In order to simulate people's herd behavior, in other words, imitating the majority's behavior, which is an irrational process, the assumption that people's final decision could be affected by the decisions of other people was inserted. Let V_i be the neighbourhood of individual i. We assume that individual *i* might get affected by the proportion of people decided to evacuate in the range of V_i. Let $q_i (0 \le q_i \le 1)$ be the potential of being influenced by others, λ_i be the proportion of people decided to evacuate in the neighbourhood range of V_i.

If individual *i* is not influenced by others, the probability of evacuating is totally decided by the individual's evacuate intention. If individual *i* is totally irrational and influenced by others, the probability of evacuating is decided by the herd effect.

$$E(q = 0) = u \tag{6}$$

$$E(q = 1) = \lambda \tag{7}$$

So the probability of individual *i* to decide to evacuate is given by

$$E = (1 - q)u + q\lambda \tag{8}$$

The above model takes people's expected utility as the reference point of herd effect. If individual *i*'s evacuation rate is larger than his/her value function, the probability of evacuating will increase, and vice versa. While another idea is to take the majority's decision as the reference point, in other words, if the majority in the range of V_i choose to evacuate, individual *i*'s evacuate rate would go up, indicating that

$$E = u + cq(\lambda - 0.5) \tag{9}$$

where *c* is a constant decided by *u*.

For the condition that $\lambda - 0.5 \ge 0$, a boundary condition is that

$$E = 1, \text{ when } q = 1, \lambda = 1. \tag{10}$$

So

$$c = 2(1 - u), \quad E = u + 2q(1 - u)(\lambda - 0.5). \tag{11}$$

For the condition that $\lambda - 0.5 < 0$, a boundary condition is that

$$E = 0 \text{, when } q = 1, \lambda = 0. \tag{12}$$

So

$$c = 2u \text{, } E = u + 2uq(\lambda - 0.5). \tag{13}$$

So when the reference point is the majority's decision, the calculation function is:

$$E = \begin{cases} u + 2q(1-u)(\lambda - 0.5) & \lambda \text{-} 0.5 \geq 0 \\ u + 2uq(\lambda - 0.5) & \lambda \text{-} 0.5 < 0 \end{cases} \tag{14}$$

An important factor that could make change to people's decision is their decision time. Some people make decisions very quickly that they do not need to observe others decisions to make decisions, while some might need to refer to all other people's decisions to make their own ones. So we assume that people's decision time satisfies a normal distribution $T \sim N(t, \sigma^2)$, that is,

$$f(t) = \frac{1}{\sqrt{2\pi}\sigma} \exp(-\frac{(t - t_0)^2}{2\sigma^2}) \tag{15}$$

where t_0 is the mean observing time for all individuals.

SIMULATION RESULTS

The simulation was conducted on Netlogo 5.3.1. In order to simplify the simulation, the following variables were assumed to be normally distributed:

Perceived reliability of warning: $p \sim N(p_0, \sigma^2)$.

Probability of being influenced by others: $q \sim N(q_0, \sigma^2)$.

Considering that simulation of larger population could narrow the simulation errors with little influence on the simulation results, the total population was set to be ten thousand for each simulation. The value of a_i, b_i, c_i and d_i in Table 1 were set to be non-dimensional numbers ranged from 0 to 10 with initial value of 5, representing the neutral attitude towards all the losses. According to Equation (2), (3) and (4), the effective variables that changes the utility could be simplified to (a-c) and (b-d). Further simplification is conducted to set (b-d) equals zero and (a-c) varies from -10 to 10 when concerning the changes of payoff evaluation.

In order to study the time-dependent characteristics of evacuating decision-making, the variables were set to be a set of values which could roughly reflect the tendency of evacuation rate curve, and changes of these values would not make difference on the shape of the curve (Table 2).

It is easy to find that the frequency curve for people who decided to evacuate and not to evacuate goes up slowly in the beginning, and starts to explosively grow with time goes, and finally reaches to the maximum with slower and slower speed. The burst of decided people could be due to the normally distributed decision time, or the herd effect of imitating others behavior.

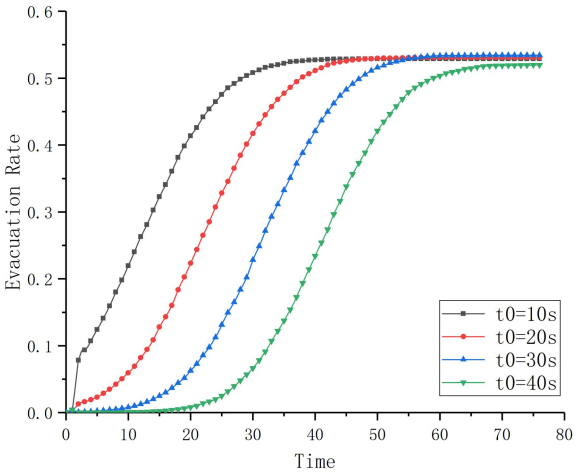

Figure 1. Evacuation Rate of Different Decision time

Firstly, the influence of decision time is evaluated and people's mean decision time (t_0 in Equation (15)) is set to be 10 seconds to 40 seconds. It is obvious that the mean decision time of the crowd does not make a difference on the final evacuation rate or the rising tend except the equidistant x-offest of the curves. A small detail could be found in the graph that at the very first time people make evacuation decisions in the condition of very short decision time, the curve is not smooth but connected by an inflection point. This phenomenon could be attribute to the large gap between the actual evacuation population at the first point and the supposed evacuation population with normally distributed decision time.

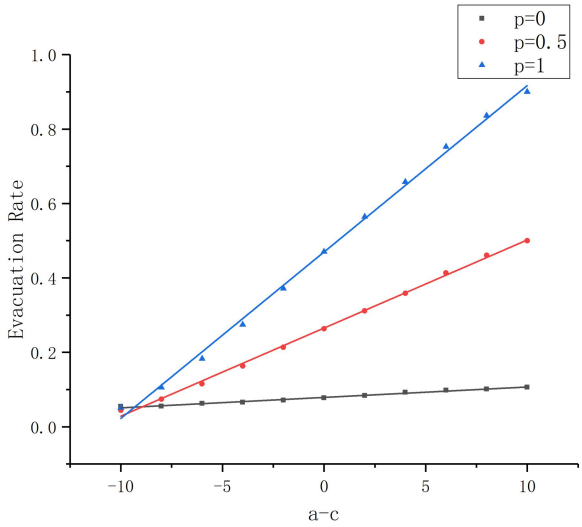

Figure 2. Evacuation Rate of Different Warning Reliability

It is intelligible that evacuation rate was a linear function of utility if we set the conformity level to be zero to minimize the influence of herd effect. While this linear tendency could be affected by the warning information that the evacuation rate of different warning reliability (p_i in Equation (2) and (3)) is simulated. As shown in Figure 2, with more reliable warning, more people would choose to evacuate, which is accorded to our assumption and previous researches on warning reliability (Meyer and Joachim, 2001; Roy et al., 2015).

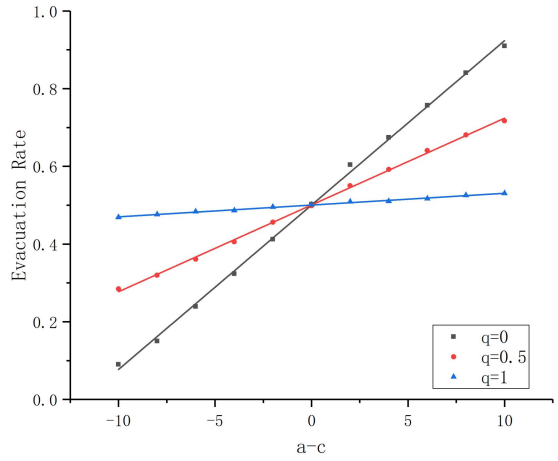

Figure 3. Evacuation Rate of Different Conformity Level (utility as reference point)

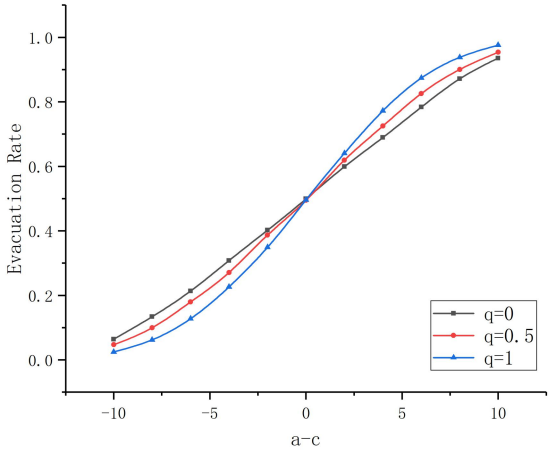

Figure 4. Evacuation Rate of Different Conformity Level (0.5 as reference point)

Besides, the herd behavior could also change people's evacuation decision as Figure 3 and Figure 4 show. If we employ the model of setting individuals' value function as comparison point (Equation (8)), it is found that when the value of utility is larger than zero, the stronger the herd effect is, the lower the evacuation rate could be. On the contrary, when the utility is lower than zero, the stronger the herd effect is, the higher the evacuation rate is. Though this result could be explained by mathematical analysis of Equation (8), it is not corresponding to our common sense. While if we employ the other model which takes the majority's decision as reference point (Equation 14), more reasonable results are found. Contrary to the result of the other model, when people's value function is larger than zero, the stronger the herd effect is, the higher the evacuation rate is. This result is consistent with both our common sense and previous findings (Helbing et al., 2000; Herbst and Mas, 2015). And an information acquired from the figure is that this kind of amplification effect is not same for each utility. For example, it reaches the most obvious point when the expected utility function equals 5 and -5, and least obvious at the zero point and the two ends of the utility function due to the limitation of the maximum evacuation rate.

The comparison of patterns of the crowd's final decision is more visualized. When there is no herd effect, the pattern of decision-making is quite dispersive because people make their decisions only based on their utility, which is totally not affected by others decisions. While for the strong herd effect condition, the pattern of decision-making changes to a relatively conterminous mode, because people do not make their decisions based on their heterogeneous utility but their neighbors' decision.

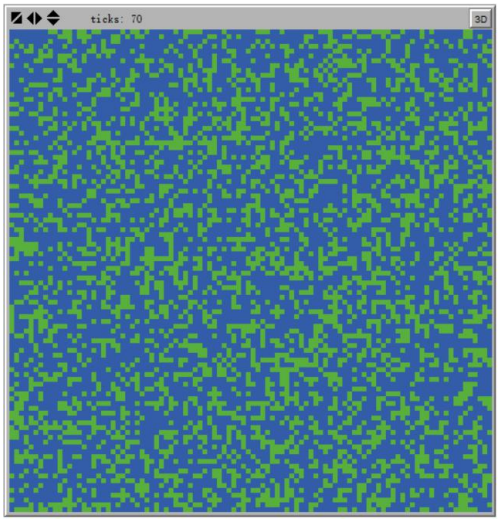

Figure 5. Spatial Pattern of Weak Conformity Level

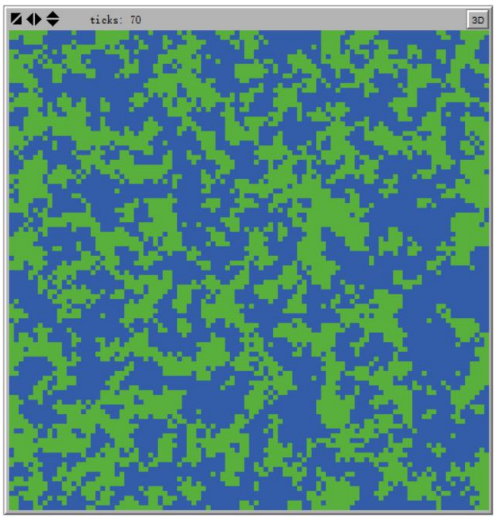

Figure 6. Spatial Pattern of Strong Conformity Level

Another finding is that if we change the neighborhood selection strategy from Moore neighborhood to the global viewing angle, which means each individual could observe all people in the same space and imitate their

behaviour, the decision pattern gets dispersal again and it doesn't change with the herd effect getting stronger. While this scenario is not realistic because people do not have the ability to observe all ten thousand neighbors in the same space. In most cases, people could only observe neighbors around them within their vision.

In order to evaluate crowd's dispersivity level, the definition of centrality and centralization potential in the field of social network are employed here (Freeman, 1979). Centrality measures the degree to which one node in a network is connected to all other nodes, and the centralization measures the concentrative degree of the whole network, which is decided by the centrality of all nodes. It's defined by

$$C = \frac{\sum (C_{\max} - C_i)}{\max[\sum (C_{\max} - C_i)]}, \tag{16}$$

where C_i represents the centrality of individual i and $C_{\max}$ represents the maximum centrality of all people. According to the simulation result, the centralization mode is quite different for different neighborhood selection strategies. The calculation result shows that the centralization does not change according to people's conformity level when all other agents are set to be agent i's neighbors. But things change when the neighborhood is set to be the Moore neighbors that the centralization level is negatively linear with the conformity level, in other words, higher conformity level leads to higher cohesion.

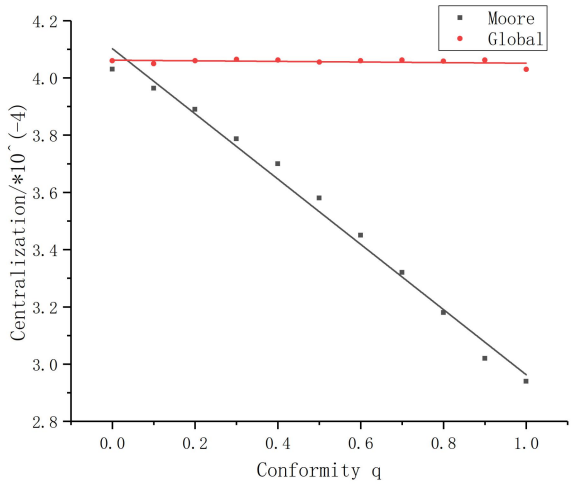

Figure 7. Evacuation Rate of Different Neighborhood

Above results are obtained under the condition of ten thousand population in a certain space, while it is not a common scenario to have such a large event held in a site able to accommodate ten thousand people. Theoretically, the average evacuation rate of simulations repeat times without number should be the same no matter how many numbers of people, but the result could change if we only repeat limited times. If we take the situation of complete herd effect as an example, theoretically the average evacuation rate should be around 0.5. From the simulation result, we can see that with the population going up, the average evacuation rate gets closer to to theoretical value, and the stability gets higher for the shorter length of variation range. While for smaller population cases, especially for the 25 people group, the median and average evacuation rate was almost 10% away from the theoretical value. And for the the extreme cases, the evacuate rate could be lower than 0.3 and higher than 0.6. This kind of case variation is due to the small sample size of each case. In many scenarios, there are only tens of people or even less than 10 people in a room, like classrooms and offices, so people's decision under emergency condition could have quite different results.

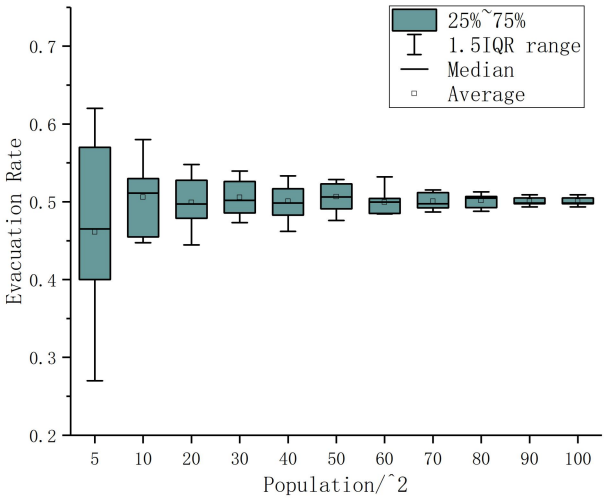

Figure 8. Evacuation Rate of Different Population

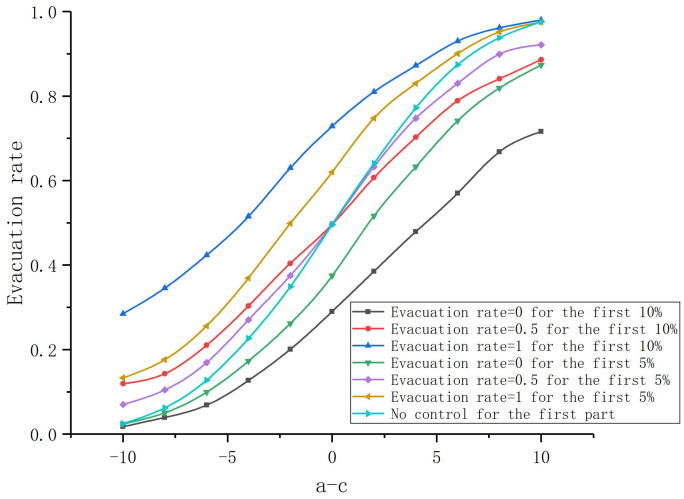

Figure 9. Evacuation Rate When Controlling the First 5% People and the First 10% People

Based on Equation (14) and the previous researches on herd effect, neighbors who first make decisions could have great impact for the others. In this simulation, the influence of the first 5% and 10% parts of neighbors who make decisions are studied. According to the simulation result, higher evacuation rate of neighbors who make decision first could effectively raise individuals' final evacuation rate. For example, when people is irresolute on whether to evacuate or not (utility=0), if all of the first 5% neighbors make decisions to evacuate, the total evacuation rate could raise by 20%, and by 40% for the condition of the first 10% neighbors decide to evacuate. Similar results could be found when the first part of neighbors decide not to evacuate. And this effect is particularly significant when individuals' first evacuation intention is quite low that the total evacuation rate could raise over 5 times and even 10 times. This remarkable effect is consistent with Dyer's empirical experiment of leadership effect in crowd decision-making (Dyer et al., 2008) and could be taken advantages in evacuation strategies during emergencies.

The variable settings of the above simulation were presented in Table 2.

Table 2. Variable Settings in Each Simulation

DISCUSSION

According to the simulation results, the shapes of the evacuation decision-making curve do not change when the decision-making mean time changes. But the changes in the position of coordinate axes show the importance of the decision-making timing. For example, the lead time of a sever earthquake usually lies between seconds to tens of seconds. For a 20-second earthquake early warning, people need to make decisions of evacuate or not in 20 seconds, so it would be quite dangerous for crowds whose decision time was normally distributed with average of 20 seconds, 30 seconds or even more. Now that the great differences of the final results in limited time with different decision time have emerged, some other questions about the decision timing should be studied. What decides people's decision-making time? Is it decided by personal characteristics, surroundings, warning information or other people's behavior? How to shorten people's decision-making time while keeping people to be rational under emergent condition? These questions could be looked into by experiments or real cases analysis and the answers to these questions could be of great importance on decreasing emergency losses.

In this simulation, we assume that the expected utility is decided by the alarm's reliability and people's payoff matrix. It is easy to understand that when the utility is over zero, people's evacuation rate goes up with the alarm reliability getting higher. So it is of importance to improve the warning's reliability but it is still unknown that how to evaluate the alarm's reliability and how to match the public's perceived reliability and the authority's technical reliability.

It is also feasible to raise people's evacuation rate by changing their payoff matrix, in other words, increasing people's benefits of evacuating (decreasing people's losses of evacuating) or decreasing people's benefits of not evacuating (decreasing people's losses of not evacuating). For the first circumstance, measures of improving evacuating convenience and increasing compensation for emergency losses could be conducted, for example, designing and constructing more convenient escape ways and increasing the compensation rate for people who take positive actions to reduce losses. For the second circumstance, the government and related departments could increase people's subjective evaluation of emergency losses by improving emergency education to help people realize the severe consequence it could result in. Apart from understanding how to improve people's response during emergencies, researches should also study further on the formation of people's payoff evaluation. For example, what kinds of factors result in people's differences of payoff evaluation? Is there any way to change people's payoff matrix, and further to change people's decision-making under emergent occasions?

As the results show in the last section, people's final decisions could be largely influenced by the first part of people who make decisions because of herd effect. Usually people are criticizing the herd effect because herd effect is a kind of expression of irrational thinking, but sometimes we can also utilize this irrational thinking to reach a better consequence. There is a great probability that people might not make an objective decision by their rational thinking, resulting in the gap between their real decision and the authorities' expected decision. Under this circumstance, if people who make decisions first could make correct decisions, and then the others, who do not have a reasonable evaluation of evacuation payoff, could just imitate others correct behavior with less considering the incorrect analysis of themselves, improving the final results for the whole. While opposite things could also happen that people who could make correct decisions are influenced by people who make incorrect decisions, worsening the emergency consequence. So the authority could find ways to educate or induce people who make decisions most quickly or other people who could largely insert influences on others to make correct decisions to narrow the gap between expected response and real response. So now the problem is detailed to be the problem of people who make their decisions quickest: What kinds of factors decide people's decision time and who are probably the one who make decisions earliest? Apart from the timing of making decisions, what else could be the influencing factors for the crowd, such as the social relationship? And ultimately how can we utilize people's psychology of herd effect to improve people's emergency behavior? In a word, there are still too many ignorant questions to be dug out.

Another important factor in this simulation is the neighborhood selection strategy. From our simulation result, the smaller neighborhood range could make crowd's cohesion level higher. Though it seems not useful for the

final evacuation decision rate, it could eventually affect people's evacuation process. Crowd of higher cohesion level are more likely to create congestion in the evacuation route and crowd of lower cohesion are more likely to avoid congestion because their dispersive decision pattern. While when the population is large or part of the room space is shielded, it is not possible for human eyes to observe all people in the same space because of the limited vision field or their personal psychological condition. So here comes the questions: How large should people's neighborhood range be? Is it only limited to people's vision field? Do all people usually set their observation range fixed or do they change according to people with different personal characteristics?

CONCLUSION

The simulation provides a method to simulate crowd's decision-making condition taking people's rational evaluation and irrational thinking into consideration respectively in two stages. The results show that the reliability of the alarms and the herd effect could have great influences on people's decision-making during emergencies, and the control of part of people who make decisions first could help the manage departments to command the emergency condition to an expected way. These results support the findings of previous researches on warning reliability, herd effect and leadership effect.

Based on the above findings, several measures reducing the emergency loss are put forward, including reducing people's decision time, improving warning's reliability, improving evacuating convenience and compensation for emergency losses, improving emergency education to help people realize the severe consequence it could result in, finding ways to educate or induce people who make decisions most quickly or other people who could largely insert influences on others to make correct decisions.

However many questions related to people's decision time, warning reliability and conformity behavior are still unknown in this field. The research questions mentioned in discussion section are all deserve to look deeper into and could help people learn more on crowd behaviors during emergencies, and reduce people's property loss and possible casualty in the end.

A Preliminary Optimisation-based Approach to Coordinate the Response of Ambulances in Mass Casualty Incidents

ABSTRACT

Mass Casualty Incidents (MCIs) may occur with no notice and require a rapid response to manage the casualties and arrange their transportation to hospitals. MCIs may result in different numbers of casualties and fatalities. Further, response time can play a crucial role in reducing fatalities and protecting lives. This paper reports on a preliminary optimisation-based approach, termed MCIER, which has been developed to co-ordinate the response of ambulances to multiple MCIs. In this approach, a realistic representation of the road network is modelled for the geographical area of interest. Also, a Neighbourhood Search Algorithm (NSA) has been developed in order to find the optimum solution to the problem under consideration. A hypothetical case study of a MCI in Newcastle-upon-Tyne has been considered to investigate the effect on response time of the time of day, and day of week, on which the incident occurs.

Keywords

MCIs, Optimization-based approach, Co-ordination, Emergency response.

INTRODUCTION

Disasters, which can be classified as natural or man-made, can occur in a short time and cause widespread damage to infrastructure, humans, fauna and flora (Pereira *et al.*, 2011). Natural disasters may occur from severe natural phenomena such as floods, earthquakes and volcanoes (Lowes & Cosgrove, 2016). For example, the earthquake in Kashmir, northern Pakistan in 2005, killing 90,000 and injuring 110,000, and the Indonesia flood in 1815, killing 92,000 (Mackway-Jones & Wiley, 2012). However, man-made disasters may include deliberate terrorist activity (Mackway-Jones & Wiley, 2012) and can occur in places where a large number of people are present. Both natural and man-made disasters may result in significant loss of life (Centre of Trauma Sciences, 2016; Department of Health, 2007; NHS England National Emergency Preparedness Resilience and Response Unit, 2015; The UK Cabinet Office, 2017) which can be referred to as Mass Casualty Incidents (MCIs) (Lowes & Cosgrove, 2016). MCIs can result in different numbers and conditions of casualties, and numbers of fatalities, and thus the medical needs and the response plans required can be different (Frykberg, 2002).

The emergency response to a major incident involves the emergency services (ambulance, fire, and police) and hospitals, which need to work together and co-ordinate their activities to meet strategic goals (The UK Cabinet Office, 2017) such as protecting lives, minimising fatalities and reducing suffering. Therefore, the emergency response may require extra co-ordination and extraordinary resources (Lowes & Cosgrove, 2016; Mackway-Jones & Wiley, 2012). Further, MCIs pose challenges including high uncertainty, time pressure, a shortage of staff and, interdependencies and interconnections between multiple services and responders involved (Department of Health, 2007; Yi & Kumar, 2007; Lerner *et al.*, 2008; Mete & Zabinsky, 2010; Wex *et al.*, 2012).

Co-ordination issues that are relevant in MCIs are discussed in (Malone & Crowston, 1994; Chen *et al.*, 2008). Task allocation, or task flow, is one of these issues related to assigning tasks to the right responders to avoid overlapping and duplicating effort (Jotshi *et al.*, 2009; Amram *et al.*, 2012; McCormack & Coates, 2015). Variations of task scheduling are considered in (Gong & Batta, 2007; Jotshi *et al.*, 2009; Amram *et al.*, 2012;

Wilson *et al.*, 2013a; Repoussis *et al.*, 2016). For example, Wilson et al. (2013a) have considered task scheduling where each casualty is assigned to a specific hospital. Further, each responder is given a set of inter-dependent tasks related to the type of injury of a casualty. Repoussis et al. (2016) assumed that a limited number of tasks is assigned to each ambulance where the duration of each task is assumed to be known. Wilson et al. (2013a) and Repoussis et al. (2016) have modelled the stochastic travel time of the ambulances as a normally distributed random variable. They referred to the mathematical model suggested by (Kolesar *et al.*, 1975), and was extended in (Budge *et al*., 2010), where two equations are provided, each of which is used to calculate the travel time based on the type of the journey, i.e. long or short journey. However, the time and day of the occurrence of the incident are neglected which could have a negative impact on the response. Further, the prediction of the travel times of ambulances in urban environments, as modelled in the work presented in (Wex *et al.*, 2012), could be difficult to assume as such environments may be subjected to severe traffic.

Another co-ordination issue, as alluded to above, is casualty transportation. In MCIs, transportation involves transferring the right casualty to the right hospital at the right time using the right emergency vehicle. Modelling a realistic representation of a road network of the geographical area of interest, to be used by emergency vehicles during the MCI, is essential in order to design an accurate response plan. During a MCI, the road network might be affected negatively due to severe traffic, such as congestion, which may cause a delay in the response. A simplistic road network has been presented in (Amram *et al.*, 2012; Zhang *et al*, 2012; Muaafa *et al*., 2014; Repoussis *et al.*, 2016; Kamali *et al.*, 2017) where distances and the travel times between two locations in MCIs are assumed to be known upon model initialization. A realistic representation of the road network within the problem environment is represented in (Hawe *et al.*, 2015) with a sufficient level of detail, e.g. length and type of roads.

Considering the actual distance between two locations and constant speed are insufficient to predict the travel time where there are other factors, such as the type of road, the time of day, which could have an impact on driving in a normal and MCI situations. Dong et al. concluded that the type of road has a minor impact on the overall travel time. Further, the time of the day is conducted to have a minor effect in (Kolesar *et al.*, 1975; Budge *et al.*, 2010; Wilson *et al.*, 2013; Repoussis *et al*., 2016). In contrast, Schmid *et al.* (2010) reported that vehicles, including ambulances, would be affected by the increasing volume of traffic during the peak time which causes congestion. McCormack *et al*. (2015) established that the time and day has a significant impact on the speed of ambulance vehicles.

As mentioned, the focus of the research presented in this paper is on major incidents such as that of the bombings in multiple London sites in 2005 (London Assembly, 2006). Man-made disasters, such as terrorist attacks, occur with no-notice where the majority of such attacks predominantly take place in urban areas which can be densely populated. As such, a preliminary optimization-based approach (MCIER) has been developed incorporating a Neighbourhood Search Algorithm and a realistic representation of the road network in any geographical area of interest. Further, the traffic congestion is modelled by changing the speed of the ambulance vehicles based on the traffic at a particular time and on a specific day with the objectives of minimising the response and the idle time. The MCIER is designed to consider the factors of (a) time of day and (b) day of week on which the incident occurs. Also, the delays in the process of ambulance preparation, collecting casualties from incident sites and dropping-off casualties at hospitals are considered. The effectiveness of the time and day of occurrence of the incidents on the response time during MCIs is assessed by simulating the ambulance response to a hypothetical case study.

Contribution of this paper

In this paper, an approach has been developed, incorporating a NSA, to solve the problem of coordinating the response of ambulances in multiple MCIs. The co-ordination problem of the emergency response to multiple MCIs includes the allocation of ambulances to casualties and, subsequently, the allocation of casualties to hospitals. In the NSA, a number of structures have been developed to achieve the objectives of minimising (i) the overall response time to deliver all casualties to hospitals and (ii) the maximum idle time of all ambulances. In addition to the NSA, the approach includes a realistic representation of the road network in the problem environment under consideration, which provides a level of detail needed to generate ambulance travel times based on accurate distances of the routes to be used.

PROBLEM DEFINITION

The emergency response co-ordination problem consists of a number of casualties n_c, where $c_i \in C$ and $1 \leq \mathrm{i} \leq n_c$ located at a number of incident sites n_{is}, where $is_i \in IS$ and $1 \leq \mathrm{i} \leq n_{is}$. Further, each casualty needs to be transferred from an incident site to a hospital $h_i \in H$, where there are n_h hospitals and $1 \leq \mathrm{i} \leq n_h$, by an ambulance $a_i \in A$, where there are n_a ambulances and $1 \leq \mathrm{i} \leq n_a$. Also, ambulances are initially located at one

of n_{as} ambulance stations $as_i \in AS$ where $1 \leq i \leq n_{as}$. Each hospital has unlimited capacity and can accept any casualty, each of which has equal priority. In addition, all ambulances are considered to be the same and all are able to transport one casualty per trip to hospital. The speed of ambulances is modelled as depending on day of the week and time of day as indicated in (McCormack & Coates, 2015). Table 1 summarises the elements and parameters involved in the co-ordination problem. The solution to this problem has the objectives of minimising: (i) the overall response time, which represents the time to deliver the last casualty to hospital; (ii) the maximum idle time of all ambulances, which is the maximum time that an ambulance spends in an idle state. Thus, a solution method must make a number of allocation decisions including (a) which ambulance from which ambulance station to allocate to which incident site?, (b) which casualty will be allocated to which ambulance?, (c) which hospital should an ambulance carrying a casualty be allocated?

Elements	Definition
$\boldsymbol{C}$	Set of casualties
$\boldsymbol{IS}$	Set of incident sites
$\boldsymbol{H}$	Set of hospitals
$\boldsymbol{A}$	Set of ambulances
$\boldsymbol{AS}$	Set of ambulance stations
Parameters	
$\boldsymbol{n_c}$	Number of casualties
$\boldsymbol{n_{is}}$	Number of incident sites
$\boldsymbol{n_h}$	Number of hospitals
$\boldsymbol{n_a}$	Number of ambulances
$\boldsymbol{n_{as}}$	Number of ambulance stations
$\boldsymbol{S_d^{(t)}}$	Ambulance speed based on the day of week *d* and time of day *t*
$\boldsymbol{T_b}$	The time between receiving the initial emergency call to attend an incident site and an ambulance departing from the ambulance station
$\boldsymbol{T_d}$	On arrival at hospital, the time taken for an ambulance crew to drop-off a casualty before departing to collect another casualty
$\boldsymbol{T_c}$	On arrival at an incident site, the time taken for an ambulance crew to collect a casualty from the incident site and depart for hospital

Table 1. Problem elements and parameters

MODEL

The model of co-ordinating the emergency response to MCIs includes a problem environment being defined which includes a MCI scenario and a road network. Subsequently, a solution method is applied to the problem environment in order to create a response plan; please see Figure 1.

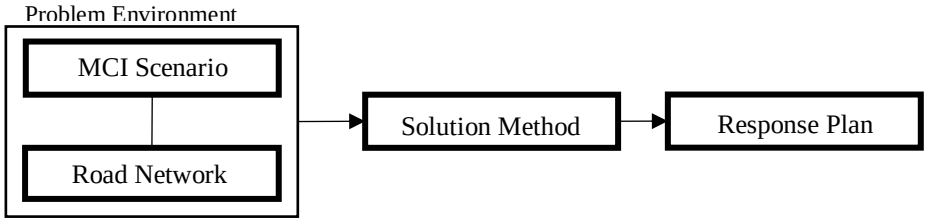

Figure 1. Overview of the MCIER approach

MCI scenario and road network

The problem environment requires a number of defined parameters to initialise the MCI scenario including the number and location of C, IS, H, A, and AS. A road network of the geographical area of interest is constructed using Ordnance Survey MasterMap (OSM) (Survey, 2019). It is one of the available sources of highly-detailed geographic data of Great Britain. The road network is represented as an undirected weighted graph $G = [V, E]$, where V is a set of vertices and E is a set of edges. Roads are represented by edges where each road has a type and a length. The start and end of each road are represented by vertices. The locations of ambulance stations and hospitals are established by converting their actual postcodes to the northing and easting coordinates using Grid

reference (Gridfinder, 2011). Then, these are assigned to the nearest vertex in the road network. Further, incident sites are located at vertices.

Objective functions

In order to evaluate a solution, two objectives are used, $f_1(s)$ is the overall response time that represents the time taken to deliver the last casualty to hospital and $f_2(s)$ is the maximum idle time of all ambulances. The optimization problem is to find an allocation of tasks to ambulances, which first minimises $f_1(s)$ and second minimises $f_2(s)$, i.e.

$$f_1(s) = \max_{i,j} \sum_{k=1}^{n_t} TD_{k,i,j} \qquad f_2(s) = \max_{i,j} IT_{i,j}$$

where i and j indicate the i^{th} ambulance originally located at the j^{th} ambulance station respectively. Further, k represents the k^{th} task allocated to an ambulance, where n_t is the number of tasks. Also, the duration of each task, $TD_{k,i,j}$, assigned to an ambulance must be established. For example, the time taken to transport a casualty from an incident site to a hospital can be established using knowledge of the route to be taken in terms of distance and the speed of the ambulance based on day of week and time of day.

Solution method and response plan

Pseudo-code for the developed Neighbourhood Search Algorithm (NSA) is presented in Algorithm 1. The NSA produces a new response plan at each iteration. However, the previous plan will be kept unless an improvement is made in the new plan. At each iteration, an attempt is made to find an improved plan by selecting and applying one of five neighbourhood structures each of which makes changes to the current plan. The neighbourhood structures include (a) allocate a casualty to a different hospital (CH), (b) swap two casualties between two different ambulances (SCDA), (c) swap the position of two casualties in the same ambulance (SCSA), (d) move a casualty from one ambulance to another (MC), (e) assign a casualty from the ambulance that has the highest workload to the one that has the lowest workload (BW); please refer to Figure 2 for details. In relation to (e), this structure was inspired by the work presented in (Amiri *et al.*, 2010).

An initial solution is generated by allocating a number of tasks to each ambulance. These tasks are (a) travel to the incident site, (b) collect the assigned casualty, and (c) transfer the casualty to the assigned hospital. It is important to consider the possible delays that may occur during the response process which will affect the response time. Delays related to (a) the preparation time, (b) the collection time, and (c) the dropping-off time are considered. Figure 3 presents an example of how tasks are allocated to a single ambulance including the delays associated with each task. There is no prior knowledge, or assumption, of the duration of each task which depends on from where the casualty is collected and to which hospital the casualty is delivered. In relation to travelling to/from an incident site, and to/from a hospital, Dijkstra's algorithm is employed to find the shortest path between two locations. The effectiveness of the day and time on the response time for the same path has been investigated and is presented later in this paper.

Algorithm 1. NSA

1.	$\boldsymbol{plan} \leftarrow$ **INITIALIZE**()	Initialise response plan (*plan*)
2.	Calculate $\boldsymbol{time}$ for $\boldsymbol{plan}$	
3.	Define a set of neighbourhood structures $\boldsymbol{N_s}$	$N_s = \{N_0, \ldots\ldots, N_n\}\ where\ n = 4$
4.	$\boldsymbol{i} \leftarrow \boldsymbol{0}$	Set the termination condition
5.	**While** $\boldsymbol{i} \leq \boldsymbol{n-1}$ **do**	
6.	$\boldsymbol{copyPlan} \leftarrow \boldsymbol{Plan}$	Preserve the original plan
7.	$\boldsymbol{rand} \leftarrow$ **RND**()	$rand\ (0,4)$
8.	$\boldsymbol{op} \leftarrow$ **SELECT**($\boldsymbol{rand}$)	Select structure $op \in N_s$
9.	Apply the selected structure $\boldsymbol{op}$ and generate $\boldsymbol{plan'}$	Create next $plan$
10.	Calculate $\boldsymbol{time'}$ for $\boldsymbol{plan'}$	
11.	**if** $\boldsymbol{time'} < \boldsymbol{time}$ **then**	
12.	$\boldsymbol{plan} \leftarrow \boldsymbol{plan'}$	
13.	Remove $\boldsymbol{copyPlan}$	
14.	**else**	
15.	$\boldsymbol{Plan} \leftarrow \boldsymbol{copyPlan}$	Retrieve the original plan
16.	$\boldsymbol{i}$++	
17.	**end if**	
18.	**end while**	
19.	Issue the final $\boldsymbol{plan}$	

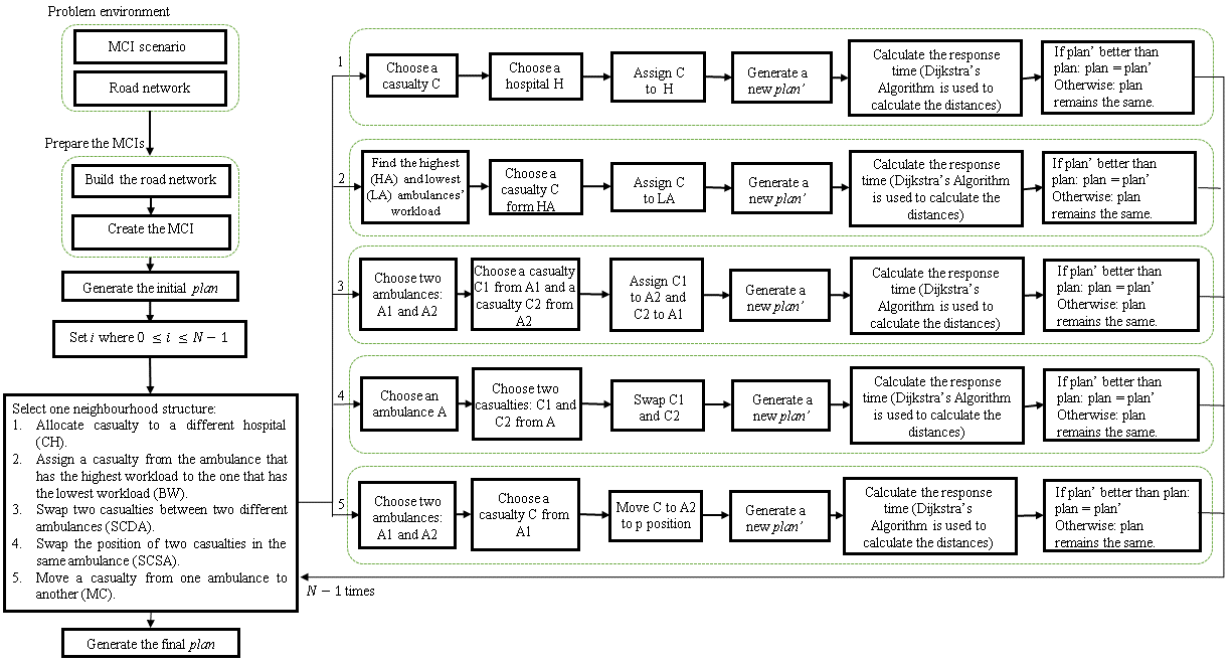

Figure 2. Details of The MCIER approach

Figure 3. An example of the tasks allocated to a single ambulance

Validation

For validation purposes in terms of determining the best response plan, for a simple MCI problem, both an exact method, i.e. a Greedy Algorithm (GA), and the NSA were used. The simple MCI problem considered consisted of 12 ambulances initially distributed between 3 ambulance stations, 35 casualties distributed between 2 incident sites, with each casualty needing to be transported to one of 3 hospitals; please see Figure 4. The distances between locations are indicated in Table 2. The response time obtained by both the GA and NSA were the same, i.e. one hour and 32 minutes.

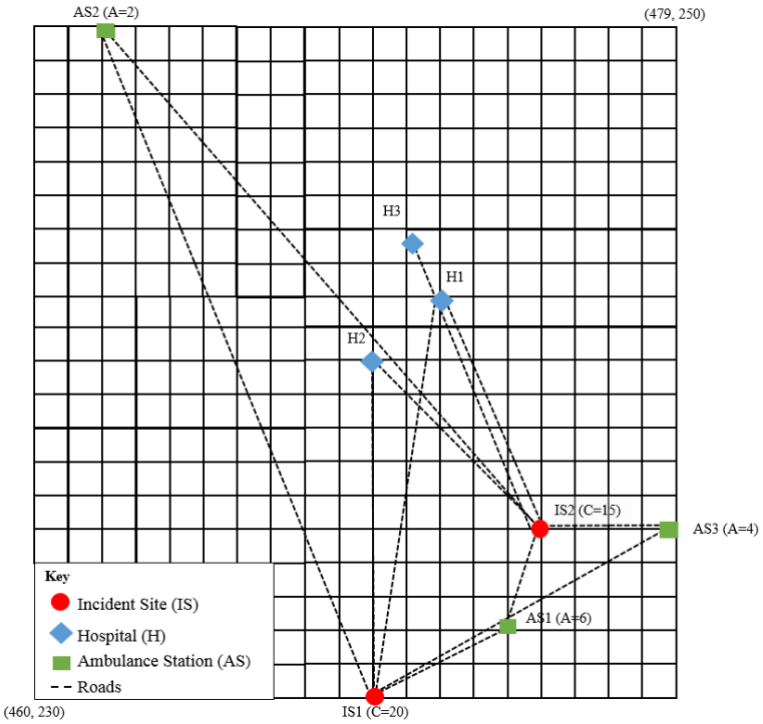

Figure 4. A Grid representation of a simple MCI problem

In this research, a NSA has been designed and used since the co-ordination problem will be further developed to include multiple dimensions such that an exact method will not be applicable (Hu et al., 2005). In addition, it is acknowledged that the execution of an exact method may be time-consuming whereas the NSA developed will not, which is critical in emergency response situations.

Another validation has been carried out for the road network using a route planner and Dijkstra's algorithm to ensure that the calculated distance between two locations is reasonable. A number of vertices have been selected on the map of the area of interest, which will be discussed later in this paper, and the distance between every two locations was calculated and compared. It is noticed that the path that was generated using Dijkstra's algorithm passes through buses and taxis lane which is not allowed in the AA route planner as it is created for normal vehicles. Further, ambulance vehicles are allowed to use some of the roads in an unintended direction if this would reduce the response time. However, this is not allowed for normal vehicles. Therefore, these reasons might cause minor differences in the total distance.

	IS1	**IS2**
AS1	4.47 km	3.16 km
AS2	21.54 km	19.95 km
AS3	10.30 km	4.0 km
H1	12.17 km	7.62 km
H2	10 km	7.1 km
H3	14.04 km	9.85 km

Table 1. The distance table for the simple MCI problem

CASE STUDY OF A HYPOTHETICAL MCI

Overview

Two incidents were assumed to occur on Sunday at 16:00 in the city of Newcastle-upon-Tyne in the North-East of England; Newcastle City Centre (NCC) and Byker Metro Station (BMS). These locations have been selected as such locations are densely populated and present major challenges for the emergency services in dealing with

MCIs (The UK Cabinet Office, 2017). Also, as indicated in Table 2, the environment consists of 2 hospitals including the Royal Victoria Infirmary (RVI) and Freeman Hospital (FH); 2 ambulance stations including St John Ambulance Station (SJA) and Sandyford Road Ambulance Station (SRA); 8 ambulance vehicles are located at SJA, and 7 ambulance vehicles are located at SRA. It is assumed that all ambulances are available when the incidents occur. The average speed of the ambulances during the time of the incident occurrences is assumed to be 23 km/h based on the average ambulance vehicle speed data presented in (McCormack & Coates, 2015). Figure 5 shows a representation of the road network of the city of Newcastle-upon-Tyne in which all locations of interest are labelled. The road network shown in Figure 5 consists of 7413 vertices and 9962 edges. The range of edge lengths is from 1.1 meters to 1145.4 meters. Only 9.1% of the edges are longer than 150 meters. The easting and northing of the top right coordinate of the map are (428014, 567866) and the bottom left coordinate are (422109, 563146) respectively. This case study aims to assess the co-ordination of the response to a multiple site MCI such that the response time is minimised, which is the time of delivering the last casualty from NCC and BMS to the RVI or FH. Also, the maximum idle time of all ambulances is minimised. The busy time, which is the duration of carrying out all the allocated tasks of each ambulance, and the idle time of each ambulance are recorded during the simulation.

Ambulance Stations		**No. Ambulance vehicles**	**(Easting, Northing)**
SJA	St John Ambulance Station	8	(422655, 564475)
SRA	Sandyford Road Ambulance Station	7	(425399, 565102)
Hospitals			
RVI	Royal Victoria Infirmary		(424457, 565003)
FH	Freeman Hospital		(426116, 567650)

Table 2. Hospitals and resources available at ambulance stations

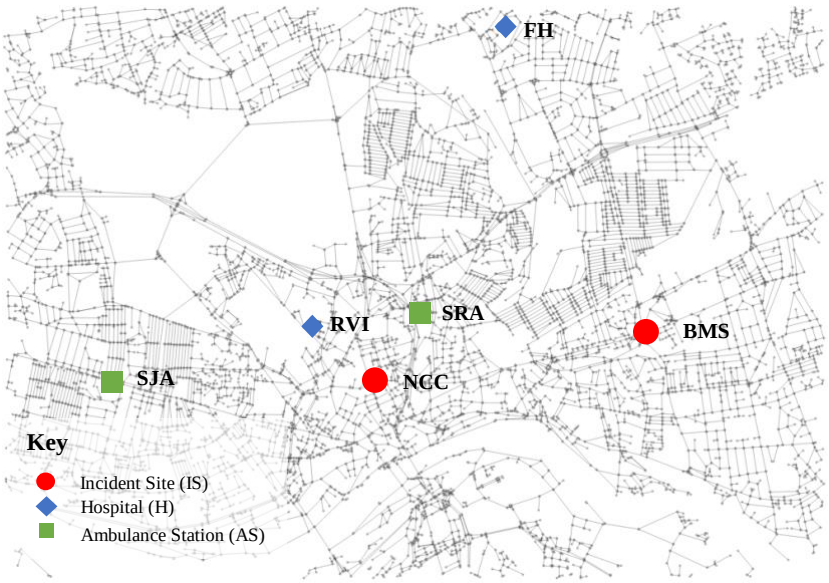

Figure 5. The road network map generated

Definition of scenario 1 and scenario 2

Both scenarios contain 35 casualties distributed between two incident sites (i.e. NCC and BMS) each of which has a different casualty distribution. In scenario 1, there are 25 casualties located at the NCC site and 10 casualties located at the BMS site. In contrast, scenario 2 involves 25 and 10 casualties located at the BMS site and the NCC site respectively. These two scenarios, with varying casualty distribution, were selected in order to find out to which hospitals the casualties will be delivered when the choice of hospital may not be intuitive.

PRELIMINARY RESULTS AND DISCUSSION

The algorithm was applied a hundred times, each time with 5000 iterations. The case study with two scenarios have been assumed each of which has a different casualty distribution; see Table 3 and Table 4. For both scenarios, the best four unique plans were selected and discussed. The NSA structures were evaluated in order to find their effectiveness on the response plan.

The response plans of the MCI scenario

Result for scenario 1

Table 3 presents the best four plans ($P1 - P4$) that all of which are unique and their corresponding response time. In all plans, the casualties located at the NCC site are all 25 transferred to the nearest hospital i.e. the RVI.

Plans	NCC (25)		BMS (10)		Response time (mins)	Total of casualties	
	RVI	FH	RVI	FH		RVI	FH
P1	25	0	5	5	47.5	30	5
P2	25	0	6	4	47.5	31	4
P3	25	0	7	3	47.5	32	3
P4	25	0	8	2	47.5	33	2

Table 3. A number of possible response plans ($P1 - P4$)

Result for scenario 2

The best four plans ($P5 - P8$), along with their corresponding response time, were recorded. Table 4 presents these four plans all of which are unique. In all plans, most casualties located at both incidents are transferred to the closest hospital, i.e. the RVI, where only a few of the casualties at both incident sites are transferred to the FH.

	NCC (10)		BMS (25)		Response time (mins)	Total of casualties	
	RVI	FH	RVI	FH		RVI	FH
P5	10	0	22	3	70.6	32	3
P6	9	1	21	4	70.6	30	5
P7	9	1	18	7	70.6	27	8
P8	8	2	18	7	70.6	26	9

Table 4. A number of possible response plans ($P5 - P8$)

In contrast to all four plans (P1 to P4) for scenario 1 in which all 25 casualties located at the NCC incident site were transferred to the RVI hospital, plans 6 to 8 in scenario 2 indicate that most casualties should be transferred from the NCC incident site to the RVI and one or two to the FH. Specifically, plans 6 and 7 have 9 casualties assigned to the RVI and 1 to the FH, whereas plan P8 has 8 casualties assigned to the RVI and 2 to the FH. In scenario 2, the reason why all casualties are not taken to the nearest hospital (RVI) is that doing so does not reduce the overall response time, i.e. the time to deliver the last casualty to hospital. That is, the ambulances to which these casualties are assigned do not lie on the critical path in terms of the overall response time.

The evaluation of the NSA structures

The NSA structures were evaluated to find the effectiveness of all structures in combination on the response time of the four plans generated for scenario 1 ($P1 - P4$) referred to in Table 6. It is noticed that the BW structure has a major effect on the response time as it made a number of improvements in all plans. It is noted that the SCDA, SCSA and MC structures will not change the overall response if (i) all casualties are the same and (ii) the casualties selected to be swapped are located at the same incident site and are assigned to the same hospital. However, since the casualties selected to be swapped may be located at different incident sites or allocated to different hospitals, then the overall response time will be affected (i.e. increased or decreased). For example, consider applying SCDA for two particular ambulances. A swap may decrease the overall response time if the next casualty allocated to an ambulance is located at the nearest of the multiple incident sites to the hospital at which it has just delivered a

casualty. Conversely, this swap may increase the overall response time if the next casualty allocated to the ambulance is located at the furthest of the multiple incident sites to the hospital at which it has just delivered a casualty. Indeed, the same argument applies to the casualty allocated to an ambulance immediately prior to a swap being applied.

Plans	CH	BW	SCDA	SCSA	MC	Total no. of improvements	No. of iterations to reach the best plan
P1	3	25	1	0	1	30	1519
P2	0	38	1	1	2	42	1472
P3	**3**	**28**	**3**	**0**	**2**	**36**	**1372**
P4	0	25	2	2	5	34	1589

Table 5. The effectiveness of the NSA structures on the response time of plans ($P1 - P4$)

Further, the number of iteration of reaching the best response time for these plans is considered in the last column in Table 5. It is noticed that the best response time has been reached faster in plan P3 which is in the iteration 1372. In order to find the optimum plan between the proposed plans ($P1 - P4$) in terms of idleness, the maximum idle time is recorded for all plans. Table 6 shows that the best plan of the four is P4 where the response to the MCIs is completed with the lowest idle time. Figure 6 illustrates the response plan of P4 including the delays in between tasks.

Plans	Idle Time (mins)	%
P1	8.00	16.8
P2	8.00	16.8
P3	8.00	16.8
P4	**6.00**	**12.6**

Table 6. The maximum idle time of plans ($P1 - P4$)

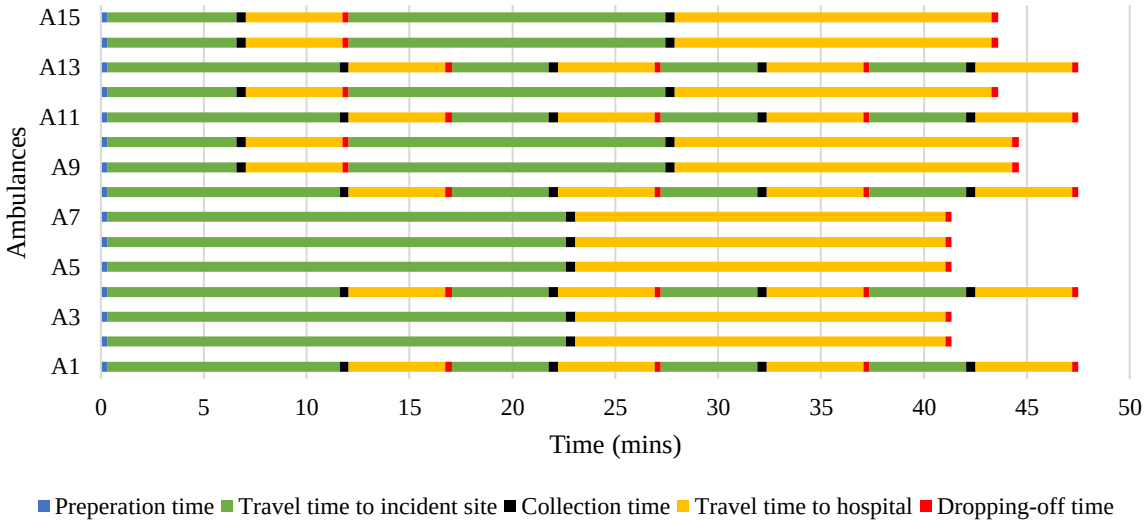

Figure 6. A Gantt chart of the response plan of scenario 1- $P4$

The effectiveness of the day and time on the response plan

The impact of the time of day and day of week on the response time has been investigated in scenario 1-$P4$. Different level of a traffic congestion have been considered based on the road traffic in a certain time of day. There are modelled by changing the speed of the ambulances where ambulance speed data is derived from the work presented in (McCormack & Coates, 2015). Figure 7 shows the differences in the response time when considering the same MCI scenario 1 but vary ambulance speed depending on different days and times. From

Monday to Friday between 5:00 and 16:00 the response times increase and fluctuate over the day based on the traffic congestion. However, on the weekend, the response times increase from 7:00 to 14:00 on Saturday and from 7:00 to 12:00 on Sunday. The response time reaches its minimum on most days at 5:00. The variation in the response time during the time of day and the day of week leads to the necessity of considering these variations when simulating the response to MCIs.

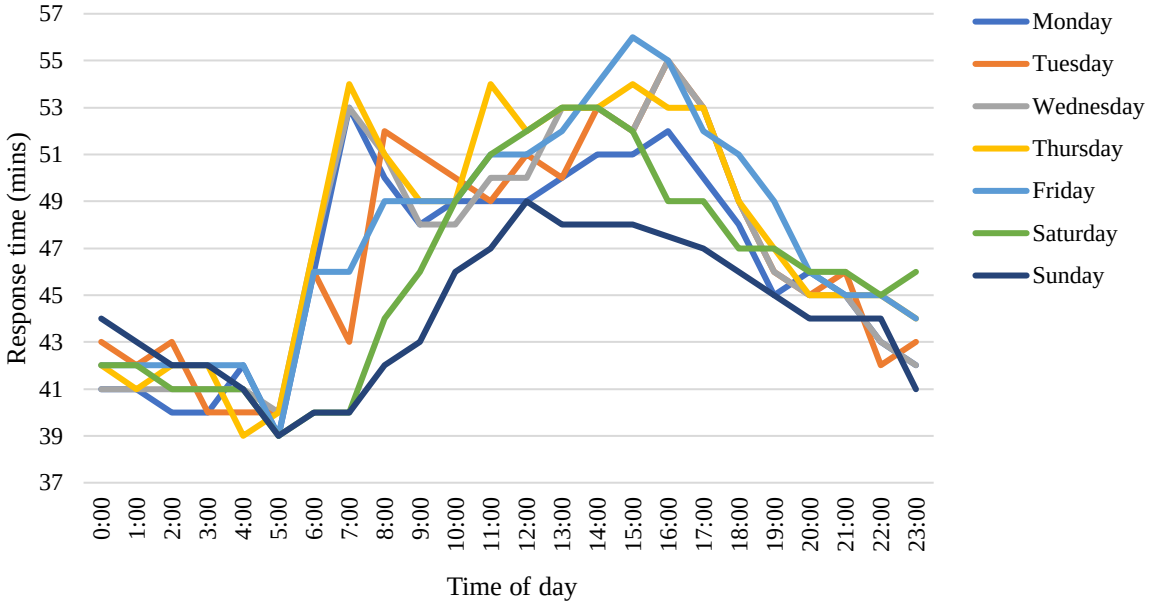

Figure 7. The response times of scenario 1- *P*4 considering ambulance speed on different days and times

CONCLUSION AND FUTURE WORK

MCIs can result in different numbers and conditions of casualties, numbers of fatalities, and thus the medical needs and the response plans required can be different. The shortage of resources, i.e. ambulances, could affect the response operation. Thus, decisions should be taken in a coordinated manner. Co-ordination involves resource allocation (i.e. deciding which ambulance should be assigned to which incident), task allocation (i.e. which casualty is assigned to which ambulance and which hospital should a casualty be assigned to); all of these are crucial in order to distribute the resource among the casualties and avoid tasks overlapping.

In this paper, a NSA has been developed and used to produce the best possible plan for the proposed case study. The case study involved multi-incidents and was proposed to occur in Newcastle-upon-Tyne on a specific day and time, i.e. Sunday at 16:00. A number of experiments were carried out with varying casualty distributions between incidents. The objectives of the MCIER have been set to minimising the overall response time and, then, minimising the maximum idle time of all ambulances. An investigation has been made to find how the time of day and day of week affect the response time. The results show the necessity of considering the time and day of the incident occurrence when developing any MCI decision support system. There is more work to be done in the area of MCIs regarding modifying the current approach to be dynamic in nature. This will involve receiving and updating real-time information from the environment to improve the current response. Further, consideration must be given to the occurrence of new incidents during the operation as several MCIs could occur while the response to other incidents is ongoing. Finally, the capacity and treatment specialism of receiving hospitals, and the capacity of ambulances along with the dynamic nature of casualties' health state will be considered.

ABSTRACT

Improving disaster operations requires understanding and managing risk. This paper proposes a new data-driven approach for measuring the risk associated with a natural hazard, in support of developing more effective approaches for managing disaster operations. The paper focuses, in particular, on the issue of defining the inherent severity of a hazard event, independent of its impacts on human society, and concentrates on hurricanes as a specific type of natural hazard. After proposing a preliminary severity measure in the context of a hurricane, the paper discusses the issues associated with collecting empirical data to support its implementation. The approach is then illustrated by comparing the relative risk associated with two different locations in the state of North Carolina subject to the impacts of Hurricane Florence in 2018.

Keywords

Risk, Severity, Natural hazard, Analytic methods

INTRODUCTION

Disasters are catastrophic events that often cause many causalities and require the mobilization of significant numbers of resources to protect against their impacts (de Boer, 1990). Due to the increasing population of the world, and the increasing vulnerability of that population, these impacts are growing and require urgent attention. Rodriguez et al. (2011) argue that the political, economic and social considerations of global society force organizations to find more efficient ways of managing these destructive events. Assessing the characteristics of the events, and their possible destructive effects, is particularly important in the context of humanitarian relief operations, since they can have a significant impact on the ability to provide relief to those who need it in the wake of a disaster.

Resource allocation is a challenging problem in disaster management. Organizations spend their time and effort to find efficient ways of pre-positioning and distributing resources in order to provide better service to affected communities. Access to timely and appropriate information can play an important role in clarifying the situation and making appropriate decisions. Organizations should thus be aware of potential data sources to support such decision making. With this in mind, this study discusses a data-driven approach for quantifying disaster risk in terms of community characteristics and the inherent severity of a hazard event. We have a motivation of assessing the county-based risk of the hazard event to help organizations with their decision making, especially in efficient asset placement, in disaster management.

BACKGROUND

The social science literature includes many studies on measuring relative risk based on the likelihood of a hazard and the characteristics of the impacted community (Aerts et al., 2013, Willis et al., 2006). Arnette and Zobel (2019) adopt such an approach for quantifying risk as part of their model to optimize the placement of assets to support opening disaster shelters. Specifically, they use a common measure of risk that is a function of the probability of the occurrence of a hazard, H, the extent to which the population is exposed to that hazard, E, and the social vulnerability of the population (independent of any particular hazard), V:

$$R = H * E * V \quad (1)$$

By then letting H_{ij} represent the likelihood that a hazard of type j will occur in location i, where E_{ij} represents the corresponding level of exposure of the population in that location and V_i represents the corresponding vulnerability, Arnette and Zobel (2019) are able to calculate the total combined risk associated with multiple potential hazards in location i as follows:

$$R_i = (\sum_{j=1}^{n}(H_{ij}E_{ij}))V_i \quad (2)$$

What is missing from this measure, however, is an explicit representation of the *severity* of these potential hazard events, independent of their impacts on the given location. This is important, since one would expect a more severe event to have a larger destructive impact on a given location than would a less severe event. This implies that if one were able to capture the relative severity of the hazard itself, then the varying levels of risk that a location is subject to under different circumstances could be characterized more effectively. This current study is a first step towards being able to explicitly incorporate a measure of exogenous severity into such an analysis.

Although the severity of hazard events is widely studied in the literature, the treatment of the concept varies depending on the type of study and its objectives. For example, Rodriguez et al. (2011) propose a decision support methodology to assist NGOs with the assessment of the consequences of disasters and provide a comparative analysis of different statistical learning techniques. The authors use a scenario-based approach to assess the severity of disaster in terms of its impacts by considering such factors as casualties, injured and homeless people, infrastructure damage, etc. De Boer (1990), in turn, combines the causes and the effects of a disaster to create a Disaster Severity Scale which includes a variety of attributes such as the effect on the surrounding community, the cause, the duration of that cause, the radius of the disaster area, and the time required by rescue teams for initial treatment. Alternatively, the study of de Boer et al. (1989) defines a Medical Severity Index of Disaster to support decision making in medical care supply chain operations in disaster situations. This index quantifies the severity of the incident by considering the level of injury and the requirement for treatment, along with other factors like disaster type, population, and location. Zhang and Huang (2018) also assign a severity value to all types of disasters, based on the number of deaths that occur, noting that droughts, extreme temperatures and earthquakes have the highest severity values and storms have lower severity but higher uncertainty.

The common thread among each of these research efforts is the assessment of severity by using measures that reflect the actual impacts on a population of a disaster event that is caused by a natural hazard. In contrast to this, our effort instead considers the inherent severity of the hazard itself, rather than that of the disaster, which should be measurable even in the absence of human impact. This is important because if one ultimately wishes to compare different communities' ability to resist the effects of a disaster, then it can be important to know the actual severity of the hazard itself, independent of its complex interaction with the communities. This would allow for more effectively comparing the relative contributions of different characteristics of the communities and their populations towards their ability to resist against and recover from a disaster.

MEASURING SEVERITY

In particular, our focus in this paper is on developing the capability to characterize the exogenous severity of a particular type of hazard event, a hurricane, in specific locations. Although the well-known Saffir-Simpson scale is frequently used to characterize the severity of an entire hurricane, based on the storm's maximum wind speed (NHC, 2018), different locations that are impacted by that same hurricane may experience very different conditions and thus not be subject to the same level of severity. Chouinard et al. (1997) discuss this general tendency to describe the severity of a hurricane as a function of the wind speed only, despite the presence of other potential measures of severity such as pressure deficit and maximum significant wave height. Aerts et al. (2013) also argue that not just high winds but also heavy rainfall and flooding due to storm surge are the main source of the destructive impacts of hurricanes. In addition, Schembri (2018) explicitly states that the main issue with Hurricane Florence, in particular, was rainfall rather than wind speed. Given these assessments, and the motivation for developing a localized measure of severity that can be related to risk in a specific location, as in equation (2) above, we focus on localized measurements such as rainfall, wind speed, wind direction, and flood warnings as potential indicators of hurricane severity.

This use of multiple indicators to represent the different aspects of the severity of a hurricane can easily be extended to the severity of other types of natural hazard such as that of an earthquake, which can be expressed in terms of magnitude, intensity, energy and acceleration (Gutenberg and Richter, 1942). In the long run, our hope is to define a generalizable approach for characterizing the core elements of severity that can be applied across different types of hazard. In this initial study, however, our focus is on hurricanes and on measuring their particular severity.

As a simple approach for measuring the localized severity, S, of a hurricane, we initially use a convex combination of a set of multiple indicator variables, *s*, each of which is normalized to maintain a consistent contribution:

$$S_i = \sum_{k=1}^{m} w_{ik} s_{ik} \quad (3)$$

In this case, *i* represents the specific location for which the hurricane's severity is being measured, *m* represents the total number of indicator variables chosen to be included in the measure, and *w* represents the weighted contribution of each indicator variable, as specified by the decision maker. Including weights in (3) allows for a decision maker to assign a greater relative importance to one or more of the indicator variables, and thus to prioritize the effects of wind over the effects of flooding, for example, under certain circumstances. Absent the motivation to make such a prioritization, however, we would expect each indicator variable to be weighted the same. Creating a single aggregated value for severity allows us to incorporate this severity measure into the measure of risk given in equation (2). In general, however, the set of indicators could be combined in some other way, or even conceptualized as a vector of different severity dimensions. In the context of this initial research effort, the straightforward formulation given in (3) simply allows us to establish how such a localized measure can be used to represent the complexity of the varying degrees of severity associated with a particular natural hazard.

EMPIRICAL DATA COLLECTION

We first explore the ability of a severity measure to characterize the local behavior of a hazard by applying our formulation of this measure to the analysis of a specific instance of a hurricane: Hurricane Florence, which struck the southeastern United States in September 2018. Florence was classified as a tropical storm on September 7th before strengthening to a major hurricane by September 10th and then weakening again to a Category 1 storm by the 13th of September. It made landfall near Wrightsville Beach, North Carolina on Friday, September 14th and then weakened further over the next few days as it moved inland and then northward. The following discussion details the process of collecting the empirical data upon which the analysis is based.

Weather data collection – We focused our data collection efforts for Hurricane Florence on the state of North Carolina. Historical weather data for each county in the state was retrieved from the National Oceanic and Atmospheric Administration (NOAA), using the *countyweather* package in R and including all data from September 7th to September 21st, 2018. The *countyweather* package, which requires an API key from NOAA, pulls all available weather data (both daily and hourly) from multiple weather stations. The core variables that it retrieves are temperature, wind speed, wind direction, and precipitation. Because the weather data is sparse for many counties during the specified date range, however, we ended up using only the daily average wind speed (in m/s) and the average precipitation (in mm).

In order to perform our preliminary analysis, we selected four specific counties with nearly complete data for the two variables of interest: these consisted of two adjacent counties from the coastal region (Carteret and Onslow) and two additional adjacent counties from the mountains (Buncombe and Henderson). Any missing data points in these counties were either estimated from hourly data, when available, or interpolated from the corresponding daily data (from the current day and the day before) in the adjacent county.

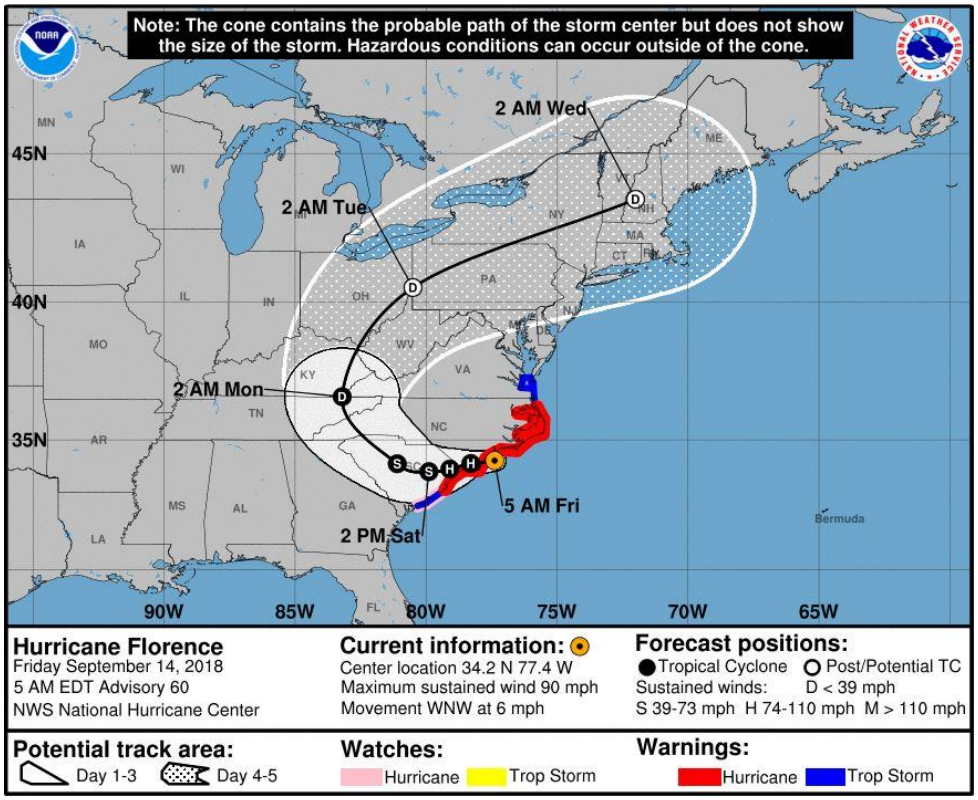

Figure 2. The National Hurricane Center map showing the forecast track of Hurricane Florence.
Source: https://www.nhc.noaa.gov/archive/2018/FLORENCE_graphics.php?product=5day_cone_with_line

The motivation for selecting two different county groups was to allow for comparing the difference in severity between the counties that were first struck by Hurricane Florence and the counties over which it passed as it exited the state several days later. Figure 1 highlights the locations of the selected counties in red, and Figure 2 shows the path of the hurricane beginning with landfall and continuing until it finally exits the western part of the state 2-3 days later.

Vulnerability data collection – The Social Vulnerability Index (SoVI), which is a composite measure made up of more than 30 variables that capture important socioeconomic and built environment characteristics, is frequently used to quantify the social vulnerability of U.S. counties to hazards, based on their socioeconomic and demographic features (Cutter et al., 2003). In order to further incorporate the severity measure into the calculation of risk, this study used the most recent SoVI data set, which is based on 2010-2014 Census data.

Exposure data collection – For the exposure calculation within the risk function, we used the estimated base county population data for 2018 and multiplied it by a sheltering needs factor to estimate the proportion of the population needing assistance. Given that Mileti et al. (1992) suggest that such a sheltering needs factor can vary from a minimum of 0.05 to a maximum of 0.20, we set the factor at 0.20 for the coastal counties and at 0.05 for the counties in the western mountains, in order to reflect the inherent differences in the population's hurricane response between these two regions. To perform a more detailed analysis of actual sheltering behavior, rather than to simply illustrate the underlying modeling approach, both a displacement factor and a more accurate measure of sheltering need should be provided, as in Arnette and Zobel's (2019) work in Colorado and Wyoming. Unfortunately, such data is not yet readily available for the state of North Carolina at this time.

Table 1. County-level data

County	SoVI	Population
Onslow	-3.67	177,772
Carteret	1.03	66,469
Henderson	1.7	106,740
Buncombe	0.45	238,318

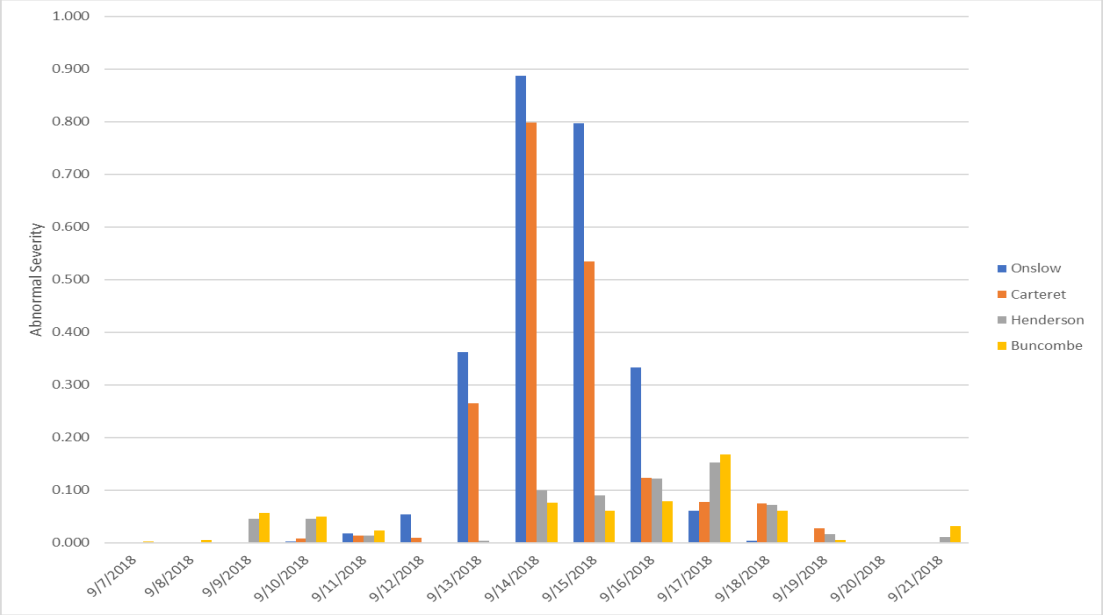

Figure 3. Abnormal severity related to Hurricane Florence

PRELIMINARY RESULTS

In order to generate a measure of the severity of the storm for each county during the specified time period, we calculated the average (normalized) wind speed and the average (normalized) precipitation over the five years previous to Hurricane Florence and created a weighted average of the two sub-measures, as in equation (3), using equal weights. This historical weighted average was used as a baseline against which the corresponding (normalized) values from September 2018 were compared. The amount by which the 2018 values exceeded the historical baseline was then taken as the actual measure of severity, with any values that fell at or below the historical weighted average being set to zero. Figure 3 presents the results.

It can clearly be seen in Figure 3 that September 14th is the day on which the hurricane reached its greatest severity along the coast, with slightly more severe weather being experienced in Onslow County. The severity in Carteret County, which is further north, drops off more quickly than that in Onslow County as the hurricane moves west and south. It can also be seen that the much reduced severity in Henderson and Buncombe counties grows in a similar way, but to a lesser extent and with a time lag of several days, as the depleted storm moves over that region. This behavior echoes expectations, given the forecast track of the hurricane as presented in Figure 2.

We then took the individual county-level severity values and incorporated them into an adjusted risk measure based on equation (2). Because we are considering only a single hazard event, and are characterizing the actual behavior of that event as it occurs, we assume a hazard probability of 1.0 and introduce the severity measure as the contribution of the hurricane to the local risk in each county:

$$R_i = S_i E_i V_i \tag{4}$$

The risk given by equation (4) thus reflects the relative extent to which each county was actually affected by the hurricane. Figure 4 subsequently illustrates the results of graphing the risk progression over the duration of the storm.

Because all three independent variables in equation (4) are normalized to the same [0, 1] scale, even a cursory comparison of Figures 3 and 4 clearly shows the significant influence of the severity measure on the measured risk value. The vulnerability also plays a significant role, however, as can be seen in the relative differences between the two coastal counties as well as those between the two mountain counties. Onslow County was subject to more severe conditions, yet its much lower population vulnerability leads to less overall risk during the height of the storm than Carteret County, despite its larger population. Similarly, despite its significantly lower vulnerability, Buncombe County's much larger population gives it a higher level of risk relative to that of Henderson County. In each case, it is obvious that the risk grows as the storm approaches and hits, and then drops as it moves away.

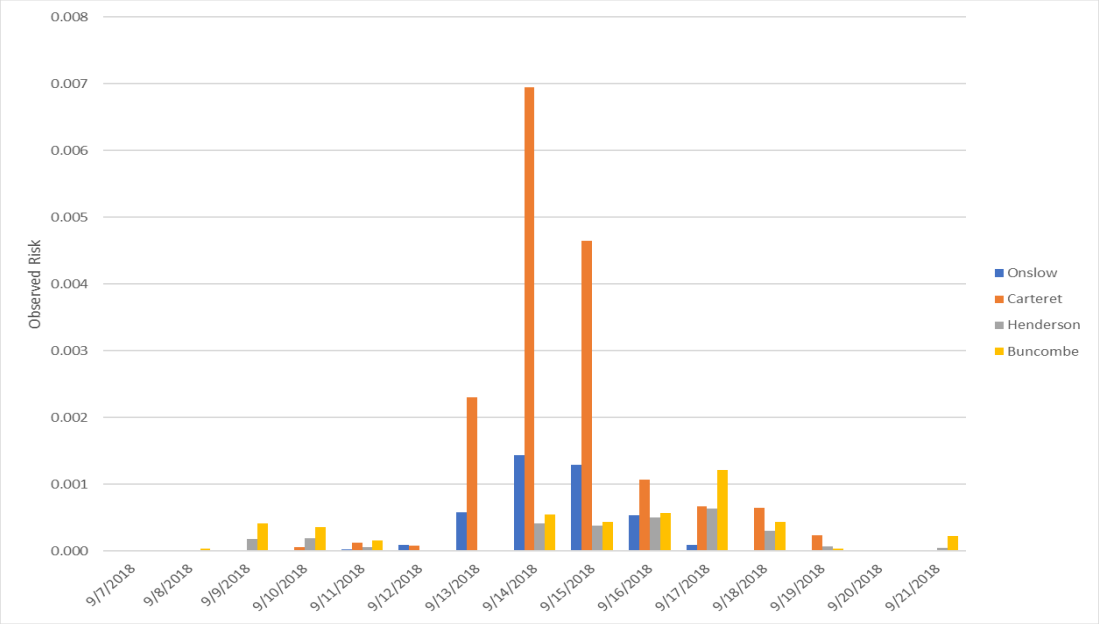

Figure 4. Observed risk related to Hurricane Florence

CONCLUSIONS

The purpose of this study is to provide a preliminary definition and illustration of a measure of the inherent severity of a natural hazard that can be incorporated into a localized measure of risk. Although a hazard can have a destructive impact on a given county, however, the inherent severity of that hazard is not the only factor affecting the risk to which that county's population is exposed. Indeed, the same level of severity may lead to different consequences in two different counties due to the relative vulnerability of the populations and the number of people who are actually exposed to the hazard event in a meaningful way.

It is important to recognize that this particular analysis was conducted in the context of a historical hazard event, and that the components of the severity measure were therefore given reasonably precise values. In order to calculate the risk for an upcoming event, not only would appropriate forecasts need to be available for the components' values, but also some notion of the probability of the event would need to be reintroduced into the discussion, since it may not affect a given community at all. This implies that the severity measure may also be effective in the context of slow-onset disasters, or at least disasters with less uncertainty, because it would be easier to make more accurate forecasts of future behavior. It also implies that scenario-based analyses on the severity of hazard events could give realistic insights about the possible outcomes of the hazard events that have possibility of occurrence in the future.

The focus of this paper was on a single natural hazard, and on the behavior of that particular hazard as it actually impacted several counties in North Carolina. This allowed us to assume a probability of occurrence of 1.0, and to effectively replace the hazard likelihood in equations (1) and (2) with the severity of the event. In general, however, if we wished to instead assess the future (forecast) severity and risk, we would need to also include the probability that the particular event would occur. This, in turn, would allow for considering the probability that different types of hazards might occur, and it would extend the applicability of the approach beyond just the set of indicator variables representing a single type of event.

Easily accessible weather data makes the severity calculation quick and easy to update, and the relative simplicity of both the severity (as defined above) and the risk function should make it very straightforward to extend the approach and adapt it to a variety of different problems. As a related future research direction, we are planning to include other accessible information, such as flood/storm warnings, into our severity measurement, and to consider other functional forms for the severity that may more effectively capture the relative contributions of its different characteristics in this context.

ABSTRACT

After large-scale disasters, diverse partner agencies rely heavily on an information-sharing environment that supports collaborative work. In the U.S., this occurs under the Incident Command System (ICS), a structured organizational framework for coordinated action. We explore obstacles to information sharing and coordination observed at a county-level Emergency Operations Center (EOC) operating under ICS during the response phase of a large-scale regional disaster exercise. Textual observations collected in situ are analyzed for both the effect/manifestation and cause/source of barriers to information sharing. Two-thirds of barriers that manifest as computational issues are not caused by technology breakdowns, and a third caused by unclear processes manifest as computational issues. Overall, obstacles to collaborative work that appear to be related to computational issues are generally attributable to non-technical causes. This indicates that resources directed at improving collaborative management of disasters by enhancing technological capabilities are likely to be misdirected.

Keywords

Information Sharing; Disaster Response; Qualitative Analysis; Collaboration; Coordination

INTRODUCTION

Collaborative action during and after large-scale disasters is characterized by complexity, uncertainty, and the need for information. To achieve effective collaboration, independent yet partner agencies and organizations, each with their own jurisdictions, practices, policies, technologies, missions, and cultures, need to coordinate and share information. These independent and diverse partner agencies rely heavily on an information-sharing environment that supports collaborative work. In the U.S., this occurs under the Incident Command System (ICS), developed after 9/11 as a structured organizational framework for coordinated action. Although management of a disaster has numerous facets, a critical component is the capability of diverse federal, state, local, tribal, territorial, international, and private sector (FSLTTIP) entities to share information for activities such as damage assessment and response, asset requesting and tracking, and situational awareness. It is this information-sharing component, and the interoperability of the systems to support these activities, that is the focus of this paper.

In June 2016, Cascadia Rising, the largest regional disaster response exercise ever conducted in the Pacific

Northwest took place. This multi-state, international response to a massive earthquake and tsunami scenario provided the opportunity to observe the information sharing and interoperability among multiple partners during a complex, dynamic, non-routine event. Students were trained to conduct fieldwork study observations of emergency operations and coordination centers (EOCs/ECCs) as they activated to conduct and coordinate simulated field response operations both within their jurisdictions and with neighboring communities, state EOCs, Federal Emergency Management Agency (FEMA), and major military commands. Field study observations were conducted at state and county locations, providing an opportunity for analysis of information sharing and interoperability issues. Here we focus on a county EOC engaged in disaster response.

Prior work on information sharing during disaster response has tended to focus on the technological challenges, highlighting the technical issues that enable or inhibit information sharing, and viewing additional technology as the solution (Allen et al., 2014; Maitland et al., 2009; Reddy et al., 2009). Some researchers have investigated disaster response from an organizational perspective (Bharosa et al., 2010; Lee et al., 2011); however, there is still a preference for the development of information technologies to support the collaborative processes (Allen et al., 2014) rather than addressing the coordination of emergent groups during non-routine events characterized by complexity and uncertainty.

Based on previous studies (Haselkorn et al., 2014, 2015, 2016), we hypothesized that during the large-scale disaster exercise we would observe considerable informal information sharing as well as obstacles to information sharing that were not caused by technology, although they might manifest themselves that way. We posited that the uncertainty and complexity that characterizes non-routine events, even operating under ICS, would produce many obstacles to information sharing associated with human, organizational, and process issues. In this paper we unpack the symptoms that we observed and identify the etiology of the issues, thus allowing us to make suggestions to improve coordination and information sharing during the response phase of a disaster.

This paper is organized as follows: first, we briefly describe ICS and the exercise upon which this qualitative analysis is based; second, we review the relevant literature relating to information sharing and interoperability challenges unique to disaster events; third, we review our methods, including the development of a framework and management tool that supported qualitative analysis of information sharing during disaster response; fourth, we describe and discuss our results; and finally, we discuss the implications of our results and present additional research opportunities. Our analysis shows that the majority of barriers that manifest themselves as computational issues are, in fact, often due to a different underlying cause. This has implications for stakeholders, decision-makers, and practitioners working in disaster response roles, providing insight into more effective allocation of funds/resources to solve the relevant underlying issues, rather than those that may not be as problematic as previously assumed.

BACKGROUND

Disaster Response

A key element of disaster response in the U.S. post 9/11 is the ICS, a structured management framework for meeting the demands of small or large emergency situations (Department of Homeland Security 2008: 45-46). The ICS and its overarching plan, the National Incident Management System (NIMS), are mandated for use by all agencies that receive federal preparedness grants in the management of domestic incidents—which effectively means that the ICS will be activated in all emergencies (Dawes et al., 2004).

In the event of an emergency in the state of Washington, the ICS is implemented through EOCs—physical locations staffed by personnel who are structured according to the ICS. When incidents occur, they are typically managed at the lowest possible geographical, organizational, and jurisdictional levels—jurisdictions, working in collaboration with county and other local emergency management agencies, provide the initial response to the local incident. It is expected that local (city, county) departments assess what has happened in their area, including what is needed in terms of resources and action, and report this to the local EOC. In situations where the capacities or resources that are required exceed what the local jurisdictions can provide, the local jurisdiction may request assistance from the State Governor by proclaiming a local state of emergency. Depending on the scale of the disaster, the Governor may follow up with a State Proclamation of Emergency, initiating applying ICS at the state level, leading to the activation of a State EOC (SEOC) in order to respond to impending or existing disasters and emergencies. The proclamation by the Governor is a prerequisite for access to the full range of federal disaster recovery programs available to the state. Once established, the Washington SEOC supports state agency, local jurisdiction, and tribal nation operations in response to an emergency or disaster. The primary roles of the (S)EOC are to communicate, coordinate, dispatch, and track resources, and to collect, analyze, and disseminate information. At all levels, the ICS structure is designed to offer scalable components that function at a level consistent with the complexity of an event (Washington State 2008).

CASCADIA RISING: REGIONAL DISASTER EXERCISE

The four-day-long Cascadia Rising Disaster Exercise of June 2016 simulated the challenges and issues that would be faced in the event of a regional catastrophic earthquake. The scenario for the exercise was the most complex disaster scenario that emergency management and public safety officials in the Pacific Northwest could face—a Magnitude 9.0 subduction zone earthquake along the Cascadia Subduction Zone, followed just minutes later by a 100-foot tsunami:

> *"In the early morning hours (PDT) on June 7, 2016, a 9.0 magnitude earthquake resulting in the complete rupture of the 700-mile Cascadia Subduction Zone fault line occurs. The duration of the earthquake lasts over four minutes. The affected area encompasses 140,000 square miles directly impacting the states of Oregon and Washington and the Canadian province of British Columbia. Over 10 million people reside in the direct impact zone. The disaster causes widespread damage to critical infrastructures and the built environment and causes thousands of deaths and injuries."* (FEMA 2010)

Cascadia Rising was a multi-state effort involving agencies across the FSLTTIP. In Washington state, the main exercise was led by the Washington State Emergency Management Division. Exercise participants entered into an ICS structure to simulate the disaster response phase and engage in numerous post-disaster missions, many involving complex information-sharing scenarios, such as the introduction of assets from the federal government, the requesting of those assets by county EOCs through the SEOC, and the tracking of those assets by the SEOC and Washington Army National Guard (WANG). Each EOC was required to fully activate and staff their respective operations to manage disaster response within their jurisdiction while simultaneously coordinating with other EOCs and departments, agencies, and simulated first responders to meet exercise objectives.

A primary goal of Cascadia Rising was to test the effective coordination and integration of government agencies at all levels, working with the military, tribal nations, non-government organizations, and the private sector. Of particular interest were the core capabilities that enable this diverse community to conduct complex disaster operations as a unified team.

At the local and state level, one focus was the handling of resource requests and resource tracking during emergent and complex events. Of particular interest to organizers was the use of two internet-based information management systems intended to support these activities: (1) WebEOC—a mature system implemented with diverse configurations across many, but not all, of the participating agencies, and (2) the Washington Information Sharing Environment (WISE)—a more recent system, developed and used by the WANG to gather and make visible event-related information.

RELATED WORK

Coordination can broadly be defined as the "act of working together harmoniously" (Malone and Crowston 1990), and it is therefore central to work in organizations (Abraham and Reddy 2008). In proposing their coordination theory, Malone and Crowston (1990) described how effective coordination is invisible—it is poor coordination that becomes apparent and that we can observe. Coordination has been studied in various contexts in the literature, for example in hospital settings (Abraham and Reddy 2008), in geographically distributed research and development teams (Hinds and McGrath 2006), and in families (Leshed et al., 2014). Coordination in emergency management deals with specific challenges to information sharing according to the nature of emergency response. Characteristics, complexities, and obstacles in information sharing during emergency response have been extensively studied by Information Systems for Crisis Response and Management (ISCRAM) scholars and examined from various points of view (Barr et al., 2011; Gryszkiewicz and Chen 2010; Hellingrath and Widera 2011; Maitland et al., 2009; Scholl and Carnes 2017; Wikberg et al., 2017). Maitland et al. (2009) considered and compared information management barriers and information technology issues and identified their similarities and differences and requirements for resolving them. Gryszkiewicz and Chen (2010) proposed design requirements for information sharing in crisis management through semi-structured interviews with emergency managers in Sweden. Scholl and Carnes (2017) identified managerial challenges experienced by emergency responders and participants in the 2014 Oso/State Route 530 landslide disaster.

Non-routine events such as large-scale disasters are synonymous with uncertainty, and characterized by their complexity, the need for information, and the speed at which decisions need to be made (Allen et al., 2014). Mendonça et al. (2007) suggest several key characteristics of disaster management: First, the incidents occur relatively rarely, which limits the opportunities for training. Second, time constraints during an event leads to the convergence of planning and execution. Third, there is uncertainty as the evolution of the situation is unpredictable. Fourth, there is a need to manage interdependencies within a wide range of physical and social systems. And fifth, multiple decision-makers, groups, and organizations will need to come together and negotiate while also responding to the event. Such large-scale events necessitate collaboration and coordination among

multiple organizations because integrated information must be available in a timely fashion (Reuter et al., 2015).

At such times, organizations, each with their own distinct mission, culture, and working practices and which work far more independently on a daily basis, are expected and required to collaborate and coordinate, share information, and align under a common command structure. Although a mechanism such as the ICS provides such a structure and is in fact mandated in the U.S., other scholars point to the fallacy of applying a military-style structure in response to an incident, feeling that such an approach overlooks the need for collaboration, cooperation, and transparency by numerous organizations with different cultures and structures (Mendonça et al., 2007).

Empirical studies into coordination and information sharing during disaster response have tended to focus on technological challenges, giving less attention to the organizational aspects or coordination and information-sharing practices and policies. Such studies highlight technical issues that enable or inhibit coordination and information sharing, viewing technology as the solution (Allen et al., 2014; Maitland et al., 2009; Reddy et al., 2009). There has been a recent trend to investigate the organizational and social aspects of disaster response (Bharosa et al., 2010; Ley et al., 2014; Reuter et al., 2015). Nevertheless, the refinement of collaborative and coordination practices that are facilitated by information technologies is often overlooked in favor of the development of new or additional information technologies to support the collaborative processes (Allen et al., 2014).

Through observations of first responder exercises, Manoj and Baker (2007) identified three categories of communication challenges in emergency response: (1) technological—the challenges faced by the rapid deployment of interoperable communication networks after a disaster; (2) sociological—the challenges of obtaining and sharing information among ephemeral groups that are brought together in unfamiliar settings and times of uncertainty; and (3) organizational—challenges that arise due to the changes in management and decision-making frameworks that occur during a disaster. Although Manoj and Baker's work (2007) specifically examined the barriers to communication during disaster response, the technological and organizational categories provide a useful lens through which to look at interoperability and barriers to information sharing during non-routine operations and disaster response.

Technological Approaches

In the aftermath of the September 11, 2001, attacks in New York, the 9/11 Commission emphasized the importance of integrated, all-source information, and pointed out the U.S. failure to "connect the dots." This led to a focus on numerous technological approaches, such as: more and varied sensors to gather data, communication devices and networks to move that data, common operating pictures and visual analytics systems to help make sense of that data, dispatch systems to mobilize based on the situational awareness, and asset request and tracking systems to support the mobilization. The hope was that a single "killer app" incorporating all these capabilities would be used by all the relevant agencies, putting everyone on the same page in support of collaborative effort. (*Virtual USA* was an example of the Department of Homeland Security attempting such an effort.) In recent years, federal stakeholders have accepted that, for reasons that are often not technical in nature, it is unlikely that all relevant agencies and partners will adopt a single application, no matter how effective. This has led to the latest technological challenge—a distributed architecture that focuses on technical interoperability in order to link sensors, share data, and allow each partner agency to use whatever application they desire to make use of that data.

Technological approaches like these have been prevalent in the literature on improving EOC communication. For example, Dawes et al. (2004) focus on critical infrastructure damage after 9/11, and Graves (2002) explores the increased complexity of information technology and the need to integrate these technologies and devise contingencies for them in the face of disasters (Brooks et al., 2013). Similarly, Militello et al. (2007) view collaboration infrastructure to support post-disaster practices from the perspective of keeping technology functional, pointing out that updating shared displays are some of the first tasks to be neglected—particularly if the systems are not used outside of disaster response operations.

Organizational and Process Approaches

During disaster response, the ICS framework alters the day-to-day working practices of government agencies and organizations in the profit and non-profit sectors. It has long been established that "every emergency is local" (Dynes et al., 1972) and the ICS is often initially activated at the lowest geographical, organizational, and jurisdictional level. However, since the majority of the funding for large-scale disasters comes from the federal government, tensions between local and federal participants may inhibit information sharing and require state-level participants to mediate tensions while also dealing with the local aspects of the emergency (Brooks et al.,

2013).

Haselkorn et al. (2014, 2015) and Timmons (2007) found that at the individual level, first responders tend to revert to their normal information-sharing practices during times of crisis rather than modify their practices to align with the crisis response framework (i.e., ICS) (Brooks et al., 2013). This "normal" sharing is often described as "informal" communication—relying on personal contacts and existing trust relationships—as opposed to formal communication coming through the predesignated command structure and mediated by government information systems. In Norway, which adopts an equivalent structure to ICS, Rimstad et al. (2014) studied the information flows during the response to the 2011 terrorist attacks in Oslo and on the island of Utoya. Despite the formal organizational structure imposed by the ICS equivalent, important information was also obtained through personal social networking between responders. Similar informal communications were observed by Bharosa et al. (2010) with personal phone calls among Dutch responders facilitating information flows during a crisis response exercise. Schraagen et al. (2010) examined information sharing during crisis management and compared rapidity and accuracy of information sharing between hierarchical and network team organizations through a control experiment (Altay and Labonte 2014). They concluded that network teams were faster, more accurate, and shared more information in difficult scenarios.

Organizational challenges also arise when the plans laid out in emergency response documents are not sufficient or suitable to deal with a specific situation that may arise post-disaster. For example, through analysis of multiple emergency response exercises, Brooks et al. (2013) found that emergency managers were often repairing disrupted organizational routines by bridging unforeseen gaps in the emergency response plans. Here we can draw parallels with Suchman's *Plans and Situated Actions* (Suchman 1987, 2006) whereby there is a difference between the plans that are made in advance and the actions that are required *in situ* at a particular time—although the plans and processes exist, the situations are dynamic and reliant upon interdependence between heterogeneous organizations. Consequently, it is impossible to plan for all contingencies and a degree of ongoing improvisation is necessary (Reuter et al., 2015). The value of emergency response planning is the thought that goes into it, but plans cannot guide a specific action during a specific event—preparedness is best achieved through practice of the plans and their contingencies (Dawes et al., 2004). Mendonça et al. (2007) view improvisation from the technological perspective, using the term *emergent interoperability* to describe the information technologies that need to be "mixed and matched" to support the accomplishment of disaster response tasks by individuals who are part of various organizations each with their own distinct practices and adhocracies.

This background information and our own work identify many obstacles to information sharing associated with human, technological, organizational, and process issues. The Cascadia Rising exercise provided us with the opportunity to directly observe the obstacles to information sharing. Then, using a qualitative analysis approach, we unpacked the symptoms that we observed and identified the etiology of the issues, allowing us to suggest improvements to coordination and information sharing during disaster response.

METHODS

Data Collection

Supporting Researchers in Multiple Roles

The decision to study a multi-state, multi-actor, multi-location, large-scale exercise brought several opportunities and challenges. Our research design had to: (1) be unobtrusive by allowing our researchers to perform within the exercise as observers and evaluators—pre-defined accepted roles within such exercises; (2) obtain rich text and contextual data that would support post-event analysis useful to a diverse group of faculty and research scientists; and (3) capture work and information sharing across multiple sites. With strong support from the Washington State exercise team,[1] our researchers were included on the exercise evaluation team, attended exercise training sessions, and were embedded at a number of key state and local sites. To prepare for the pre-defined role of observer/evaluator, research team members without prior emergency management experience were required to meet minimum qualifications set by FEMA, illustrating a basic knowledge of emergency management. All observers completed the 100, 200, and 300-level ICS online training, and attended a day-long training at the SEOC. In this way, our team was able to contribute to the state's After-Action Report (AAR), the mechanism for sharing lessons learned across the emergency management community.

[1] Special thanks to Ed Taylor, State Exercise Program Manager, and Jason McMillan, Kitsap County Operations Coordinator.

Fieldnote Jotting Through Slack

We used *Slack*, a communication and messaging tool popular with small and medium sized companies (Benner 2017), for capturing real-time observations and for more general coordination among field observers. Slack "channels," visually distinct conversation threads, were set up prior to the exercise for each location with a team member.

One experienced field researcher trained in ethnographic field work was deployed to Kitsap County. In the course of the exercise where many people were working on computers, she found it was unobtrusive to make fieldnote jottings on her computer as events unfolded (Emerson et al., 1996). It was then easy to paste fieldnote jottings into the Slack channel for her county at brief and regular intervals. This had two unexpected advantages. First, Slack has searchable archiving features built in, making it relatively easy to work with the data repository. Second, researchers at multiple sites—and from multiple disciplines—were able follow data collection in near real time. In several instances this led to tracking and follow-up clarification (i.e., better documentation) as information moved (or not) across exercise sites. Importantly, it also led to data collection of more depth and more diverse topics, as remote researchers with different interests requested follow-up information on events as they occurred.

Qualitative Analysis Approach

The qualitative analysis reported here focused on the Slack-recorded observations from the one trained field researcher at the *Kitsap County EOC*. Prior to coding of these observations all names of emergency response personnel participating in the exercise were anonymized to protect their identities. While Slack is an online tool its security program is aligned with ISO 27000, AICPA Trust Service Principles, and NIST standards. All data in transit and at rest is encrypted and only trained students and faculty were granted access to Slack channels related to the Cascadia Rising Exercise. A research group of graduate and undergraduate students met weekly for two quarters (20 weeks) to learn and then conduct the process of qualitative data analysis using the Kitsap EOC observations. To better understand the observations of the activities at the county EOC, all class participants completed the 100-level ICS online training. A team of four—one undergraduate student, two graduate students, and one university research scientist—was selected to form the coding team. The analysis of the Kitsap field notes began with an initial reading of the observations, as recorded, to familiarize the four analysts with the substance of the data, understand the flow of communication and information sharing activity within the Kitsap County EOC, and begin to identify recurring themes (Strauss and Corbin 2008). The four analysts worked individually and then jointly on close readings of the observations to identify text blocks representing incidents of information sharing or other coordination activities performed by the exercise participants. This allowed the researchers to reduce the data to only those portions of text related to the exercise, which facilitated the coding process described below.

The team began the exploratory, open-coding analysis by iteratively going through data, asking questions, and making comparisons to develop a common understanding of the observations and to identify the emerging themes (Strauss and Corbin 2008). The first theme to develop resulted from asking the question, "what happened?" In other words, "what is the effect or manifestation of the information sharing barrier that was observed?" Merriam-Webster defines an effect as "something that inevitably follows an antecedent (such as a cause or agent). Similarly, asking questions, such as "how" or "why" the effect occurred was used to determine the cause or source of the observed effect. One way to think about the cause-effect relationship between the information sharing breakdowns is to consider the genotype-phenotype relationship (Hollnagel & Marsden, 1996). The effect, like the phenotype, is observable; while the genotype, like the cause, can only be inferred. In this analysis, we first identified the observable barriers of information sharing breakdowns as "effect", then during the iterative, open-coding analysis, we divided the effect theme into seven different categories (see Table 1). When developing the categories for the "cause" theme, we found that while potential causes of information sharing breakdowns are different from the observable (effect) resulting from information sharing breakdowns, we could use the same categories. Accordingly, the cause/source theme used the same codebook, but this time it was used to infer possible causes behind the observed barriers. In some cases, cause and effect were coded similarly which means the observed barrier (effect) was caused from similar category. For example, Observation #11 ("*Planning GIS is trying to create a damage map, but there is a technical issue due to a recent update."*) was coded by computational mechanism issue as effect, while more investigation showed that the source of this observation is computational mechanism issue too. The above process occurred over several weeks, with all team members refining and agreeing upon the codes to be used in the analysis for classifying causes and effects of barriers to information sharing.

Qualitative Analysis Tool

To support the closed coding (using the coding scheme), one of the analysts designed and created programmed Excel spreadsheets, named Code Wizard, to support collaborative qualitative coding (Ganji et al. 2018). Code

Wizard consists of two main spreadsheets: one for individual coding performed by coders individually and independently, and one for aggregating coded data for team discussion meetings. Code Wizard, which was evolved during the study, provided the following benefits: (1) minimized training for coders to perform collaborative coding; (2) allowed the team to easily modify, remove, or add a selected barrier; (3) enabled real-time changes during discussion sessions; (4) provided insights into the reasons behind coders' disagreements to be discussed in weekly discussion meetings; and (5) accelerated the agreement level of coded issues by assigning different colors to the categories, allowing the agreement to be easily visualized (See more details in Ganji et al. 2018). Figure 1 presents a sample of the spreadsheet used by each of the analysts.

	Time/ Date	Unit of Analysis	Link to Source	Categories	
				Cause	Effect
1	10:08 6/7/16	It is not clear if the information is from a citizen or someone else.	go to	Paper Mechanism Issue	Source Breakdown
2	10:08 6/7/16	The agency that the information is coming from is not on the form.	go to	Paper Mechanism Issue	Source Breakdown
3	10:08 6/7/16	I ask about this and the player shows me other written forms that similarly require a lot of guessing because the way they are filled out is vague.	go to	Content Breakdown	Content Breakdown
4	10:20 6/7/16	One of the planning team goes to track down who handed off two confusing paper information forms. Guesses are made based on pen color and handwriting as to who to talk to.	go to	Source Breakdown	Content Breakdown

Figure 1. Qualitative Analysis Tool (individual spreadsheet) Used by Each Analyst to Code the Data

Once all four analysts coded the Slack data, results were merged into one spreadsheet showing the codes assigned by each analyst (see Figure 2). The merged spreadsheet was also designed to calculate Fleiss' kappa (Fleiss et al., 1969) as a statistical index for evaluating the inter-rater reliability coefficient of investigated text data. Using this merged spreadsheet, the coding team met weekly to review and discuss coding choices, allowing analysts to ask questions, make comparisons, and iterate until they achieved an inter-rater reliability of $\kappa = 0.80$[2]. The team conducted coding data in two steps. First, the analysts coded data for the effect theme in three rounds of coding to meet the acceptable inter-rater reliability threshold. Second, two rounds of coding were performed similarly to identify types of causes/sources to achieve our threshold. The themes that emerged from our analysis are detailed below and include excerpts of the observations to illustrate findings.

[2] Although there is no general agreement on a minimum Fleiss' kappa value for a strong consensus, exceeding 0.8 is widely considered as "almost perfect agreement" in the literature [14].

	Time	Unit of Analysis (Help? Codebook)	Link to Source	Coder 1 Primary	Coder 2 Primary	Coder 3 Primary	Coder 4 Primary	Agreement (Pi)
1	10:08 6/7/16	It is not clear if the information is from a citizen or someone else.	go to	SB	SB	SB	SB	1.00
2	10:08 6/7/16	The agency that the information is coming from is not on the form.	go to	CT	SB	SB	CT	0.33
3	10:08 6/7/16	I ask about this and the player shows me other written forms that similarly require a lot of guessing because the way they are filled out is vague.	go to	CT	CT	CT	CT	1.00

5	10:20 6/7/16	Another confusing message doesn't have a log number from the message center, so it was not routed through the center. So, the planning players are unsure who to go back and get information from.	go to	CT	CT	PM	SB	0.17

Figure 2. Qualitative Analysis Tool (merged spreadsheet) Used to Discuss Coding Choices by all Analysts and Achieve Agreement

RESULTS

Our analysis revealed that observations recorded during two days of the Cascadia Rising regional disaster exercise at Kitsap County represented 45 issues or breakdowns in cooperation and information sharing. Further analysis found that these issues could be coded using seven categories for both effect (i.e., how the issue manifested) and cause (i.e., the source of the issue). See Table 1 for the seven categories used to code the issues as causes and effects.

Category	Definition
Computational Mechanism Issue (CM)	Perhaps poorly designed computer-based form or system
Content Breakdown (CT)	Unclear or incomplete content; missing information
Coordination Breakdown (CD)	Individuals/groups knew the process, but process did not work, or they did not follow it
Interoperability (IO)	Systems do not work well together, may occur when two systems have two different standards
Paper Mechanism Issue (PM)	Paper form not working, perhaps due to poor design or missing information
Source Breakdown (SB)	Source not identified; whenever we think something went wrong regardless of paper or system
Unclear Process (UP)	People unsure how to do things due to unclear or undocumented process including the lack of training

Table 1: Classification System and Definitions developed to identify cause-effect relationships of information sharing

breakdowns

Almost half of all obstacles to information sharing were coded as manifesting as either computer system issues (13) or coordination issues (9), while coordination issues (10) and unclear processes (12) were coded as the actual cause of almost half of all information-sharing breakdowns. Very few breakdowns manifested as issues with paper mechanisms (1), while content (2) and information source issues (2) caused very few breakdowns.

Table 2 shows those observations manifesting as computational mechanisms issues[3]. Unclear processes were the cause of four of these 13 issues. Upon first reading, these issues may appear to be caused solely by a technical issue. For example, Observation #14 includes several mentions of technology (e.g., "multiple systems", "GIS", and "Adobe PDF viewer"). However, looking beyond these surface detail and examining additional text that preceded and followed Observation #14, the coders classified the cause as an "unclear process," explaining that if exercise participants understood how and which systems to use, the inability to coordinate and share information may have been overcome. Similarly, for Observations #15, #16, and #19, participants are having difficulty with the system designed to record damages on a regional map. While one may infer the cause as a computational mechanism issue, the analysis team explained that had the process been more clearly conveyed they would not need to spend valuable time trouble-shooting the system to determine if the feature worked correctly, hence they classified the cause as "unclear process."

Three of the manifestations of computer system mechanisms were classified as caused by issues of interoperability. Observation #13, #22, and #45 describe issues related to the inability of systems to share data across disparate systems. In the case of Observation #13, both versions of WebEOC had the ability to track events and resources, but a standard definition of "significant event" was not available. As a result, an event that was tracked in one version of WebEOC could not be tracked in a different version WebEOC.

Only one time, was an issue with "coordination" identified as the cause of a "computational mechanism" manifestation (see Observation #33 in Table 2). In this case, functionality which was expected to be available by the start of the exercise, was not implemented. Throughout the exercise it because apparent that tracking all issues, assign a priority, and sort on the priority was a function that would provide great value to the resource scheduling team.

Finally, five of the 18 manifestations of "computational mechanism" issues were also classified as caused by "computational mechanism" issues. Various technical issues are explicitly called out in the observation, and a thorough reading of the Slack jottings surrounding these issues, resulted in the analysis team agreeing that these issues were caused by a failure of technology.

#	*Observation*	*Cause*
11	Planning GIS is trying to create a damage map, but there is a technical issue due to a recent update.	Computational Mechanism Issue
13	The Deputy PIO is working on an internal communication issue. The PIOs would like to use WebEOC to communicate with each other internally. That functionality has not been implemented for Kitsap County in the same way it works at Camp Murray. These PIOs want to track things in WebEOC that don't quite qualify as "significant events" but may be bits of information that they would get information requests about.	Interoperability
14	Looks like multiple systems are in play for the road damage. Original maps are created in GIS. Trying to get the details without being too pushy. Seems some edits are also being made in an Adobe PDF viewer. Though, the player I spoke with said, "It's not doing what I want it to do.	Unclear Process
15	I've been looking at the Public Works trying to do rapid mark up on PDFs of maps. It doesn't seem to be working.	Unclear Process
16	A National Guard player is at the smart screen loading a map. He is attempting to edit the map which is a PDF by drawing over it with a stylus. "It's not doing what I want it to do."	Unclear Process
17	He will also convert it to a JPG so it can be shared.	Computational Mechanism Issue

[3] In order to fully understand an observation, the analysis team often referred back to Slack jottings that both preceded and followed the observations shown in the table.

18	There is a problem with editing the map in the PDF viewer. If you change the map view, the edits above it will be off.	Computational Mechanism Issue
19	[participant] from county public works and a National Guard player are troubleshooting the map on the smart screen. They are looking up the smart screen manual on [participant] phone. It seems that the smart screen should support easy and fast markup of the map so that Public Works can quickly get out information to crews of where damage is. The national guard player is going through several permutations, but none of them seem to work. For rapid assessments and documentation, it seems this system needs some reworking.	Unclear Process
22	Kitsap assessment tool has a web-based tool to upload a situation report. The web app is partially broken. A recent ArcGIS system update broke the ability to talk directly to the damage assessment collection tool. One of the National Guard players: The EOC GIS displays are all different, no standard.	Interoperability
26	Message forms are coming in, but it can't be brought in to the GIS tool. Data is being put into the GIS system by hand.	Computational Mechanism Issue
27	Can't download data from the web app. A CERT volunteer and the GIS planner continue to work on fixing the system.	Computational Mechanism Issue
33	The WebEOC functionality they were looking for (logging lower priority information) probably won't be implemented during the exercise.	Coordination Breakdown
45	The web-based tool is pre-loaded with important locations such as drug stores, food stores and fire stations throughout the county. It is designed to work with their GIS, though there was a hiccup with that yesterday.	Interoperability

Table 2: Observations manifesting as Computational Mechanism Breakdowns and their causes as identified by the coding analysis team.

Table 3 represents the nine observations that manifested as coordination breakdowns. Seven of these nine issues were also caused by coordination breakdowns. Observation #9 is the description of the process where the county commissioner, officially declares a "state of emergency." This declaration is required in order for other tasks to be completed, thus many people are idle due to the breakdown in coordination. The two interoperability causes identified in Table 3, Observation #29 and #34, are related to operational and technical interoperatbility issues, respectively.

#	***Observation***	***Cause***
9	This declaration could be made locally by the county commissioner, but so far that has not happened. The commissioner is inaccessible which is delaying the declaration. This is delaying some of things that need to occur.	Coordination Breakdown
12	Several stickers are beings added retroactively to the map.	Coordination Breakdown
25	Too few GIS workstations here.	Coordination Breakdown
28	We have a very incomplete [picture] of what the damage is in the county.	Coordination Breakdown
29	ACCs and Police Departments are overwhelmed.	Interoperability
30	Plans are not solidified on commodities for citizens.	Coordination Breakdown
34	Damage assessment, some blips some parts still not talking to each other.	Interoperability
35	The message center is not operational today.	Coordination Breakdown
36	Still use the message forms. Deliver them where they need to go.	Coordination Breakdown

Table 3: Observations manifesting as Coordination Breakdowns and their causes as identified by the coding analysis team.

To summarize, a qualitative analysis, grounded in the data, revealed that breakdowns in information sharing among people and agencies had many symptoms and many causes, and they were not always aligned. Two-thirds of barriers that manifested themselves as computer systems issues were not caused by computer systems issues, and a third caused by unclear processes manifested as computer systems issues. In the following section we discuss what results like this one mean for improving collaborative management of disasters.

DISCUSSION

In this qualitative investigation of the response to a large-scale regional disaster, focused on the activities of a county EOC, we sought to identify the cause-effect relationships that made it difficult to achieve desired information sharing. Specifically, we identified the observable effects of information sharing breakdowns and then inferred possible causes of these breakdowns, using the classification system described above. While not all may agree with the particular classifications, we believe that the qualitative coding methodology and the analysis tool used here contributes to the knowledge regarding the causes of breakdowns in complex socio-technical crisis management systems.

According to the *Cascadia Rising Disaster Exercise After Action Report* (FEMA 2016), a long history of regional coordination and collaboration led to overall successes during the exercise, improving situational awareness and decision-making capabilities and bridging gaps in communications and problem-solving. Still, as we observed at the county-level EOC and as was acknowledged in the AAR, there were significant obstacles to information sharing and coordination. In fact, the general conclusion of the Cascadia Rising After Action Review was that we as a regional community are not prepared for a disaster of this magnitude. But where should we focus our investments and energies to become better prepared?

This study suggests that in a crisis information sharing environment, computer systems are more likely to manifest a problem than they are to be the cause of it. Results indicate that although the effect of an obstacle to information sharing or coordination may be related to a computer system or software, the cause of the problem is more often than not due to other factors. Computer issues were as likely to be caused by unclear processes as technical issues. Some of these issues could be attributed to individuals' lack of training with such systems, exacerbated by the infrequency of using computer systems that are designed for or being adapted for use during disaster response. Overall, obstacles to collaborative work that appear to be related to computational issues are generally attributable to non-technical causes. This indicates the danger in attempting to improve collaborative management of disasters by enhancing technological capabilities. Interestingly, when we discussed this conclusion with disaster practitioners, their general reaction was, "That's not surprising. We knew that." Yet the investment in technical fixes to crisis collaborative systems continues to be considerable.

Coordination issues in support of collaborative work could be attributed to various factors. The extent of the Cascadia Rising exercise scenario meant that the state had to call upon federal and military assistance in order to respond to the disaster. Consequently, there were individuals who were working together for the first time and unfamiliar with operational procedures involving these new players. Such challenges are common in disaster response due to different organizational cultures and distinct individual and coordinative work practices Ley et al., 2014). The shared ICS structure is designed to overcome some of these challenges, but in many cases did not achieve this, either because several jurisdictions used modified versions of the ICS—which is acceptable but can lead to problems with coordination (Lee et al., 2011)—or because ICS is more effective as a going-in position than as a playbook to manage unexpected challenges. Our results indicated that coordination breakdowns were common, about 1 in 5 of all obstacles whether viewed as cause or effect. Coordination issues were the most significant cause of missing content. This missing information meant that necessary collaborative work was delayed or could not be completed.

Interoperability issues, viewed not just as machine issues, were also significant. There are many levels of interoperability, from technical levels that link networks and data to mission-centric operational and policy levels of interoperability (Haselkorn et al., 2016). While prior studies of disaster systems have focused on "lower-level" technological interoperability problems of data sharing and networking, we took a broad definition of "system" and included "higher-level" interoperability such as conflicting policies or misaligned practices. From this perspective, interoperability was a prevalent cause (1 in 5) but not as prevalent an effect (about 1 in 10). As the literature suggests, response emergency managers, faced with interoperability issues, improvise and devise low-tech workarounds to support information sharing (Brooks et al., 2013). During Cascadia Rising we also saw evidence of this. For example, as response teams were trying to find geographic information system (GIS) data, they discovered that there was no data clearinghouse that could be used across organizations. This led responders to improvise—reaching out to regional workers they had connections with and finding suitable data. They then, however, struggled mightily with integrating this data into a useful situational picture.

More than a quarter of all information breakdowns we observed were categorized as being caused by an unclear process. Supporting this, the AAR found that almost all jurisdictions reported a lack of understanding of the resource request process, finding that in some cases the personnel had not received adequate training required to make and track resource requests (FEMA 2016). Like the improvisation described above, this further speaks to the fact that resources should be allocated to support how people actually work—informally based on past shared experiences and trust relationships—rather than on new technology that changes, and constraints work processes. Unclear processes were the single biggest cause of obstacles to information sharing in support of collaborative

crisis work. Introducing new technology that impacts how people work is likely to make this problem worse, not better.

CONCLUSION

State-of-the-art human centered design methods are based on the perspective that technology is a tool in support of accomplishing human missions and meeting human needs. Without an alignment of human issues such as shared missions, policies, and operational concepts, no amount of technology can achieve effective collaborative work. Operational professionals such as those working heroically to minimize the destructive impact of earthquakes and other hazards know this intimately. This study found information-sharing obstacles associated with computer systems to be the single most **visible effect** during a major crisis exercise, but they were far from the most significant **underlying cause**. This evidence, in support of what practitioners already know from experience, argues for a shift in how we invest in our collaborative crisis management "systems."

ABSTRACT

Inter-organisational learning from exercises and response operations is crucial for improving overall response capacity for coping with cross-domain crisis events. In order to compile and disseminate experiences and acquired knowledge in the form of lessons learned, post-exercise reports are written. This paper presents a review of 17 Swedish post-exercise reports. The review was conducted with the aim to investigate whether such reports contained enough information to support inter-organisational learning, i.e. if learning goals were stated, how the event was described, method for evaluation, conclusions, and whether recommendations for change were sufficient for supporting inter-organisational learning. It was found that most reports did not support organisational development and lacked recommendations that were useful outside the own organisation or the context of the specific exercise scrutinised. The results indicate the need for an exercise evaluation framework for inter-organisational exercises.

Keywords

Crisis management, post-exercise reports, inter-organisational learning, double loop learning.

INTRODUCTION

Learning is crucial for any kind of organisation and is in some respects particularly challenging for actors in the domain of crisis management (Baroutsi, 2018; Wang, 2015). Exercise evaluation has been described as crucial for learning, as it in many cases is the only feedback given to exercise participants (Baroutsi, 2018). Inter-organisational learning from actual crisis events or inter-organisational exercises is perhaps the most challenging type of learning as this demands the identification of lessons learned that are applicable not only to specific organisations or actors, but to a collective of such organisations or actors. Exercise reports, particularly those based on inter-organisational exercise events, are consequently very important sources of knowledge that need to be disseminated within the crisis response community in order to facilitate learning about inter-organisational crisis management. In 2014, the Swedish Civil Contingencies Agency (Myndigheten för Samhällsskydd och Beredskap, MSB) published a guideline introducing the fundamentals of exercise planning (MSB, 2017a), and in 2016 the agency published a guideline on exercise evaluation (MSB, 2017b). According to MSB (2017b), the purpose of exercises is to generate knowledge of strengths and deficiencies to systematically develop or maintain the ability to handle emergencies, i.e. organisational learning. Another purpose is to test plans, actions and organisations in a simulated environment, where failures will not lead to injuries or serious consequences in the society. Post-exercise reviews should answer the questions 'how did it go?' and 'why did it happen?'. In order to do so, the exercise evaluator needs to consider the conditions for the exercise, the participants' actions and the outcome of the participants' actions (ibid.). Furthermore, MSB (2017b) recommends the use of

indicators for exercise evaluations. An indicator indicates whether a certain ability has been demonstrated during the exercise. Indicators are often defined in terms of observable data, such as questions that can be answered by true/false, or measurable data such as time, numbers or percentages.

Granåsen et al. (2018) have pointed out that a systematic approach to identifying lessons learned for inter-organisational crisis management, in other words, the crisis management *system*, is needed. In a literature review by Granåsen et al., it was found that different aspects of crisis management capability can be organised into nine thematic clusters: interaction, relationships, coordination/C2, system performance, preparedness, situation awareness, resilience, decision-making and information infrastructure. The review surveyed 150 papers that had been identified as relevant out of a total of 1197 publications found in a database search. The nine clusters identified highlight the ambiguity of what capabilities are important in inter-organisational work as well as the potentially confusing usage of terminology within the field. Nevertheless, the authors suggested that these clusters can be used to support analyses of exercise reports in the sense that lessons learned that are applicable to one or more of the identified clusters can most likely be of importance to actors.

According to Argyris (1977, p. 116), organisational learning is 'a process of detecting and correcting errors'. As emergencies are quite rare, exercises are important opportunities for detecting and correcting problems within the crisis management system. In addition, they are vital for organisational learning within the crisis management domain. Argyris (1977) denotes the cases where it is possible to detect and correct errors without changing the organisation's underlying objectives or policies as single loop learning. Cases that require a change of the organisation's objectives or policies are referred to as double loop learning. Further, Argyris (1991) argues that highly skilled professionals are very good at single loop learning but are often relatively bad at double loop learning. According to this line of reasoning, organisational change cannot be expected to take place as a consequence of everyday operations, as such operations rarely challenge established work practices. Rather, it is deviating, unusual events that challenge organisational practice and demand inter-organisational cooperation (Quarantelli, 1998; Bigley & Roberts, 2001; Trnka & Johansson, 2009). Such crisis events are fortunately rare and some organisations will only ever encounter them in exercises or simulations. This fact stresses the importance of capturing knowledge and experiences generated during such exercises in order to support both organisational and inter-organisational learning, particularly when knowledge that could support double loop learning is concerned. How is then such knowledge captured, stored and disseminated? In most cases, the main output after an exercise, be it a single-organisation exercise or an inter-organisational exercise, is a report written by an evaluator who is either internal or external to the participating organisation(s).

The objective of this study is to explore if post-exercise reports identify and describe conditions and experiences that support inter-organisational learning, i.e. is it possible to identify lessons learned, suggestions for change and action from these kinds of reports and apply it to other organisations? The study was carried out as a review of exercise reports within a Swedish context. The review investigates how regional inter-organisational exercises in Sweden have been evaluated in terms of:

- Whether the exercise reports actually describe inter-organisational aspects, i.e. do they reflect the nine thematic clusters of inter-organisational learning identified by Granåsen et al. (2018)?
- How the exercise goals and evaluation approach were described in the reviewed reports – are they suitable for inter-organisational learning or even organisational learning?
- Whether the reviewed reports support single or double loop learning as described by Argyris (1977)?
- Whether the results are applicable outside the realm of the specific exercise or organisation?
- Whether there are recommendations in the report, and to what extent these are applicable to other organisations?

METHOD

The present study is based on reviews of post-exercise reports from 17 regional cooperation exercises in Sweden during 2008-2017. The search for post-exercise reports was performed partly in a document database in MSB's integrated decision support system (RIB), and partly on the internet. The inclusion criteria were that the report must concern an exercise describing an event that in a real situation would affect several organisations, even if only one organisation participated in the reported exercise. There should thus be a potential for reporting on issues of interest in an inter-organisational context, i.e. show potential for learning about such events. Furthermore, a time limit of ten years was applied (2008), and reports were selected from what was deemed to be a representative set of counties. Due to demographical aspects, such as funding for exercises and reporting tradition/culture, some counties were found to have carried out more exercises than others. Consequently, more reports were available in those counties.

The search for post-exercise reports on the internet was carried out in two steps. In the first step, a search for 'samverkansövning' (i.e., cooperation exercise, normally indicating an inter-organisational exercise) was carried out on the web pages of all county administrative boards in Sweden. In the second step, three different searches were made using Google and the search terms 'samverkansövning' (i.e., cooperation exercise[1]), 'regional övning' (i.e., regional exercise), and 'utvärderingsrapport & övning' (i.e., evaluation report & exercise). The search in RIB generated 35 results, of which nine contained post-exercise reports that met the inclusion criteria. The internet searches yielded four additional post-exercise reports that met the inclusion criteria. As only one post-exercise report from a county with a nuclear power plant was found, one county administrative board (county 4 in Table 1) was contacted directly. Four post-exercise reports were obtained in this way. In total, exercise reports from seven of 21 counties in Sweden were included in the analysis.

All reports were written in Swedish. The exercises covered emergencies such as the release of radioactive material from nuclear power plants, heavy rainfalls, landslides, shortage of fuel, interference with payment/financial systems, pandemic flu, epizootics, large oil spills at sea, air accidents and threats of violence against schools. The reviewed post-exercise reports were written by eleven authors representing six organisations, i.e. one municipal rescue service, three county administrative boards, one university and MSB. One author, employed at MSB, wrote seven reports, one author employed at a county administrative board was a co-writer of three reports, and another author employed at a county administrative board was a co-writer of two reports (Table 1). All other authors wrote one post-exercise report each.

Table 1. Reviewed post-exercise reports

Exercise	Year	County	Author(s), employed at
1	2016	1	A, municipal rescue service
2	2017	2	B, county administrative board
3	2013	2	C, MSB
4	2010	2	D, county administrative board
5	2008	2	E, county administrative board
6	2012	3*	C, MSB
7	2017	4*	F & G, county administrative board
8	2016	4*	H & G, county administrative board
9	2016	4*	F & G, county administrative board
10	2015	4*	I, county administrative board
11	2011	5	C, MSB
12	2016	6	J, county administrative board
13	2011	7	C, MSB
14	2014	8	K, university
15	2012	8	C, MSB
16	2010	9	C, MSB
17	2008	9	C, MSB

* County with a nuclear power plant.

RESULTS

The reviewed post-exercise reports generally had the same structure: (1) background to the exercise, (2) description of the exercise scenario, (3) description of the purpose and goals for the exercise, (4) description of the evaluation process, (5) evaluation, and (6) areas for improvement. In ten of the post-exercise reports there was also a description of the exercise planning process and planning organisation (included between (1) and (2)). Two post-exercise reports lacked a description of areas for improvement.

The capability clusters identified by Granåsen et al. (2018) were applied in an effort to see what type of inter-organisational aspects the reports addressed. It was found that most reports (more than ten) addressed the clusters interaction, relationships, situation awareness, coordination/C2, preparedness, and information

[1] All translations from Swedish have been made by the authors.

infrastructure, while largely ignoring (less than ten) system performance, resilience, and decision-making. Table 2 describes the distribution of reports for each cluster. *Situation awareness* positions itself on the borderline as it occurs in nine reports, which is just about half of the reports included in this review.

Table 2. Number of reports in each cluster

Cluster	Capabilities found in post-exercise report goals or areas of improvement that are also mentioned by Granåsen et al. (2018)	Number of post-exercise reports
Interaction	Communication, collaboration, information sharing, collaboration practices, inter-organisational crisis management, participant interaction, managing collaborative actions, information flow.	16
Relationships	Formal and trust based relationships, resource allocation (shared), formal and informal networks, predictability, awareness of tasks, roles, material and personal resources, creating a collaborative culture, building a collaborative institution, organisational structure and practices.	15
Coordination/C2	Hierarchies between actors, C2 coordination, coordination centres, hierarchical multi-agency organisational structure, inter-organisational coordination, strategy.	13
System performance	Team performance, system/organisational capacity, capability and function, general organisational performance, operational efficiency.	5
Preparedness	Training and evaluation of disaster preparedness plans, contingency planning, preparedness (institutional, individual, collective, local emergency), emergency plan, learning related work activity.	15
Situation awareness	Situation assessment, shared situation awareness, situational picture.	9
Resilience		0
Decision-making	Analysis of crisis situation.	1
Information infrastructure	Information and communication technology (ICT), use of coordination technology equipment, inter-organisational IT use.	14

The main focus of the reviewed post-exercise reports was on interaction, relationships, coordination, preparedness and infrastructure. This was expected as the inclusion criteria directed the search towards inter-organisational exercises. Somewhat more surprisingly, *system performance* was noticeably absent in the goal descriptions (stated as goals in five reports), even though it was mentioned as a purpose in eleven of the exercises,. This is surprising as the overall performance of the organisation probably could be turned into an assessable indicator. *Decision-making* only occurred in one report, which may be less surprising as the focus of the identified exercises was inter-organisational cooperation, indicating that decision-making aspects probably were not the primary focus. If they were, they were probably approached from the angle of team decision-making or cooperation. *Resilience* was not found at all. However, this term is relatively new in a Swedish context, and resilience-related aspects may very well have been exercised although this terminology was not used. Information systems for supporting information sharing between organisations were rarely mentioned. The only system that was consistently referred to was WIS, an IT-system designed to support diary-like status

reports posted into a shared database. However, the post-exercise reports usually described technical difficulties with WIS rather than evaluating the potential benefits of using it. No reports provided suggestions for improving WIS. In general, the reviewed reports seem to reflect capabilities that are crucial for inter-organisational work in crisis response.

The stated goals for each reported exercise differed, although all but three stated goals that were classified as 'qualitative' in the analysis. The remaining three exercises did not report any stated goals whatsoever. No exercise was given goals that could be classified as quantitative, such as, for example, 'all fire brigades must reach the incident area within X minutes'. According to the post-exercise reports, indicators were used to evaluate the goal achievement in seven of the exercises. For each of the exercise goals, between one and 14 indicators were used for evaluation, with an average of 5.3 indicators per goal. Table 3 presents four examples of goals from two different exercises (exercise 10 and 14) that demonstrate a great difference in the number of indicators.

Table 3. Examples of goals and the number of related indicators found in the exercise reports

Exercise	Goal	Number of indicators
10	*The actors have a good ability to understand their own role in a nuclear accident*[2].	2
	The actors have a good ability to communicate internally and externally, as well as explain the decisions taken and their related consequences.	13
14	*The actors have a basic ability to work in accordance with the county's guidelines for coordination in a crisis situation.*	14
	The actors have a good C2 ability and a good ability to cooperate with other actors in: (a) search and rescue operations at sea, (b) oil spill clean-up operations at sea, (c) oil spill clean-up operations in coastal environments.	3

Table 3 also presents examples of how goals were formulated in the exercise reports. As can be seen, goals were formulated in terms of *abilities*, often related to several different situations and skills ('good ability to communicate internally and externally, as well as explain the decisions taken and their related consequences'). However, there does not seem to be a direct relationship between the complexity of the goal statement and the number of indicators used to assess whether the goals were reached. For example, the second goal in Table 3 relates to 13 indicators, while the fourth goal, the description of which is by no means less complex than the second goal, only relates to three indicators. In turn, indicators manifest themselves in different ways in different reports. Table 4 shows four randomly selected goals from the various reports and how the indicators were described. As can be seen, most indicators were defined as observable events that can be answered by *yes* or *no*.

[2] All citations and examples from exercise reports have been translated from Swedish by the authors.

Table 4. Examples of indicators for different exercise goals

Exercise	Goal	Indicators
2	*Achieve reporting of operational picture and a shared situational awareness*	• Requested information is delivered to the county administrative board within the stipulated time. • Requested documentation is delivered to the county administrative board with the requested information. • WIS (an MSB system used for information sharing on the internet) is used among actors as a tool for reporting operational picture. • A shared situational awareness is created between the involved actors during orientation and coordination meetings, using the regional methodology for achieving a shared situational awareness. • The shared situational awareness provides sufficient support for orientation and coordination on a regional level.
3	*Basic ability to cooperate according to the regional cooperation agreement.*	• If necessary, the regional TIB group ('officials on standby group') is contacted by the alarm centre within 30 minutes. • If necessary, a first orientation and coordination meeting is held within one hour after the first alarm. • Within two hours, the TIB group has made a decision on the continued orientation and coordination of the actions taken due to the event.
7	*The county administrative board has a basic ability to provide relevant means of communication at the forward command post*	• There is access to Rakel (a TETRA-based Swedish communication system) and it can be used. • There is access to Skype and it can be used. • It is possible to connect to the county administrative boards' intranet.
14	*Basic ability to cooperate based on local and regional oil spill response plans in the event of a major oil spill at sea.*	• The actors assess the need for support from other organisations. • The actors formulate the need for support from other actors. • The actors request support from other actors. • The actors receive a response to their request for support from other actors.

As can be seen in Table 4, some indicators, for example 'There is access to Rakel (a TETRA-based Swedish communication system) and it can be used' is relatively easy to assess. Others, such as 'A shared situational awareness is created during orientation and coordination meetings between the involved actors, using the regional methodology for achieving a shared situational awareness', can be very challenging to assess, if at all possible. In terms of evaluation methods, various qualitative methods, such as interviews, observations, evaluator judgement, surveys, protocols, and after-action reviews were applied. Interestingly, all but one report stated that methods were combined in different ways to evaluate the concerned exercise. Applied in twelve of

the evaluations, surveys were by far the most common method used. . However, surveys were in all cases combined with other methods, most commonly observations and evaluator assessments. In three cases, interviews were utilised. 'Evaluation seminars', probably resembling after-action reviews, were relatively common, with five occurrences in our data set. The least common method was 'protocols', which evidently was a form of pre-arranged checklists used to assess whether or not the participants in the exercise reached the specified goals.

Table 5. Goal type, evaluation methods, and use of indicators identified in the reviewed reports.

Exercise	Type of Goals	Methods applied	Use of Indicators
1	Qualitative	Evaluator's rating, Documents and logs from the exercise, Observations, Evaluation seminar.	No
2	Qualitative	Evaluator's rating, Observations, Documents and logs from the exercise, Evaluation seminar.	Yes
3	Qualitative	Survey, Evaluator's rating, Review of documentation and logs from the exercise, Evaluation seminar, Observations.	Yes
4	Qualitative	Evaluator's rating, Survey	No
5	Qualitative	Observations based on Observation protocols, Review of documentation and logs from the exercise, Evaluation seminar, Survey, Interviews.	No
6	Qualitative	Reports from evaluators, Evaluation seminar	Yes
7	Qualitative	Evaluator's rating, Survey, Evaluation seminar.	Yes
8	No goals	Survey, Observations.	No
9	No goals	Survey, Documentation from exercise	No
10	Qualitative	Survey, Evaluator rating based on Observation Protocol, Evaluator's rating.	Yes
11	Qualitative	Survey, Evaluator's rating, Observations, Review of documentation and logs from the exercise, Evaluation seminar	No

15	No goals	Survey, Observations	No
16	Qualitative	Survey, Review of documentation and logs from the exercise, Observations, Interviews.	No
17	Qualitative	Documentation and logs from the exercise, Survey	No

The outcome of these evaluations were in all cases descriptive, independent of whether goals were articulated and/or indicators were used. No statistical or other form of numerical analysis was conducted in order to

compare the outcome of the exercise with set goals, earlier exercises, or other exercises.

However, the results were discussed in a variety of ways. Six evaluations discussed whether or not the exercise goals were fulfilled. Three discussed the strengths and weaknesses of the exercise. One presented lessons learned. The other evaluations discussed the participants' experiences, whether or not the design of the exercise was appropriate, the number of participants in the surveys conducted, etc.

Based on the outcome of our analysis, an effort was made to determine whether or not the exercise reports could be considered to support double loop learning, as described by Argyris (1977). It was found that only five reports seemed to achieve this goal (Table 6). This analysis was based on the following criteria: Reports were deemed to support single loop learning if the recommendations focused on improving existing procedures, structures or functions, such as exercising more to perfect a procedure, improve individual skill, or improve an existing technical system. Reports were deemed to support double loop learning if the report questions revolved around the way work was conducted, and if there were recommendations going beyond conclusions in the style of 'more exercises are needed', or other suggestions that can be labelled as single loop learning. The type(s) of goal(s) formulated for each exercise was also taken into account. Table 6 illustrates the number of reviewed reports that support single loop learning vs. double loop learning.

	Type of learning	
	Single loop	Double loop
Indicators used for evaluation	6	1
Indicators not used for evaluation	6	4

Lastly, we performed an analysis of the recommendations provided in the reviewed reports in an effort to answer the question whether the reports support learning outside the specific exercise context. Eight of 17 reports did to some extent support learning outside the own organisation or specific exercise context. In some cases, the recommendations require a degree of interpretation on behalf of the reader to achieve this. In general, recommendations may be hard to implement even within the realms of the own organisation or exercise context. Table 7 presents a set of randomly selected suggestions for improvements from different reports. As shown, some of the recommendations were written in such a way that they include a motivation as well as suggestions on how to implement the recommendation. In other cases, the recommendation consists of a few words, which implies that readers need to provide a context as well as a way to implement the suggested recommendation themselves. It can also be concluded that there seems to be no agreed format for providing recommendations in post-exercise reports of the kind reviewed in this paper.

Table 7. Random examples of conclusions/future improvements in the post-exercise reports

Exercise	**Conclusion/suggested future improvements**
2	*One of the goals with the exercise was to achieve a shared situational awareness. Today, there is a defined method for achieving a shared situational awareness. Simplified, the method is based on all actors providing information, which is then compiled into a regional shared operational picture. During the exercise the information was distributed by the WIS system, except for restricted information. As there was a new version of WIS, which was not fully functional during the whole exercise, problems occurred with both the submission of information and the compilation of a common operational picture* • *Further development work should be carried out based on the established method. This work should highlight information gathering, compilation, updates and dissemination of the common operational picture. Knowledge about and the ability to use WIS is important. The work should include routines for both the regular approach and for a backup system in case the regular system fails. It is also important to highlight how restricted information is to be handled and distributed.*
3	*Develop the work on shared situational awareness by:* • *Determining what information shared situational awareness*

	should include. • *Providing procedures for reporting.*
6	*The following points need to be addressed to increase the county's ability to handle a nuclear accident:* • *Confusion about concepts* • *Clarification of roles, responsibilities and mandate* • *Communication with units at sea* • *Alarm numbers and messages* • *Receiving stations* • *Synchronisation of plans* • *Transport issues and traffic diversion* • *Endurance* • *Development of exchanges of liaison officers* • *Increase of the ability to command county administrative board staff.*
17	*The three closing questions in the questionnaire discussed the future. Some answers that stood out are reported below.* ***Have you discovered a need for constitutional changes to better manage a pandemic? If so, please specify.*** • *The Working Hours Act may constitute an obstacle. A review of possible exceptions from the act is needed.* • *A legal prerequisite for distributing fuel or taking action with mandates similar to those of an incident commander, according to the Civil Protection Act (SFS 2003:778,) is needed* ***What support does your organisation expect from the county administrative board for the continued planning for pandemics?*** • *A handbook on the legal aspects of crisis management.* • *Exchange of experiences from the planning process within the county.* • *Epidemic intelligence and exercises.* ***What support does your organisation expect from other actors than the county administrative board for the continued planning for pandemics?*** • *Support from the Swedish Institute for Infectious Disease Control in the production of instructions and advice for contingency planning.* • *Knowledge from the county council's infection protection unit.*

In general, the exercise reports focused on describing what happened and what actions were carried out during the exercise. Only a small number of the reports were devoted to analysing the problems that arose during the exercise, i.e. finding the underlying reasons for the problems that occurred, how the problems were solved during the exercise, and what measures that need to be taken to prevent the problems from occurring again. It is also difficult to follow the link between the problems that arose during the exercise and the suggested improvements.

Naturally, the evaluation of the exercise took its starting point in the goals of the exercise. However, as most of the exercise goals were formulated as abilities, there is not much in the way of analysis, and there are only a few suggested improvements in the cases where the exercise goals were met, even if the evaluation showed that

there was room for improvement.

DISCUSSION

When analysing the 17 reports in the light of the nine thematic capability clusters identified by Granåsen et al. (2018), it was shown that the reports largely reflect capabilities important to inter-organisational crisis response work. This is promising as the thematic clusters reflect a large set of academic writings on inter-organisational work, and thus indicate that the core of the exercises were conducted in such a way that there was potential for learning and improving overarching crisis response system capabilities. However, some challenges and room for improvement remain, as suggested by the results presented above.

The 'indicator approach' suggested in the MSB (2017b) guidelines is positive in the sense that indicators, at least in some respects, can be assessed objectively and with well-defined measures, such as time, distance, frequency, etc. However, the connection between indicators and theory in terms of learning, particularly organisational and inter-organisational learning, is weak, even in a best-case scenario. Hollnagel (1997) discussed that researchers and evaluators often grasp for *what is measurable* rather than *what should be measured*. This implies that many of the measures performed using the MSB guidelines may capture experiences that are less useful for supporting aspects of double loop learning, or even single loop learning. In several cases, indicators of the type 'was IT-system X used during the exercise? ' were found. Even if it is possible to count the number of times IT-system X was used or not, such an indicator, nor reporting the outcome of it, does not explain *why* it was/wasn't used. Furthermore, the present review shows that the type of indicators used vary greatly between similar goal formulations, indicating that the theoretical or methodological support for assigning indicators is poor. A plausible hypothesis is that the number of indicators for a given goal reflects the possibility to identify observable events rather than a reflection of the complexity of the goal. Some goals are related to only two indicators, whereas others are related to as many as 15. In addition, the descriptions of the various indicators suggest that there is a great variation in the types of method needed to assess whether they have been fulfilled or not, ranging from system log files to subjective self-estimates. This is not a problem in itself, but reflects the ambiguity in the way indicators are chosen and applied in exercises.

The present review showed that when indicators were used to evaluate an exercise, the focus for the evaluation tended to be on whether the goals of the exercise had been met or not. However, as most exercise goals focused on ability and not learning, the result of the evaluation tended to present a 'test result', rather than a starting point for future improvements of the crisis management system. This view indicates that the exercise was viewed as a confirmation of the quality of an existing ability, rather than a learning event. The level of detail in indicators and goals also varied greatly, ranging from the ability to handle a specific IT-system to more generic abilities to establish inter-organisational cooperation. This variety of indicators and goals suggests that challenges remain when it comes to creating guidelines and training for exercise planners and evaluators, if useful exercise reports in an inter-organisational context are to be assured.

Another aspect of the evaluation in the reviewed reports was the descriptive, qualitative, approach utilised. While a qualitative approach is useful for describing what took place during the exercise and why, it has limited value in terms of comparability between different exercises. For example, if no quantitative performance assessment is carried out it becomes impossible to analyse the development of performance over time. The same goes for comparisons between exercises or organisations. In sum, all kinds of statistical analysis are effectively rendered impossible.

Moreover, support of double loop learning was found in fewer post-exercise reports using indicators than in post-exercise reports where indicators had not been used. In the single case where a post-exercise report used indicators and the report resulted in double-loop learning, the double loop learning was supported by reports by observers rather than evaluation reports based on indicators from evaluators. Clear ways for incorporating double loop learning aspects in exercises, as well as methodological support for evaluating and reporting this, seems to be lacking or be outside the scope of most regional exercise evaluators' training.

The challenges posed by crisis events today also point to a more overarching question: given that most exercises aim to improve existing capacities or assure that abilities are kept on an acceptable or good level, will crisis management systems be able to handle increasingly complex and challenging events? The literature shows that crisis response organisations always need to prepare for extraordinary events, suggesting that such organisations need to be able to perform not only at an acceptable level but at an *exceptional level*. Consequently, this needs to be reflected in exercise goals, at least in some cases. This implies that failure during exercises must be a possibility, something that was noticeably absent in the reviewed reports.

Only about half of the reviewed reports contained recommendations that were found to be useful outside the context and the organisations taking part in each respective exercise. However, it should be noted that the

recommendations identified frequently require a fair degree of interpretation on behalf of the reader as they do not always motivate why the recommendation is given or how the recommendation should be implemented. It is naturally challenging to create such recommendations, particularly in an inter-organisational context, but our review shows that there is a need to investigate if it is possible to create a method or guideline concerning the format of such recommendations as they are crucial for knowledge sharing in an inter-organisational crisis response context. One suggestion could be to organise the lessons learned from an exercise according to the nine clusters suggested by Granåsen et al. (2018) and provide recommendations for each cluster in a structured way.

How should exercise reports then be improved to better support inter-organisational learning? The answer is multi-faceted and cannot be answered based on this investigation alone. However, some suggestions can be made based on the outcome of this study. Firstly, there is a lack of common terminology that could be supported by creating an inter-organisational ontology that describes phenomena that are important for inter-organisational exercises. Such an ontology could be based on the clusters provided in the paper by Granåsen et al. (2018). Secondly, the way data is collected during exercises must be aligned in such a way that it is possible to compare different exercise events with each other. Exercise evaluators should have similar training and be supported by a data collection framework, including observation protocols and other data collection tools. Similar indicators should be used across different exercises. All exercises cannot be treated in the exact same way when it comes to evaluation, but a small set of approaches to evaluation should be sufficient to cover most situations. Thirdly, exercise reports should have a similar structure and disposition, making it easy for readers to find the sections they are most interested in. Conclusions should preferably be arranged in the same way. Recommendations that apply to both immediate needs (single loop learning) and more fundamental challenges (double loop learning) should be given.

One way of supporting the effort to improve data collection during exercises, as well as the task of writing useful post-exercise reports, could be to introduce an IT support system that structures the exercise evaluators' work . Such an IT-system should preferably be possible to carry around, like a tablet, be connected to a database for storing and sharing exercise data between participating organisations in the inter-organisational context, and have the ability to record sounds and videos. The physical device needs to be rugged and have enough battery capacity to endure the realities of field observations. Essentially, the exercise evaluation support system should be a digital notepad, using semi-structured observation protocols and having the ability to document different situations that the exercise evaluator finds important. The database capturing the collected data should provide output that is structured according to the logic of the inter-organisational exercise reports suggested in the previous paragraph. This does not imply that analysis should be automated, only that a structured approach to data collection is supported and that a shared format for collecting the same data is assured.

CONCLUSIONS

This review has identified a number of challenges for knowledge sharing from exercises in an inter-organisational context. In the analysis, it was found that:

- Exercise goals are in many cases formulated as 'abilities', indicating that exercise goals focus on assuring that the involved organisations have the ability to perform certain tasks, rather than relating to learning or development.
- The type and number of indicators used to assess the exercise goals vary greatly between exercises. In many cases, the indicators concern specificand easily assessable issues, such as 'was system X used?', without a clear description explaining why this is important or how it should be interpreted in an inter-organisational context. Theoretical support for the selection and usage of indicators was largely absent in the reviewed reports. In addition, there were no discussions about whether the indicator(s) used were sufficient to determine if a specific goal had been met.
- No structured data collection of quantitative measures was applied in the reviewed exercise evaluations. Neither were statistical analyses performed on the collected data. This limits the possibility to assess development over time, as well as the possibility to compare exercise outcomes or organisational performance between exercises.
- Five of 17 reports could be viewed as supporting double loop learning, i.e. supporting recommendations that could lead to change on a systems level, such as process, organisation, training or method. However, these recommendations did in most cases lack sufficient motivation and description of how such a change should take place.
- About 50% of the reports were deemed to have the potential to be useful in other contexts than that of the specific exercise or involved organisation(s). However, as in the case with double loop learning, the

recommendations and lessons learned generally did not provide suggestions on how to implement them in other contexts than the reported exercise.

- With the exception of one nuclear energy emergency exercise where an 'internet diary' was used to share information between the actors, WIS was the only IT system for information sharing mentioned in the post-exercise reports. Regarding the use of WIS, conclusions in the post-exercise reports were limited to the need for education and training of individual users, and the need for routines concerning how the system should be used for sharing an operational picture. None of the examined post-exercise report suggested technical improvements to WIS, despite the fact that several reports mentioned that there are deficiencies in the system and that users experience difficulties when using the system.

An investigation is needed in order to formulate a framework that supports planners and evaluators of inter-organisational exercises in conducting exercises and evaluations that are useful, not only for the exercised participants/organisations, but also for other actors. The authors of the present study therefore suggest an outline for such a framework based on the clusters identified by Granåsen et al. (2018). This should include training provided to all inter-organisational exercise evaluators, and be supported by a rugged, field-worthy IT system, such as a tablet, that aligns data collection by providing observation protocols and the ability to collect sound and video recordings. Inter-organisational crisis response capabilities are crucial, but training and exercising such capabilities is costly and resource-demanding. It is therefore highly important to ensure that experiences and lessons learned from such exercise events can be utilised to their full extent. In most cases, the primary product capturing lessons learned from an exercise is the post-exercise report, which thus must be written in such a way that it is relevant beyond the scope of the specific exercise or organisations involved, and include recommendations that are useful for a wide range of actors in the crisis response community.

ACKNOWLEDGEMENTS

This paper presents a study carried out within the research project KOMET, sponsored by the Swedish Civil Contingencies Agency.

ABSTRACT

Spontaneous volunteers influence crisis and disaster relief efforts as both an effective aid and a stressing factor for emergency organisations. Managing the negative impacts of spontaneous volunteering has thus become part of command and control deliberations. In this paper, we take a closer look at integrating spontaneous volunteers into the formal response system to mitigate negative impacts. Working with participants from formal response organisations, we gathered qualitative data regarding the management of spontaneous volunteers during the European migration crisis in 2015. Through thematic analysis, we extracted topics to systematically describe the interaction between emergency organisations and spontaneous volunteers. As implication thereof, we propose how computer supported systems can be applied to better manage spontaneous volunteers. In our discussion, we focus on the registration process and *ad hoc* verification of spontaneous volunteers to better integrate them in the formal response process.

Keywords

Crisis and disaster management, spontaneous volunteers, command and control, volunteer management

INTRODUCTION

Volunteers have a considerable impact in Crisis and Disaster Management (CDM), which is particularly true for spontaneous volunteers. Spontaneous volunteers have no affiliation to formal organisations and participate to address sudden, urgent needs. The nature of their role, and whether their activity should be supported or suppressed, is subject to debate. On the one side, proponents of a top-down approach, leaning towards the command and control paradigm, at times consider spontaneous volunteers a hindrance or nuisance (Cone et al., 2003; Sauer et al., 2014; Whittaker et al., 2015). On the other side, spontaneous volunteers are often the first, and a very important, form of relief in the immediate aftermath of an incident (auf der Heide, 2003; Twigg and Mosel, 2017; Whittaker et al., 2015). Whatever side one may prefer, research has shown that the appearance and convergence of spontaneous volunteers at the disaster site can have negative side effects for organised relief efforts (Dynes, 1994b; Fritz and Mathewson, 1957; Sauer et al., 2014). As the presence of spontaneous volunteers is a common aspect of CDM (auf der Heide, 2003; Drabek and McEntire, 2003; Twigg and Mosel, 2017; Whittaker et al., 2015), response efforts should incorporate spontaneous volunteers in their decision making (Barsky et al., 2007). However, the rather static and bureaucratic command and control model is not well suited for spontaneous and loosely organised relief efforts (Drabek and McEntire, 2003) and needs adaptions to lessen negative effects of spontaneous volunteering while strengthening their problem-solving capabilities.

In this paper, we present the results of our research on the necessity and nature of adaptions to the command and control model, to better accommodate spontaneous volunteers. These results were abducted through thematic analysis on qualitative research data: interviews and group discussions were conducted in the context of the European migration crisis in 2015. The contribution of our work is the systematic description of four distinct dynamics that affect spontaneous volunteer management. Further, we describe and discuss possible technological approaches implicated by these dynamics.

RELATED WORK: CIVIL SOCIETY IN CRISIS AND DISASTER RELIEF

The importance of citizens' initiative in relief work, especially in the early phase, has been emphasized repeatedly, starting with one of the earliest works in disaster sociology (auf der Heide, 2003; Dynes, 1994b; Helsloot and Ruitenberg, 2004; Prince, 1920; Twigg and Mosel, 2017; Whittaker et al., 2015). However, from the perspective of formal organisations for crises and disaster relief such initiatives are not always seen positive, as they are hard to control and difficult to plan for (Sauer et al., 2014; Skar et al., 2016). Formal organisations have previously been reported to primarily follow procedures aimed at establishing order after the chaos of a crisis or disaster (Dynes, 1994a). Yet research does not support the need to control antisocial and destructive behaviour in the face of a crisis (Drabek and McEntire, 2003; Helsloot and Ruitenberg, 2004). On the contrary, researchers have considered informal activities essential for effective, if not necessarily efficient, relief (Dynes, 1994b). This creates a situation where civil society provides the required resources, yet in a form of response that is inefficient (Dynes, 1994b). Harris et al. (2017) describe the role of spontaneous volunteers as *paradoxical*, in that they are simultaneously needed and not wanted by crisis managers. This conflicting situation results in a need to manage the activities of citizens in a way that reduces inefficiency, while allowing flexibility.

Spontaneous Volunteers and Convergence

Formal organisations in CDM use the term *volunteer* primarily to describe persons that contribute through predetermined structures of an official response body (Whittaker et al., 2015). This definition makes volunteers part of the formal response system, where they act in accordance with established procedures. Through regular service volunteers get socialised in the field of CDM. This form of volunteerism is traditionally popular in Central Europe and Scandinavia with levels of participation in voluntary or charitable organisations regularly exceeding 50% of the population, reaching 67% in Norway (Plagnol and Huppert, 2010). Britton (1991) refers to such organised and affiliated volunteers as *permanent disaster volunteers*.

A trend contrary to permanent disaster volunteers has been noted at the turn of the century: volunteering 'decreasingly corresponds to strong identification and long-lasting membership' with organisations (Hustinx and Lammertyn, 2003). Indeed, there has been a noticeable number of publications addressing volunteers that contribute to disaster relief without joining an official response organisation. Various terms have been used for such participation, including: *informal* (Whittaker et al., 2015), *unaffiliated* (Barsky et al., 2007; Zettl et al., 2017), *episodic* (Hyde et al., 2014; Starbird and Palen, 2013), *freelancing* (Cone et al., 2003) or *spontaneous* (Harris et al., 2017; Sauer et al., 2014; Simsa et al., 2018; Twigg and Mosel, 2017). While these terms are not mutually exchangeable, they all describe volunteers who are active outside the formal response system; even though they occasionally are integrated into formal efforts (Scanlon et al., 2014). Spontaneous volunteers (as we refer to them in this paper), who may lack both training and equipment, pose an issue for official response organisations, as they may endanger their own health and disrupt organised response (Whittaker et al., 2015).

One phenomenon of spontaneous volunteering is *convergence*: the physical movement of persons or material towards the disaster site, as well as the transmission of information and requests towards communication centres of a disaster site (Fritz and Mathewson, 1957). In our research, we are primarily interested in the convergence of persons[1]. Spontaneous volunteers are motivated to render aid and offer support, and so they will mobilise and move to the incident site (Dynes, 1994b). This individual and unorganised mobilisation can cause congestions of persons and vehicles, posing an additional logistical challenge for official crisis management (Drabek and McEntire, 2003). Convergers may 'overrun' local infrastructure (Fritz and Mathewson, 1957), deplete resources (Cone et al., 2003) or overwhelm those trying to coordinate response (Drabek and McEntire, 2003). An over-abundance of helpers in the disaster area may even engender more victims (Dynes, 1994b). Emergency and relief organisations have adopted concepts to address personal and material convergence. Examples are the Volunteer Reception Center of the US Federal Emergency Management Agency or the Operations Coordination Centre, employed by the United Nations Office for the Coordination of Humanitarian Affairs. Both are concepts intended to cover the reception of individuals or whole organisations, respectively. While (some) organisations have procedures at hand to handle physical convergence, Waldman and Kaminska (2015) propose virtual reception centres, which could yield benefits for both volunteers and formal relief organisations. However, little literature is available on digitalisation of volunteer reception on site.

If spontaneous volunteers' convergence on a disaster site is inevitable, then their participation in relief efforts

[1] The convergence of goods and information impose their own. separate problems; relating to supply chain management and information management, respectively. Even 'official' convergence is problematic (Dynes, 1994b; Fritz and Mathewson, 1957).

should be actively managed – to prevent injury or damage, to reduce disruption of organised response, and to increase effectiveness of CDM (Sauer et al., 2014; Whittaker et al., 2015).

Efforts of Civil Society during the Migration Crisis in Austria

September 4th, 2015, saw the beginning of the 'March of Hope', which heralded the height of the migration crisis for Central Europe: over 500 people, on their way westwards to seek refuge, broke their immobilisation near Budapest's main train station by proceeding on foot towards Austria (Kallius et al., 2016; Kornberger et al., 2018). This led the Austrian state to open its borders. Subsequently, efforts of the civil society played an essential role in providing aid and shelter for newly arriving migrants, thereby averting a humanitarian catastrophe (Simsa, 2017). A lack of response from state institutions prompted collective action of citizens – for example, humanitarian relief at Vienna's main train station was operated by a volunteer movement that had not existed before (Kornberger et al., 2018). This was a highly visible, if just one of many, examples of citizen activism to cope with the influx of refugee seekers. Approximately 300,000 would cross the borders of Austria (population 8.7 million) until the end of the year, posing a continuous humanitarian and logistical challenge (Kornberger et al., 2018).

METHODOLOGY: STUDY

This study was set up immediately following the extensive efforts of civil society during the migration crisis in 2015. We investigate the following research questions from the viewpoint of the formal crisis response system:

RQ1 How was the spontaneous volunteer effort during the recent migration crisis perceived by representatives of the formal response system?

RQ2 What organisational structures, measures, or tools were in place to integrate spontaneous volunteers into formal relief efforts?

RQ3 What were the obstacles encountered in the integration of spontaneous volunteers into formal relief efforts, if any?

To address these questions, we conducted two group discussions and two complementary interviews. Both group discussions were held with representatives of formal organisations that provided disaster relief as part of their ongoing work. Interview partners were representatives from public agencies, mediating between formal organisations and volunteers. The participants and their referential identifications are given in Table 1.

Affiliation	Participants	Method	Denotation
Formal relief organisation	CDM professionals from tactical and operational levels who worked with volunteers over the course of the migration crisis.	Group discussion	*<f-1>…<f-6>*
Mediation agency	Persons in leading roles who work to conciliate formal organisation's open volunteer positions and citizens who want to become active as volunteers	Semi-structured interviews	*<m-1>,<m-2>*

Table 1. Study participants

While group discussions examined the challenges that the formal response system experienced in the involvement of untrained citizens, the interviews investigated mediating agencies and how the crisis changed their work routines. Group discussions and interviews were of semi-structured nature. Detailed questions and guidelines were prepared in accordance with our research questions. However, participants were encouraged to speak freely and were allowed to deviate from the original topic to some degree.

The group discussions and interviews yielded a total of 6.2 hours of audio data. This audio data was transcribed entirely; forming our data set. Eventually, we conducted a thematic analysis (Braun and Clarke, 2006) on this data set. This approach was abductive, i.e., the themes were derived from the data (as opposed to fitting data into pre-existing themes). Coding of the data set was done according to our research questions. Encoded text passages constituted our initial data items. Data items were arranged into *topics* on a semantic level; an exemplary topic is the collection of data items addressing the use of pen and paper to register volunteers on site. Topics can exhibit a high level of inter-connectedness, forming over-arching *themes*. Identifying and describing these themes was the first analytic step not directly based on the original data set.

As themes became entangled with each other, adaptions were needed to disentangle them, while asserting their grounding in the original data set. Some themes were discarded for lack of proper grounding in the original data

set, others were merged or split to account for internal variances or contradictions of existing and emerging themes. For our analysis, themes provide both a layer of abstraction from original data and a lens through which to view and interpret topics and data items. Thus, the analysis process becomes iterative: as we discover new themes in the original data set, we can look at and interpret previously identified topics and themes from a different perspective. Sometimes this led to adaptions of existing themes. We reiterated this process until individual themes were sufficiently distinct from each other.

Our themes captured organisational and technological aspects of the interaction between volunteers and formal organisations. Themes held answers to our research questions, but did not offer a satisfactory amount of insight about their effect on relief efforts. We introduced the concept of a *dynamic view* to help us derive implications that our themes have; implications for the integration of spontaneous volunteers as an effort by command and control to conduct efficient relief. The dynamic view offers a new lense on our analysis, by asking how each theme affects relief efforts. We ensure a continued relation to our research questions by not changing the themes themselves, but aggregating them based on their meaning for the integration of spontaneous volunteers.

ANALYSIS RESULTS: DYNAMICS OF INTERACTION

Figure 1 is intended to guide the reader through our work via four dynamics (elements III, IV, V and VI). They will form the basis of discussing eventual technological support (elements A and B). The dynamics are rooted in a perceived need to contribute (element I) and affect the efficiency of relief efforts (element VII).

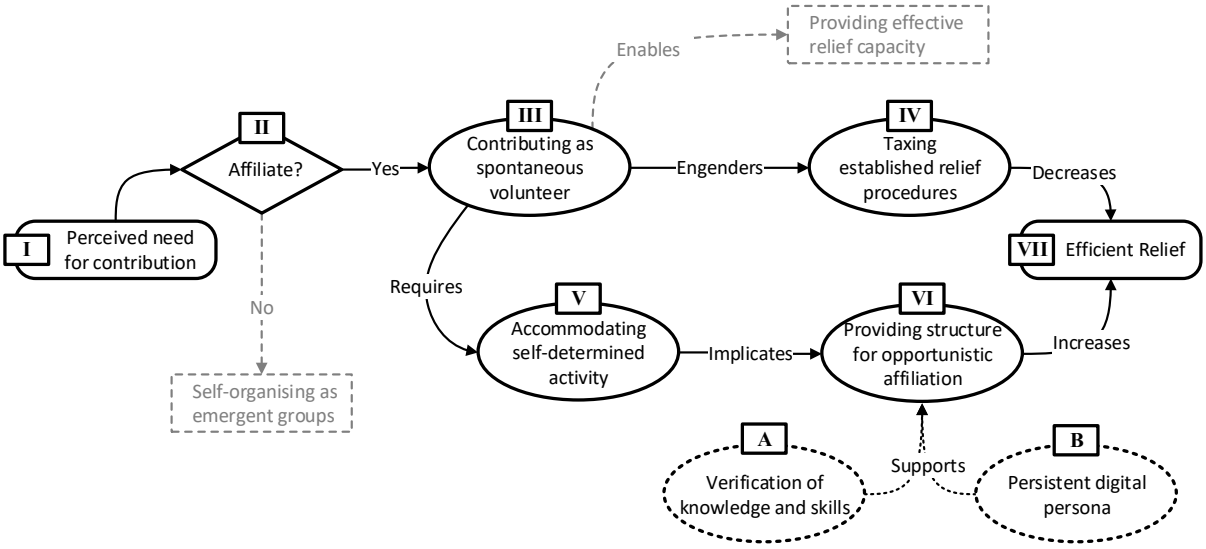

Figure 1. Dynamic view of interactions between spontaneous volunteers and emergency organisations

Motivation to Volunteer (Figure 1, I)

Volunteers in CDM are, per definition (Plagnol and Huppert, 2010; Whittaker et al., 2015), conducting relief efforts of their own free will, without coercion. Thus, their motivation must be intrinsic, i.e., be the result of their own initiative. The actuator, purported by literature (Dynes, 1994b; Lowe and Fothergill, 2003) and affirmed within our own data, is the perception of a need for one's own contribution – to 'do something'. The focus of this paper is on spontaneous volunteers (who are not affiliated with any formal organisation), in contrast to affiliated volunteers (who have registered with a formal organisation).

Becoming a Spontaneous Volunteer (Figure 1, II)

After a volunteer perceives a need for contribution and decides to 'do something', we make a distinction between two forms of volunteer activity. This was articulated by representatives of formal relief organisations in our own data.

> *Like spontaneous volunteers that came to [incident site] and said, 'I have two good hands, put me to work where you need me'. That's a different approach than going 'I drive over there with some soup and then I'll decide where to distribute it, without coordinating'. In my opinion, those are two different demographics. (<f-4>)*

Does a citizen become a volunteer, approach a formal organisation for guidance, or even for orders, or does s/he pursue activities of his or her own choice? Deciding for the latter, for whatever reason[2], entails a whole different set of problems, which exceeds the scope of this paper. Instead, we focus on citizens that intend to approach formal organisations, at least for guidance in their efforts, if not outright tasks or orders.

Contributing as Spontaneous Volunteer (Figure 1, III)

Spontaneous volunteers contrast affiliated volunteers (Whittaker et al., 2015) or permanent disaster volunteers (Britton, 1991) in three aspects, as far as our own data is concerned. Firstly, the volunteer decides time and place of their contribution. <*f-1*> recalls that many volunteers chose to participate for a limited time on very short-term notice; giving the example of someone showing up to help for two hours because they missed their train.

Secondly, a 'project-related' <*f-1, f-5*> form of volunteering, whereby volunteers choose the circumstances of their contribution, instead of entering a long-term affiliation with an organisation. <*f-1*> notes how 'the classical volunteer' will disappear over the next decades, while project-related engagement will rise – a trend they increasingly noted during the migration crisis. <*f-5*> concurs by stressing the difficulties in dealing with it.

> *This realisation that you [<f-1>] mentioned, that there are more project-based volunteers, is also noticeable for us and now there is this reflection: how do you handle that, how can you integrate that reasonably? (<f-5>)*

Thirdly, confirming previous research by Hustinx and Lammertyn (2003), <*f-5*> states how project-oriented volunteers often relate less to the organisation that provides the frame for their activity:

> *There are many volunteers at work in [relief organisation's] facilities that have basically no relatedness to [relief organisation]. Indeed, it was the case that some people, primarily with migratory background, who worked as translators, told me they never heard of [relief organisation], asking me what that is and if it's a new thing. (<f-5>)*

It stands to reason that the migratory background of volunteers was the reason they never heard of that specific relief organisation. The point, however, is that, in line with the more transitory nature of participation, volunteers may pay less attention to which organisations provides the frame for their contributions. Overall, data gathered from representatives of the formal response system suggest that there is a decreasing socialisation of volunteers in the emergency system.

Taxing Established Relief Procedures (Figure 1, IV)

Spontaneous action of individuals may lead to stress in the formal response system, decreasing relief efficiency through increased administrative overhead or contravening other efforts by unfocused action (Figure 1, IV → VII). Without guidance or information concerning the overall operational picture, spontaneous volunteers may inadvertently undertake actions that contravene other relief efforts (<*f-6, m-2*>). This includes the donation of commodities, the handling of which binds further resources (<*m-2*>). Lack of guidance may be caused by shortage of commanding personnel as well as unawareness (<*f-1, f-3, m-2*>) or unwillingness (<*f-2*>) of volunteers to integrate into command and control structures. A second stressor stems from the administrative overhead when registering newly arriving spontaneous volunteers. Formal organisations require volunteers-to-be to formally register for legal coverage and insurance. This is done mostly on premise, using pen and paper (<*f-1, f-2, f-4*>), binding resources at various levels.

To mitigate the stress of spontaneous volunteer participation, programmes for pre-registration of volunteers had previously been established and technological support attempted, c.f. (Auferbauer et al., 2015, 2016). <*f-1*> states that the purpose of such pre-registration, then, was to not have spontaneous volunteers on site, yet the situation was different during the migration crisis:

> *You couldn't put people to good use if they just showed up then, because they caused more trouble than they were helping. […] But that is different now, because now we need people who come [to shelters] directly. […] Today, in running operations, when someone comes over, they are welcomed and invited to start immediately (<f-1>)*

[2] Including: dissent regarding the objectives set or the way they are to be achieved; a lack of presence of visibility of formal organisations; or personal preference to work apart from hierarchical structures.

It appears that volunteers who were already enrolled in the organisation's volunteer programme (i.e., pre-registered volunteers) also queried information in advance; to be briefed where to go and whom to report to (*<f-2, f-4>*). This indicates that even pre-registered volunteers will not necessarily wait for orders and can be part of unwanted convergence.

Accommodating Spontaneous Participation (Figure 1, V)

Formal relief organisations try to accommodate spontaneous participation through their existing organisational structures. Yet sometimes the volume of participation outgrows the expansion capacity of these structures:

> *<f-4>:I hope [regional command] drew experience from this. That we need to educate and train more people for leadership positions.*
> *<f-3>: Yes, those were lacking-*
> *<f-4> Because helpers we had in great numbers.*
> *<f-3> […] That's because we in Austria, with our column-oriented system, expect a fixed number of required leadership positions. But that this system is suddenly expanded and additional leaders are required for the newly added structures, well …*

A 'column-oriented system' refers to an organisational structure with more depth than width; where a leader is responsible for the 'column' (of persons) behind them. The more volunteers participate, the more columns (and leaders) are needed, which can ultimately lead to a shortage on persons in commanding (leading) positions. *<f-2>* and *<f-3>* argued for greater scalability of existing structures, to better accommodate large numbers of new volunteers. *<f-1>* suggested using the time between incidents to qualify volunteers for leadership positions.

A faster and more flexible registration process for newly arriving volunteers is one possibility to accommodate spontaneous volunteers (*<f-1>*). In contrast to previous volunteer programmes, where *a priori* registration and training was required, spontaneous volunteers have the option to sign up on premise and subsequently contribute immediately. Registration was done with pen and paper to enable *ad hoc* data collection, due to the easy availability and high reliability of the medium (*<f-1, f-4>*). However, the paper-based medium has issues:

> *<f-2>: But the data of these contributors, do you submit them [into the established volunteer programme database]?*
> *<f-1>: No, that is currently not planned. At the moment, it is a mountain of paper that awaits digital inventory.*
> *<f-2>: That is exactly the challenge, yes. Well, such a sheet of paper, that has been signed, with some data on it – that just piles up somewhere.*

This suggests difficulties in information management and later analysis. Low interoperability of registrations forms between organisations aggravates this issue, as volunteers must repeat the registration processes at every organisation or site they wish to become active at. This, in turn, can lower the acceptance towards the process.

As spontaneous volunteers are not familiar with the nomenclature, procedures, and rules in CDM they need a form of leadership that varies compared to that of affiliated or pre-registered volunteers. Formal response organisations can benefit when allowing the creativity of spontaneous volunteers to manifest. As *<f-6>* puts it: 'Very good ideas come from that [inclusion of spontaneous volunteers], ones that we have not thought about before'. However, they must allow for inclusive styles of leadership.

> *And it worked best with [an inclusive] form of leadership. He [spontaneous volunteer] would probably have despaired with any commander that first instructs him on how to park so that the car is pointed toward the direction of escape and that the tank needs to be three quarters full (<f-6>)*

Providing Structure for Opportunistic Affiliation (Figure 1, VI)

The logical continuation of the accommodation of spontaneous volunteering leads towards providing a framework for what we have named *opportunistic affiliation*. Opportunistic affiliation is the act of utilising the participation structures provided by formal organisations on an *ad hoc* basis. The volunteer decides to 'do something' and acts on this decision by registering with a formal organisation on site. Both the decision and execution happen in a short timeframe. Management of opportunistic affiliation requires corresponding organisational structures. Answering *<f-3>*'s question as to the extent of the term *volunteerism*, *<f-6>* puts it thus:

> *I think you have to look at it as something larger. And that is a task for us as commanders. To not think of volunteers only as those who are overly socialised in our field anyway. Those don't need a lot of instructions. They are in the know anyway. It's more difficult with people that joined recently, that come spontaneously or especially the convergent volunteers who are there. For them, I have to provide structures of meaning[3]. (<f-6>)*

The statement implicates that volunteers can exist without formal structures and that structures can exist without a standing corps of volunteers. This represents an empathic view on volunteer management, compared to a traditional command and control approach. It holds formal organisations accountable to provide meaningful structures for spontaneous volunteers.

Participants found it worthwhile to address persons that are not actively looking for participation as part of the formal response system. <*m-2*> points out that many opportunities to participate are simply not noticeable. <*f-1*> mentions that 'a lot is being left out on the street. Potential, you know?' and <*f-4*> adds: 'because nobody asked them.' For this, <*f-3*> proposes a standardised symbol to signal volunteer opportunities *in situ*. The goal, from the authors' perspective, is not so much to attract persons that would otherwise not have become volunteers; rather, it is to make spontaneous volunteers aware that there are opportunities to become active as part of a larger organisation, instead of on their own.

A clearly visible point of contact for arriving volunteers can help formal organisations to both, distribute information and gain overview. <*f-3*> describes the need for a distinct point of reception to lower the entry barrier for spontaneous volunteers:

> *And then I'd go in and there'd be someone who is clearly visible as the person, I don't know, by wearing a hat or something, you know. I'd talk to him, he is my contact person now and knows what is going on. (<f-3>)*

<*f-1*> agrees that this could work well for small operations. However, they add that this concept would need scalability in case of major events. One person would be overwhelmed, with crowds of volunteers arriving. <*f-4*> states, with <*f-3*> affirming, that a single point of contact has been lacking during the recent crisis. Such single point of contact should also relay volunteers to their contact on site (if the contact point is not working as *liaison* outright), inform them about their insurance status, and their tasks while volunteering.

<*m-1*> reports that volunteers expend much effort at the beginning of the crisis; burning off most of their energy and over-exerting themselves. The problem of burn-out is especially prevalent for spontaneous volunteers as emergency organisations have no appropriate tools in place to oversee spontaneous volunteers on site. <*f-1*> speaks of 'helper syndrome':

> *Volunteers are in a grey area; they are allowed [legally] to work as long as they want. We had volunteers who were-- helper syndrome, they were there for 24 hours. Or longer. And they believe they must save the world and they are the only ones that can help. And you have to protect them from themselves. That is our task as organisation. (<f-1>)*

Apart from the aspect of over-extension, representatives of emergency organisations also ask for some procedure to debrief volunteers. A debriefing must include an offer for post-service support, or as <*f-3*> puts it: 'somewhere they can go if they suddenly aren't able to sleep anymore. You know, because 24 hours [working] in an emergency shelter? Hats off to them'. <*f-2*> states that, while they provided support for their equivalent of permanent disaster volunteers, they failed at reaching out to spontaneous volunteers:

> *We did not manage that so well. To reach [spontaneous volunteers] and tell them: 'listen, if you go home now and find that things are affecting you, longer and more frequently – we appreciate that you were here and helped us, but we can help you too!' (<f-2>)*

<*f-1, f-2, f-3, f-4*> agree that support structures must also include ways for volunteers to reflect on their experience and give feedback to the formal organisation.

> *<f-3>: It becomes easier for the people if they have the option to provide feedback.*
> *<f-1>: And the people want to talk about it. They are glad if they can talk about it. […]*
> *<f-2>: One can clearly see that now, when the focus lies on humanitarian help […], that*

[3] This is difficult to translate unambiguously. The original statement was, '*Weil denen muss ich Sinnstrukturen geben*'. The term 'Sinn' in 'Sinnstrukturen' can indicate both 'sense' and 'meaning', to be interpreted as 'sense of belonging' or as 'contribution with meaning'.

> *people are much more affected emotionally and on the whole. […] Now, on this matter, people write to us all the time, ceaselessly, page after page.*

Feedback can also be used by the formal organisation to draw an adequate picture of the situation for themselves and the public (<*f-1, f-3*>).

INTERPRETATION OF RESULTS AND IMPLICATIONS FOR TECHNOLOGICAL SUPPORT

Regarding *RQ1* (the perception of volunteer efforts by formal organisations), we encountered a generally positive stance on the side of formal organisations. Formal organisations tried to receive and integrate individual spontaneous volunteers, rather than attempt to suppress spontaneous contribution. With regards to *RQ2* (measures put in place to integrate spontaneous volunteers), we identified a need for rapid registration processes. The overhead of sign-up procedures and the timeframe between registration and volunteer activity are reduced; by providing reception (sign-up) on site and facilitating quick contribution. Even though measures for pre-registration had been put into place several years prior to the event, impact on preventing spontaneous contribution seems limited. Regarding *RQ3* (the obstacles encountered in the integration of spontaneous volunteers) we see challenges in the unpredictable influx of volunteers. These challenges are in part organisational, and in part technological of nature: in the organisational part, there is a lack of scalability in command structures and a need to adopt appropriate leadership styles. In the technological part, paper-based registration does not scale well over time or with an increasing amount of arriving volunteers. We discuss the implications of *RQ3* in the following section.

Implications for Command and Control Studies

While successful pre-registration programmes for volunteering are in place in Austria, the extent of self-determined contribution during the migration crisis is unprecedented in recent memory. We surmise that pre-registration programmes do not preclude a large amount of spontaneous volunteers. This assumption is based on the formation of large, self-organised volunteer groups, as described in literature (Kornberger et al. 2017; Simsa 2017; Zettl et al. 2017) and documented by high media coverage. Therefore, we propose a complementary *modus operandi*. The chain of dynamics (III) → (V) → (VI) implicates an evolving approach to spontaneous volunteering. The spontaneous nature of contributions and decreased identification of volunteers with formal organisations (III) have necessitated that the formal response system adapt to accommodate it by providing fast registration processes (V). This points towards a more fleeting form of affiliation, eventually leading to what we have named *opportunistic affiliation* (VI). Using opportunistic affiliation, citizens sign up on the spot (*ad hoc*) to conduct spontaneous participation through mature structures provided by formal organisations. Opportunistic volunteers often are (initially) indifferent to an organisation's identity and do not necessarily plan to become socialised within the organisation, or join it formally. Later, they potentially shift their affiliation to another organisation, to contribute towards a different project or perceived need.

Supporting opportunistic affiliation poses an organisational challenge to command and control structures. Two organisational changes appear crucial. First, a change to the prevailing traditional meaning of 'volunteer'; where they are affiliated with, and part of, a formal organisation (Whittaker et al., 2015). In the traditional understanding, a volunteer always exists, epistemologically, as part of *one* organisation; put differently, the system in which the volunteer exists is limited to one formal organisation. If volunteers affiliate with a different organisation, they become a different volunteer – their experience, capacity and skills not proven in the new system, thus facing a 'legitimacy hurdle' (Barsky et al., 2007). To support opportunistic affiliation, it is necessary to understand the volunteer as an entity that exists independent of any formal organisation. Second, command and control structures require surge capacity to manage the unpredictable influx of opportunistic affiliates. We hypothesise that pre-registered, trusted volunteers can be trained *a priori* for leadership positions in expanding command structures, as suggested by <*f-1*>. In this scenario, pre-registered volunteers would be deployed not only to support the relief efforts through direct contribution; but also to cope with the influx of spontaneous volunteers. Further operational requirements to support opportunistic affiliation are: visibly indicating participation options, offering a single, well-marked point of reception on-site, fast registration processes and support structures to prevent overworking.

Based on the organisational implications of opportunistic affiliation and the technological challenges in volunteer reception, we propose two applications for computational support that can help to the integrate spontaneous volunteers: 1) verification and long-term storage of digital volunteer data and 2) selective digitalisation of reception and registration processes to provide scalability.

Digital Verification of Experience (Figure 1, A)

Cone *et al.* (2003) have previously stated that 'without a means of real-time validation, [unknown individuals] are irrelevant to an incident commander' while Barsky *et al.* (2007) described how volunteers can become 'sidelined' because their capacity, background, and knowledge are difficult to verify. Quick and reliable verification of a volunteer's background and previous interactions with the formal response system could help to identify volunteers to fill gaps – or determine who is granted access to the incident area at all.

One technological implementation of this could be achieved through a distributed, permissioned ledger system, consisting of a complete list of a volunteer's previous experiences and activities in CDM. Whenever a volunteer participates in CDM, the formal response organisation adds the participation to the ledger (transaction). The transaction is verified by the organisation that enters it. Metadata can enhance transactions detailing the skills shown or gained of the volunteer. Finally, a body of formal response organisations (forming a trusted consortium) participating in the distributed ledger verifies every transaction. Therefore, any identification that is linked to transactions in the ledger enables a volunteer to immediately present a certified history of prior involvement with the consortium. To ensure privacy, read access needs to be restricted to the consortium and trusted individuals (e.g., the volunteer that is concerned by transactions). The concept of a distributed ledger implicates a persistent digital persona for volunteers, which we will discuss in the next section.

Persistent Digital Persona and Reception (Figure 1, B)

Computer supported registration processes can provide the scaling required when coping with opportunistic affiliation. While dedicated areas for registering, briefing, verifying, and tasking arriving volunteers have been proposed (Sauer et al., 2014), a digital counterpart has not been established (Waldman and Kaminska, 2015). We will discuss computational support by means of a three-stage process:

1) Registration: While digitalising the management of pre-registered volunteers has been addressed by researchers (Auferbauer et al., 2015, 2016), the registration of volunteers is still primarily done by pen and paper.

> *Now, [the registration protocol] is simply a sheet of paper. And the people at the other shelters, they don't know if this sheet has been submitted already or not. This is very important, so that [the volunteer] has insurance. We managed to make people internalise this: if there is uncertainty, fill out the form again. We can always discard it later. (<f-1>)*

Pen and paper are obtainable under most conditions and highly reliable. However, their scalability and sustainability are limited. Participants themselves suggested that this could be solved by *a priori*, digital registration 'as a self-service' (e.g., a smartphone application) while a volunteer is still on their way to the site (<*f-1*>). As part of the self-service registration process, volunteers should be linked to their contact on site (<*f-1, f-3*>). The last step, even in a digitalised registration process, has to be a personal check-in to brief the volunteer and not completely devoid this process of human interaction (<*f-3*>). From a process-oriented, technological perspective, this would be the step where a unique identifier is created and verified for the volunteer, based on the data they have entered digitally. This unique identifier is a prerequisite for the stage 2.

2) Digital Persona: if a digitalised registration process is implemented, a persistent digital persona for volunteers can be generated. There are two options for introducing a digital persona. The first option is to let the entirety of a volunteer's previous participation, as registered in a distributed ledger system, constitute the persona. The second option decouples a volunteer's personal data from their activity and implements a locally stored 'volunteer passport'. This way, each volunteer stores their profile locally on their own smartphone. Such a local volunteer profile is created during registration and is verified and digitally signed by the registering organisation.

3) Check-in / Check-out: Cone *et al.* (2003) pointed out that spontaneous volunteers are not part of any formal accountability system. This makes it difficult for official response organisations to contact them or track their presence. Such accountability would be necessary to prevent overworking (<*f-1, f-3*>), for debriefing (<*f-3, f-4*>) or for support requests (<*f-2, f-3*>).

> *It is not certain that in all cases that [volunteers] will come out of the shelters again [on their own]. Because they could get into a situation where I, representing an organisation, need to know: did they leave at all? (<f-3>)*

A computer supported, digitised check-in and check-out point can be supplied for volunteers that already have a digital persona. To find suitable locations that serve as such checkpoints will require further research. Technologically, there are multiple options for digitalised check-in and check-out points: near field

communication (NFC), radio frequency identification (RFID) or Bluetooth appear viable for fast data transmission between mobile devices and situated checkpoint terminals.

DISCUSSION

This paper presents a systematic description of the mutual effects between spontaneous volunteering and the formal response system's endeavour to accommodate it. Building on top of this description, we identified areas for improvement and gave indication for technical backing and assistance. There are two aspects about (technological) support for opportunistic affiliation that we will discuss in detail.

Privacy and Human Factors in Digitalisation

Throughout our research project, participants – emergency organisations and mediating agencies – emphasised the importance of human interaction. All participants highlighted human beings over web portals or information kiosks or billboards, when referring to contact points or volunteer receptions. Thus, even though we propose technological support, we would stress the importance of face to face interaction.

Creating persistent volunteer personae entails transparency that can both: foster trust and harm personal privacy. Volunteers must, at all times, have sovereignty over their data, the procession thereof must be transparent and data procession must not happen without explicit permission. However, even data that is shared willingly has implications when recording a volunteer's activity. If a volunteer's data becomes public (as the result of a data breach, policy change, etc.), it can have unintended societal effects. Volunteers may experience negative backlash, as during the migration crisis, or receive retro-active benefits for their past volunteer activity. Especially the latter can encourage misuse of the system, e.g., tempering with digital profiles.

Temporal Event Progression and Relation to Emergent Groups

Figure 1 shows a model of the interactions between formal response organisations and spontaneous volunteers during the response phase of an event. However, these interactions are embedded in larger temporal and organisational context. Figure 2 depicts said context. Elements related to opportunistic affiliation are represented by shaded elements.

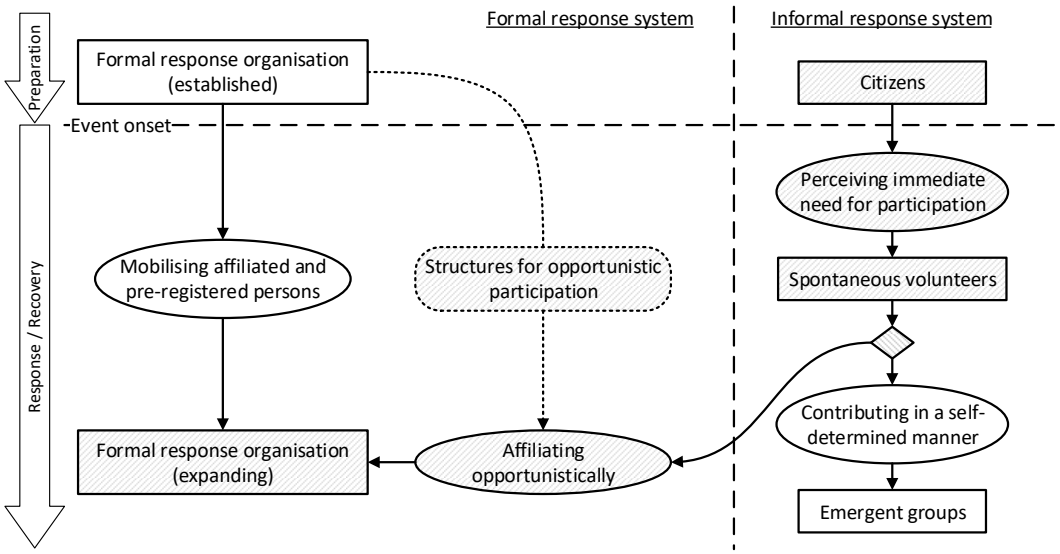

Figure 2. Temporal and organisational context of spontaneous volunteering and opportunistic affiliation

As depicted by the right-hand side path of Figure 2, citizens that do not become affiliated (opportunistically or otherwise) may participate through their own devices in an informal response system. When unaffiliated citizens collectively address perceived shortcomings in response efforts, if demands for relief are not met or existing structures are insufficient, self-organisation will result in *emergent groups* (Drabek and McEntire, 2003; Quarantelli, 1994). Emergent groups do not exist before a disaster and form new structures *ad hoc* in the power vacuum that may occur in the event's immediate aftermath (Lowe and Fothergill, 2003; Simsa et al., 2018). Research on emergent groups in the context of the migration crisis has been carried out by others. Simsa et al. (2018) link the formation of emergent groups to the inability to flexibly incorporate spontaneous participation in formal structures. Kornberger et al. (2017) point to the attractive opportunities for participation that emergent

groups offer spontaneous volunteers. Through their highly flexible structures, emergent groups present a favourable option for spontaneous volunteers, even when formal organisation have established presence. Thus, emergent groups have been proposed as intermediaries (Zettl et al., 2017) or links to spontaneous volunteers (Skar et al., 2016). Our work suggests that emergent groups are bolstered by spontaneous volunteers who have acted neither on offers for pre-registration, nor options of opportunistic affiliation (assuming these exist). Thus, we currently see two potential approaches for command and control to address spontaneous volunteers and emergent groups:

1) Offer forms of participation that are equally attractive as those of emergent groups. In this paper, we discussed opportunistic affiliation for that very purpose.
2) Accept emergence of self-organised groups and utilise their maturing structures as buffer between formal response and convergent, spontaneous volunteers.

CONCLUSION

Volunteers are an important part in crisis and disaster management, as they can provide surge capacity, but also flexibility and creativity. However, volunteers become more self-determined and spontaneous in their decisions to contribute, shifting away from long-term affiliation and detaching from formal response organisations. This autonomous and spontaneous behaviour poses a challenge for command and control structures: to integrate the activity of such spontaneous volunteers into traditional methods and procedures. Doing so is necessary, not only to utilise the capacity of spontaneous volunteers, but also to mitigate disruption of formal response efforts and prevent loss of health.

In this paper, we give a systematic description and analysis of the dynamics that emerged between spontaneous volunteers and formal organisations during the migration crisis affecting Europe in 2015. The increasingly short-term forms of volunteering lead formal organisations to accommodate spontaneous volunteers, especially through the adaption of registration procedures. The extrapolation of this trend leads to opportunistic affiliation, where structures of formal organisation are used for short-term volunteer participation, on the spot. This requires a high degree of flexibility that information technology can help to provide. We show how digitalisation of volunteer reception and a digital, secure, distributed information storage can be used to achieve both: better scaling of spontaneous volunteer management, and building trust. Implementing such a system facilitates opportunistic affiliation, one possible approach to spontaneous volunteer management.

ACKNOWLEDGMENTS

We would like to thank the participants of our group discussions and interviews for their time and contribution.

ABSTRACT

Disaster response operations require communication and coordination between agencies that seldom occurs in everyday workday situations. Furthermore, in such hybrid environments it is necessary to establish a common operational picture for the responders involved to support collaborative decision-making. The emergency responders must gain situational awareness, and this can further affect the quality of how they deal with the situation. Training in emergency situations is shown to be efficient for learning. In order to understand the complexity of working in unpredictable environments, an analysis of an audio-log from a large-scale drill was carried out. Moreover, this paper provides a definition of several categories for identifying the processes to establish situational awareness and a common operational picture among emergency responders. The analysis process revealed how the actors communicate and revealed an overall communication pattern.

Keywords

Full-scale drill, elicitation methods, situational awareness, common operational picture, information needs.

INTRODUCTION

In many complex emergency settings, both those that are man-made and natural disasters, the emergency response organizations must collaborate and understand different situations before appropriate life-saving decisions and preventions of major damages can be made. This requires planning, exercises, robust radio networks, professional actors and custom technical solutions. Developments in society indicate that the emergency organizations will face more complex operations in the future and meet new types of situations. The incorporation of the new technologies and improved collaboration and information sharing modes have added to these complexities. Taking Norway as an example, a new emergency platform (nødnett) has been operational in all districts of Norway since 2015 (nødnett.no). The system was intended to enhance interdisciplinary communication between emergency services and other organizations participating in rescue and emergency work.

Literature has revealed that the quality of the response and recovery efforts is directly linked to the knowledge and skills possessed by the staff working at disaster sites and their ability to put them into practice in a range of hazard events (Schaafstal, Johnston, & Oser, 2001; Sinclair, Doyle, Johnston, & Paton, 2012). Training in emergency situations provides valuable experience for those involved in emergency management organizations. Studies in this area show that a common factor in failures is human errors, and poor communication between the different actors involved is, in many cases, identified as a contributing factor (Lelardeux et al., 2017). Likewise, in our example of practices in Norway, there are numerous drills that have been conducted to allow responder organizations to collaborate and become acquainted with the new technologies.

Situational Awareness (SA) and Common Operational Picture (COP) are two important properties required when various emergency response stakeholders must cooperate to handle a large crisis with multiple events that might cause major critical infrastructure hazards or life-threatening consequences. The COP is created by those involved after considering the information that is available in a situation and consists of a description of what is

going on, predictions for the future, and factors such as resources and actions (Borglund, 2017). The creation of a COP is important for the success of the emergency management and it is crucial that those involved create and maintain a common situational picture of the situation (Borglund, 2017). Borglund (2017) also emphasises that the COP is important for the decision-makers to make better decisions in the coordination of the operative units through the different stages of the event. The literature describes COP as a checklist of the characteristics in a certain situation within a geographical area, and is also characterized as a display of relevant operational information, such as positions, infrastructure and different resources (Karagiannis & Synolakis, 2016). If the collaborating organizations are focusing only on their own tasks, this is a factor that limits the COP and generates information-gaps (Norri-Sederholm, Joensuu, & Huhtinen, 2017). In addition to SA, the organizations involved need to know each other's key elements, such as needs, goals, expectations, culture, capabilities and procedures in order to achieve effective cooperation (ibid).

While the idea of advancing the crisis communication infrastructure in Norway is to improve the communication between organizations, and enhance the SA and COP, there is a limitation in studies on how to analyze the development of SA and COP. This paper analyzes the SA and COP based on a full-scale drill conducted in a Norwegian city. It was a complex scenario in which multiple emergency events in three different places occurred almost simultaneously. The drill was designed in such a way that none of the involved emergency management stakeholders knew the details and had to react in "real-time" based on the information flow being exchanged. This drill focused on the collaboration in the field as well as with the command and control centers (Fire Service 110, Police 112 and Ambulance 113). The content of this article is derived from this drill.

The overall goal of this paper is to contribute to a better understanding of the complex and unpredictable working environment when the various emergency organizations need to collaborate and communicate in order to gain COP. The establishment of COP is one important aim during large police operations. Hence, the aims of this paper are threefold: First, this paper defines a method and concept categorizations that enable us to analyze the audio-log, and identify the process of establishing the SA and the COP. Second, we analyze and visualize the communication and interaction patterns between the emergency response organizations. Third, we conduct a reflection exercise to assess if our audio-log analysis method is a promising way to observe the SA and COP.

This paper is divided into five sections. The related work section reveals important related studies and the state of-the-art nature of SA and COP, while the methodology part explains the research process, data collection and data analysis. The results part presents the findings of this study and the discussion. The paper ends with conclusions and future work.

RELATED WORK

The previous studies have examined two main themes with respect to emergency operations: the bottleneck that prevents the effectiveness of the cooperation between the different agencies (Seppänen, Mäkelä, Luokkala, & Virrantaus, 2013) and collaboration both in practice and research. The challenges related to coordination in multi-agency emergency management are well documented by several studies and retrospective analyses (Comfort & Kapucu, 2006; McEntire, 2002; Perry, 2003). It is important to learn from previous events and conduct new research as new features in emergency management emerge, such as how to coordinate multi-organizational crisis communication in common call groups over radio networks. Such new and custom tools might be a solution to the fact that collaboration between emergency response organizations has been abandoned on emergency sites (Berlin & Carlström, 2011).

Several studies have been conducted focusing on team performance, and communication is an important feature for coordinating teamwork and gain situational awareness through transactions of different information (Sorensen & Stanton, 2016). Prior research on large-scale coordination in emergency response exposes several specific issues related to communication. One of the main problems seems to be that the emergency responders are unable to obtain needed information (Militello, Patterson, Wears, & Ritter, 2005). Sharing information is important, but the extent of which information that is being shared is also a factor to consider (Bharosa, Lee, Janssen, & Rao, 2009). Everyone involved has his/her own experience and professional background which is important for what information they prioritize and build situational awareness upon. This information is the basis for the action of the operative units, and for building a COP with the other organizations involved. This underlines the importance that the actors develop an understanding of the extent of the situation quickly, also relative to the use of plans, stress management and the use of technical tools (Steigenberger, 2016).

There are some factors that are significant in COP: Structure, representation, processes and management (McNeese et al., 2006). COP is a structure for available information to be collectively transformed by the actors into knowledge. COP is a representation of the knowledge, and an object that provides a process, decision and actions based on the structure and representation. Finally, it is the knowledge management that utilizes the aforementioned factors of COP that facilitate the actors` possibilities to solve the tasks in hand.

The development of COP starts from the bottom-up perspective where the actors or witnesses provide the command and control centers with basic information needs, and then the knowledge must be processed and distributed back to all relevant actors.

SA plays an important role in safety and performance. It has expanded from being used for pilots to many other domains - the difference lies in the elements you are looking for. Especially in situations where the environment is complex, the actors need to ascertain critical cues to determine which decisions to make (Endsley, 1995). In emergency management, the agencies experience chaos and need accurate information to carry out a good response. But without effective coordination and communication, which are crucial aspects of achieving COP, situational awareness is impossible to achieve (Karagiannis & Synolakis, 2016).

Another aspect of major emergencies is the information overload that is created by many inquiries which provide redundant and irrelevant information (Laakso, Palomäki, & Change, 2013). For instance, when the Command and Control Centers (CCCs) are collecting data from inquiries, they need to perceive what the basic information is, and in this case, it is the critical cues that matter. If the dispatcher does not know what critical cues to provide for SA in that situation, the potential for error will increase. There could be more than one reason as to why the dispatcher does not receive the available information; for instance, in a major event accuracy in the data collection is required because of the data overload. It is important to embrace the fact that not all information is relevant to all actors involved in the operation. Therefore, the organization`s situational understanding should involve both specific information needs for themselves, and what information they hold and need to share with other actors (Luokkala & Virrantaus, 2014). In this way those involved can both achieve SA for themselves and contribute to collaborating with regard to the actor's SA. There are three levels of SA. Endsley (1995) describes them as following:

At level 1 SA, the perception of the elements in the environment is crucial. At this level, the actors must use their senses, and in a CCC this means audio and the information they can get from the applicable technological tools (Geographical Information Systems (GIS) and other Information Systems such as health or alarm systems). An example would be a car accident where the eye-witness would report the information and some understanding of the surroundings. The GIS would relate, approximately, the location of the accident, and information about the topography. At level 2 SA, the emergency management actors would need to put together the information from level 1 and make sense of it. They would need to understand the "so what" of the information. For instance, the degree of damage to the car would indicate the energy involved and, further to this, the trauma inflicted upon the passenger. At level 3 SA, the experienced dispatchers would be able to project what might happen in the near future, such as a car in the middle of the road providing a risk of a new accident with other cars driving into it.

Several studies show that one of the key factors in human errors involves challenges related to SA (M. R. Endsley, 2018). For instance, at level 1 SA, the dispatcher may fail to perceive the critical cues that are important. There are several reasons for this, for instance a failure in the system or lack of reliable information (Endsley, 1995). In many cases, the lack of an adequate or internal model for streamlining data collection (ibid) can be the cause of errors. Furthermore, at level 2 SA, the dispatcher can misread cues and not consider them to be important for reaching the goal/s in question (ibid). If the actors fail to predict and prevent situations that can result in more damage or new dangerous situations, the reason might be missing level 3 SA.

SA depends on information that can be uncertain and highly volatile (Nunavath & Prinz, 2016) and the organizations often have challenges in finding data that fill their own information needs, and data heterogeneity between the actors is a common problem (van den Homberg, Monné, & Spruit, 2018). If the actors involved focus only on their own tasks, this is a factor that limits the COP and generates information-gaps (Norri-Sederholm et al., 2017). In addition to SA, the organizations involved need to know each other's key elements, such as needs, goals, expectations, culture, capabilities and procedures to achieve effective cooperation (ibid). SA will provide the involved actors with the opportunity to establish COP on the basis of the knowledge on common needs and the possibility to share critical information. In this sense, if not all agencies have SA, they will not achieve COP and, moreover, if they do not achieve COP, the SA will not be sufficient to take action in a multi-agency operation. Therefore, the SA and COP are closely connected and complementary to one other.

A technical solution and reliable environment for collaborating communication are important for the effectiveness of the multi-agencies' (Steigenberger, 2016) possibilities to create COP. There are different call groups in such radio network solutions, and one of the reasons for this is to avoid overcrowded information in one call group, but this is also a reason why information gets lost and fails to reach all relevant actors who would benefit of the information (ibid). In many cases, there are instructions on how the call groups should be used, and how they are required to enhance collaborating and building COP. This communication should ensure that the shared information is passed to the right receiver at the right time, and the information must be important for the SA.

To sum up, previous studies have highlighted the importance of COP, SA, crisis communication, supporting technologies and team collaboration. However, there are limited references on the methodology of how we understand what actually happens with regard to the COP, SA and crisis communication from time to time during the response. This paper attempts to offer a methodology to evaluate SA and COP *during* the response, particularly from the outset of the events until point at which the crisis stakeholders gain control of the situation.

METHODOLOGY

The overall approach of this work was a qualitative method. We combined observation, audio log analysis and interviews with the crisis management stakeholders. However, the main analysis of the situational awareness and crisis communication was based on the audio logs. The observation was carried out during the course of a drill in the field and in the relevant command and control centers (CCC). Both observations and the interviews served as confirmation if there were uncertainties in the audio logs. The methodology is based on an open coding approach which is frequently used in qualitative studies of the characteristics of communication (e.g., Panagiotopoulos, Barnett, Bigdeli, Sams, & Change, 2016).

Crisis response practice in Norway is based on an emergency radio network solution (Norwegian Public Safety Network – Nødnett). This technology is built on TETRA, which is a secured, encrypted communication infrastructure. During an emergency, the CCC will establish several custom call groups, for example a BAPS call group (fire services, ambulance and police services), a SAMVIRKE call group (used in operations which are not defined as rescue operations and where the CCC with their operative units needs to collaborate with actors who do not have access to BAPS). These call groups facilitate expedient and effective cross-sectional communication, and simultaneously ensure confidentiality and security. Additionally, there are other local call groups that are used internally in the agencies. In total, there are 13 call groups that can be established, depending on the type and severity of the crisis. BAPS is controlled and administered by the police. When talking through the radio network, there is a log system that records the conversations.

We made use of the audio logs from BAPS in order to analyze COP, SA and communication patterns in the multiple crisis scenarios of the drill (see Section Scenarios). We analyzed three audio logs consisting of 4.25 hours of recording time in each log to ensure the completeness of the information being exchanged by all actors from the involved agencies. There were mainly six actors communicating in BAPS; the operator from each CCC and the operative leaders (referring to Table 1: ILKO, ILH, ILB). Note that there were several logs of different call groups, but we only used BAPS as permitted by the emergency stakeholders. We reconstructed all the sequences of events and communications in order to make a better dataset with complete communication. The transcription of the audio logs was then coded into the following information: 1) The origin of the information; 2) The destination of the information; 3) The information content, which was furthermore grouped into a main important information exchange as listed in Table 3. This audio log was also triangulated with the real-time logs documented by the police during this multiple-crisis scenario drill.

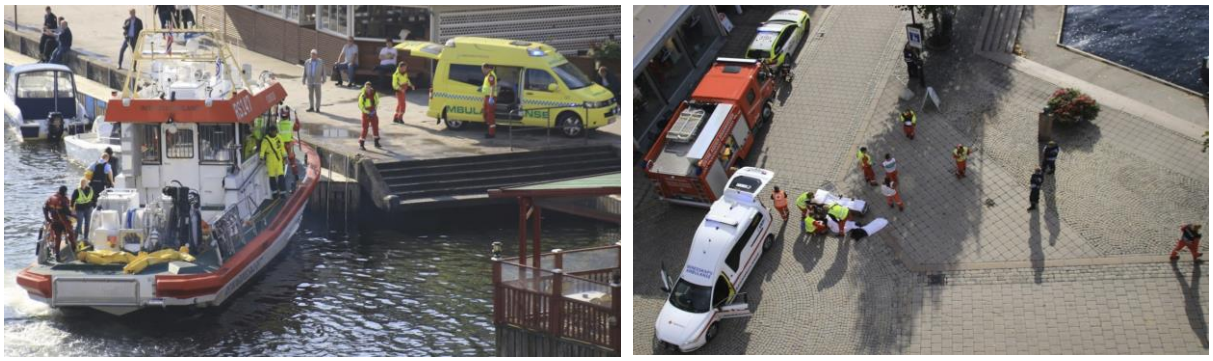

Figure 1 The drill setting in the harbor.

SCENARIOS

The scenarios were built around three different incidents that happend almost simultaneously in a city in Norway. An attack on a bus consisted of 20 student passengers (School Scenario), a traffic accident with injured people (Accident Scenario) and a large crowd attack during a music festival (Harbor Scenario). The largest and most resource-intensive effort was the one that occurred in the harbor. The drill was organized in a quite complex fashion, as it had a common goal, i.e. cooperation among stakeholders in the field and sub-goals of each organization involved. Table 1 describes some common abbreviations used by emergency organizations in Norway. The overall scenario is described in Table 2.

Table 1 Descriptions of Abbreviations used in the Exercise

Abbreviation	Description
PLIVO:	Ongoing life-threatening violence
TG:	Call group
BAPS:	Fire and Rescue services, Emergency Health services and police services – Cooperation Call group. Involved actors must listen to this call group.
FORF:	Volunteer organizations
RS:	Norwegian Society for Sea Rescue
ILKO:	Incident Commander Coordination Point, police
ILB	Incident Commander, fire and rescue
ILH:	Incident Commander Health, ambulance personnel
LA1-4	Ambulance helicopter

Table 2 describes the simplified sequences of events in the drill, summarizing the most important messages being exchanged indicating the milestones of the critical events to respond to.

Table 2 Simplified Scenario Description

Time	**Scenario events**
10:00	Emergency call: *Emergency event. Something unusual is happening on a bus at (anonymized) XX school. Uncertain about what is going on*". New emergency call: "*The bus driver has been thrown out of the bus. He is injured. The bus is driving from the scene with several passengers on board. Information about the direction the bus is going has been provided.* *Police and ambulance are moving toward the site. Opening the BAPS call group.*
10:05	Emergency call: *More specific information is received, the exact number of passengers, some description of the offender, and confirmation of the direction.*
10:10	Emergency call: *New emergency event. A traffic accident in XX intersection. Possible human injuries, unknown extent.* Police performed a triple alert (alerting all emergency CCCs in a conference phone call) and provided a common update on the new emergency event. Custom TGs and BAPS were used. Building a common operational picture.
10:15	Emergency call: *New emergency event. The bus drove into a crowd during a concert at the harbor. Several people injured. Chaos on the site*. New emergency call: *Situation update, caller has perceived the situation as a wanted event (act of terror).* Police defined the situation as PLIVO. Police need to build a common operational picture.
10:15-10:25	Emergency call: *Police CCC receives situation updates:* • *many people hit by the bus and are injured* • *some victims are under the bus, others are inside* • *people observed in the water* • *chaotic emergency site*
10:25	Alerted RS, FORF, the Norwegian Civil Defense and the municipality. Police must build a common operational picture for all agencies involved (using different TG and phone calls)
10:30	Police services had to organize assembly place for the injured/deceased The announcement of ILKO, ILB and ILH
10:30	The municipality had to establish a next of kin center
10:35	Police talked to the media
10:40	Police had to evacuate downtown (the area around the harbor)
10:40-15:00	All emergency responders focused on collaboration on assembly place for injured/deceased

RESULTS AND DISCUSSIONS

One might recall that we used BAPS audio logs as the sources for this analysis. The audio logs were divided into several parts, where the different conversations of the same timelines were split from each other. When going through the conversations the actors were identifiable (both for delivering messages and receiving messages) and the messages were systematized into broader categories, as depicted in Table 3. The categorization process involved structuring the different types of messages into categories based on the similarity of the contents and purposes of the conversations. We only present here the exchanged messages on a macro level without revealing actual conversations with regard to privacy. However, all transcribed messages are well documented and allow us to trace back all the results we achieved. This provides a picture of the SA and COP for the involved agencies.

Table 3 Communication Exchange Categories in the drill

Categories	Coverages
Situation Report	All information flows between the actors contain updated situations in the field
Confirmation	All statements showing the EM organizations have heard, known, understood, and received the information, and acknowledged that certain actions have been taken.
Action Plan	Statements which imply that the actors planned to take action in order to respond to the current state of the situation
Request	An actor requested updated information, resources or support from other stakeholders
Action	All actions taken by the responders and reported to all the participants in the call group
Common Understanding	When each agency involved in the call group confirmed that they had received and understood newly incoming situation reports.
Location	All information related to a location such as providing or confirming a current location or being in a wrong location
Contacting	An actor tries to contact one or several actors in the call group
No Answer	When the addressed actor (s) did not reply to the contact requests
Offer Resources	When one agency offers resources relative to the situation
New Emergency Event	Notifications on the new emergency events
Report Barriers	If the agencies found barriers when performed their tasks
Error	When an actor caused noise or other disruptions in the call group, for instance pressing speak-button by a mistake. An error can be either harmful or unintended for the BAPS
Information Mismatch	When actors have different situational awareness in a specific situation, for instance, if one agency is using resources on a situation that has already been solved by another agency.

As mentioned earlier, BAPS is a call group for the purpose of collaboration and information sharing. It is also used for action planning and for clarifying uncertain information for the involved actors. We need to consider that the agencies use additional other channels beside BAPS for communicating. For example, the observation revealed that the coordinators from one of the CCCs often used the telephone area of the integrated command and control system. This means that this information did not flow in BAPS. This communication was typically a one-to-one conversation. In practice, if this information turns out to be crucial for others, they must inform relevant agencies in a timely manner.

There are several possible explanations as to why the one-to-one conversation occurred: if the information is not considered to be important for all actors, it shall not be passed to BAPS. Deciding exactly what information to share or not is challenging, as is emphasized in the literature. Another explanation might be that BAPS guidelines are designed to prevent data overload.

Figure 2 shows the results of the information categorization from the drill. A large proportion of the exchanged messages are in the situation-report category - 21 percent of the messages. This is a safe way of using BAPS, simply because situation reports may be one of the most effective ways of creating a COP. But BAPS information sharing would require acknowledgement from all emergency responders. In Figure 2, the results show that only 16 percent of the messages fall into the confirmation category, which is a little counterintuitive. There are several more situation reports given than confirmations. In addition, there are several actors involved; there should ideally be a higher frequency of confirmations than situation reports as well. This is reflected in figure 1 that shows 7 % common understanding, i.e. actors from all three agencies confirming that they understand the situation report.

However, this may not portray a correct picture of the situation. The CCC observation of the drill showed that the dispatchers were simultaneously operating different tasks relative to the drill which could be the possible explanation as to why there were a lack of confirmations registered in BAPS.

The different categories can also provide an overview of the different levels of SA. For instance, situation reports can represent level 1, since they involve describing information from the situation. The actors know their own information needs and will share them with other emergency responders. The literature also mentions that it is a challenging task to capture all critical cues, and simultaneously to know the other agencies' needs.

Figure 2 shows that 10 percent of the messages involve some sort of request (request confirmation, repeating and information). These requests might represent the fact that information shared in BAPS is important for all actors, for instance for requesting confirmation ("did you hear that – this is important for you"), requesting repetition ("this is important for my operation, please repeat") and requesting information ("I need more information than I already have"). The situation reports also involve level 2 SA, where those involved update one other as to how they understand the situation. An example is when the police defines the situation as PLIVO (See Table 1 for the definition). The information they have perceived, combined with professional knowledge creates a comprehension of the situation based on disjointed elements from level 1. In this scenario, putting together the critical cues means that the actors need to consider that the situation is threatening and may result in violence, and hence take necessary measures related to that understanding. Moreover, the action category can also represent a level 2 SA, by showing that the actors need to act *in* the situation. Information from level 1 involving, for example, a bus driving into a crowd, provides an understanding of the need for health resources. Further, using this example, the categories *action planning* and *offer resources* are a sign of level 3 SA by the projection of future status. The actors project that the situation might develop into more injured people and dangerous situations.

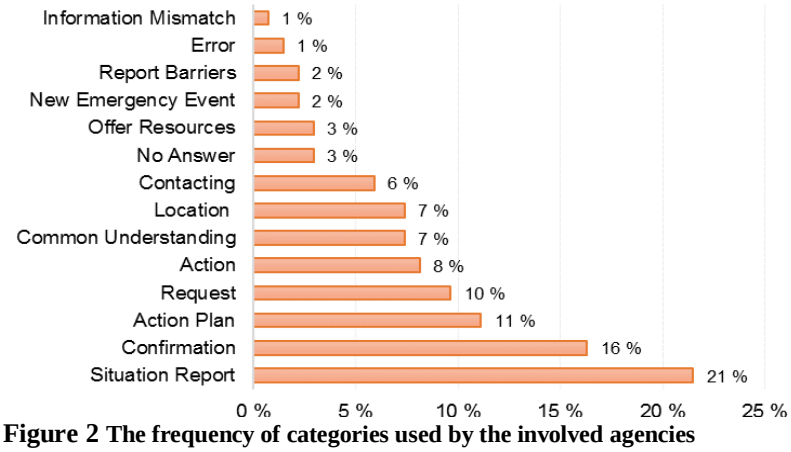

Figure 2 The frequency of categories used by the involved agencies

All involved agencies have in some degree achieved COP and the three different levels of SA. Figure 3 shows which categories the agencies` messages are divided into. We need to consider the internal communication within the agencies, and as an example, ILKO, the police operative unit and CCC112 follow each other closely in every operation and therefore we can assume that the messages are connected to all actors within the organization. The same goes for ILB, the fire operative unit and CCC110, and ILH, the ambulance team and CCC113. Figure 3 illustrates the categories that seem to be important to share amongst the actors. Considering that BAPS is a call group where common information needs are to be communicated, ILKO and ILB share information within more categories than the other actors. Figure 3 also shows that there are no obvious classifications of the categories/messages between the CCCs and the operative leaders (ILKO, ILB, ILH). The assumption as to what information that needs to be shared seems to be directly about the emergency events and does not involve coordination strategies (besides having a COP on location), nor organizational specific information (such as information about patients etc.).

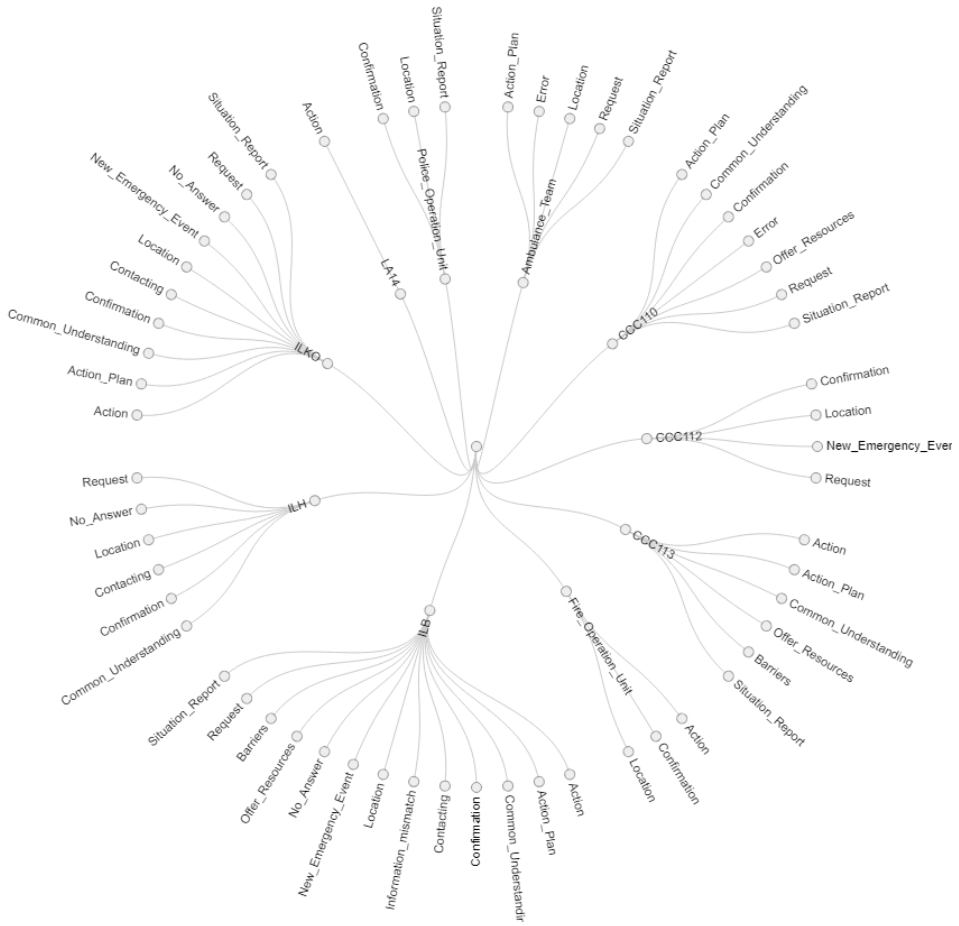

Figure 4 The categories of messages linked to involved agencies

ILKO and ILB share information between more categories and have a higher frequency of messages (see Figure 3) than do the other actors. Figure 4 shows that a large proportion of the messages in BAPS are communication between ILB and ILKO, i.e. they are either receiving a message or addressing a message directly to each other. In this case, it seems that these two actors are providing all the involved agencies with common information needs, which is natural in complex scenarios involving mass injured victims. They are on the site, and ILH carries out administration for the patients (for instance triage and transportation) and the information they hold is not typically information that needs to be shared.

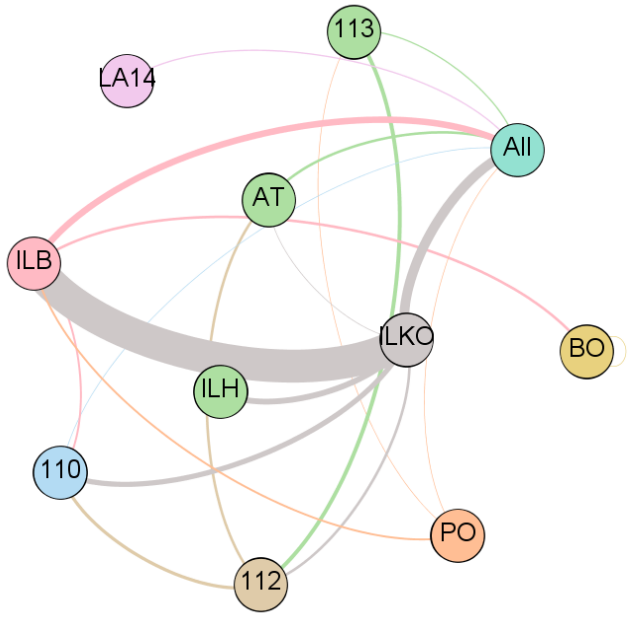

Figure 3 Information flow among involved agencies.

The information flow between the actors might illustrate the need for level 1 SA information to be reported (situational report) from the actors on the site and then be processed by the other actors involved. The information flow also can demonstrate the *structure factor* of COP, referring to the four factors of COP. Some of this information is logged by the CCCs and then the knowledge is representable for the actors with access to the log (for instance the emergency rooms that constantly view the log from CCC 113). The agencies involved have no other tools for visualization of the COP, except for a geographical information system (GIS) that shows the area and the specific resources for each agency. Communication flow is the main factor for COP in these scenarios. A common

GIS for teamwork that provides the same display for all the involved agencies (for instance placed in the CCCs) can provide a tool for explicating the four factors of COP (McNeese, et al, 2006).

The information flow in BAPS can also provide the process factor of a COP, because of the categories *action* and *action plan*. Based on situation reports and requests, the agencies hold information to build decisions and then act on them. The dispatchers in the CCCs and operative leaders on the site manage the information and, together with the collaborative actors, solve the tasks in the emergency scenario.

Using audio logs for analysis provides both great opportunities and some challenges. In this paper, we analyzed the call group for instant information sharing. This gives us the opportunity to carry out a retrospective analysis of the actual conversation during the emergency operation. The audio log systems provide the time aspect and the actual words used, which are in many cases impossible to access. By categorizing the messages between the actors and identifying the features connected to COP, it is possible to gain an overview of the involved actors' COP.

The fact that the agencies have other communication possibilities, such as calling each other in one-to-one communication, provides challenges for capturing the actors' SA in the analysis. For instance, the health services are more likely to use one-to-one communication because of the sensitive information they hold. This could also be an explanation for the much lower frequency of messages from the health services (ILH, CCC113, ambulance team) in Figure 4. Moreover, SA is a process that requires subjective data.

The COP is a factor that can be measured using the audio log such as BAPS call group because the communication provides the insiders' overview during the response stage. Other communications occurring outside of BAPS would provide very little insight, and often be unsystematic in order to be able to derive understanding of the COP establishment process. Concerning the SA, the communication outside of BAPS provides the analysis process with a much more complex component. The SA embraces all the actors' understandings of the situation, hence the internal, agency specific communication will provide SA for actors within their own professional tasks. As far as the COP is concerned, not all of the information is important for achieving this. On contrary, the analysis provided an opportunity to systematize the categories of the messages into different levels of SA. The analysis of the audio log showed that the messages between the actors involved all three levels of SA, but not the involved actors` SA of the entire operation.

CONCLUSION

We have proposed a method to analyze and visualize SA and COP from the audio log of the call group involving the fire, health- and police services. The messages could be systematized into suitable categories. This provided the opportunity to identify COP and SA features and the communication patterns during the operation. The three levels of SA were identifiable among the messages in the call group, but it did not provide a measurement for the involved agencies' SA of the situation due to the presence of internal process and communications outside formal channels that contribute to shaping the SA. Our approach contributes to improving evaluation of SA and COP during the incident response. Traditionally, retrospective evaluation of drills is often challenging because the involved actors are likely to transfer their own vision to the situation based on their own professional standpoint. (Imoussaten, Montmain, & Mauris, 2014). Our approach offers the opportunity to evaluate SA and COP in a more objective way.

The audio log provides a unique opportunity to conduct an analysis of multi-agency operations based on actual communication and the timeline during emergency operations. For future work, we plan to validate our method for real crises, or combine the methods with other qualitative methods to improve our understanding of SA and COP. We also try to relate the proposed categories in this paper to more established theories.

ACKNOWLEDGMENTS

We thank all the emergency management stakeholders in Aust and Vest Agder Counties, Norway, who have provided access to data and resources to conduct this research.

ABSTRACT

Exercises are stated to be an important means to learn how to handle crises. However, it has been discussed who should participate and what can be learnt from them. Several roles are involved in the planning, execution and evaluation of exercises, such as participants, observers, facilitators and evaluators. This paper presents an empirical study of the differences in learning experiences between participants and observers. The study was based on interviews with participants and observers involved in a series of exercises at municipality level. The result shows that the participants' learning relates to individual experiences and how well they felt they performed the task. Meanwhile, the observers' learning experiences concerned organisational issues. The findings suggest that to achieve variation in learning experiences, which is important for inventing new solutions, crisis management organisations need to allow their personnel to try different roles in the exercises to increase the learning outcome.

Keywords

Learning, exercise, crisis management

INTRODUCTION

Crises are events where substantial values are at stake and resources have to be prioritised, commonly with limited situational awareness (Boin, 2009; Borodzicz and Van Haperen, 2002; Sundelius et al., 1997). To be able to manage crises, response systems need to possess a variety of capabilities. In multi-agency contexts, essential capabilities include interaction, relationships, coordination/C2, system performance, preparedness, situation awareness, resilience, decision-making and information infrastructure (Granåsen et al., 2018).

Exercises is a means for societies to develop, maintain and ensure their crisis management capabilities (Borell and Eriksson, 2013). These are typically carried out as multi-agency, inter-organisational exercises, in which several different roles take part in the planning, execution and evaluation. Examples of such roles are participants who will do the training, observers, facilitators and evaluators (Borodzicz and Van Haperen, 2002). During the exercise, the participants carry out the tasks they would perform during an actual crisis, whereas the observers study how the tasks are carried out and how the exercise is executed. Depending on the purpose with the exercise, the participants and the observers learn different things.

Borodzicz and Van Haperen (2002) have argued that facilitators and observers learn from crisis exercises, albeit other things than the actual participants. Participants gain experience and knowledge about their functions, while observers and facilitators gain an insight into how the process works, which is useful to the evaluation and organisational development. In healthcare, Reime et al. (2016) performed a simulation exercise with student nurses, where some of the teams were participants and others were observers. In the study, six learning criteria were defined. The result showed that three of the criteria represented a higher level of learning for participants, whereas in three there was no difference. The observers in the study felt that to gain more confidence in a situation, more hands-on experience was required. Still, one conclusion was that it is important to learn from different roles. Furthermore, in a similar study, Lai et al. (2016) stated that learning effects among participants are not superior

to those among observers, even if their study showed that participation improves the ability to perform the task assigned more, compared to merely observing it. Hence, it has been claimed that observation could be beneficial for gaining more effect from resource-intensive exercises. Studies that relate to this issue have been performed, but there is a lack of empirical studies within the context of inter-organisational crisis management exercises focusing on learning capabilities rather than individual skills.

The objective of this paper is to explore whether there are qualitative differences in learning between participants and observers in crisis management exercises. Furthermore, the objective is to explore what the differences consist of and how they relate to learning, reflective capacity and creativity. The study was performed during a series of crisis management exercises involving the municipalities in the county of Östergötland, Sweden.

BACKGROUND

The process of learning through exercises is important in order to develop crisis management capability. This section presents theories of learning and different types of exercises.

Exercises

Crisis management exercises are proactive events, which are held to strengthen the participants' crisis management capability (Grunnan and Fridheim, 2017). Hence, participation in exercises is a means to strengthen skills and capabilities to handle a crisis.

Different types of exercises have been suggested to increase capability in crisis management. These could be discussion-based (e.g. seminars and workshops), or operation-based (e.g. drills and functional exercises) (Grunnan and Fridheim, 2017). According to Peterson and Perry (1999), tabletop, functional, and full-scale exercises are common types. Collaboration exercises consist of both drills and strategic exercise elements (Berlin and Carlström, 2015). The aim of these exercises is to bring actors together, in order to jointly solve situations by complementing each other's abilities.

Tabletop exercises are discussion-based exercises where the participants examine a given situation (Steward and Wan, 2007). In this form of exercise acting is not required. Instead, the participants discuss how they intend to act (Van Laere and Lindblom, 2018). *Simulation exercises* is a form of tabletop exercise, in which the participants act out their functions in real time according to a scenario. A simulation should reflect reality as closely as possible, so that the participants can experience elements such as time pressure, uncertainty and inadequate information (Borodzicz and Van Haperen, 2002). *Functional exercises* are more complex than tabletop exercises and focus on one or a few functions (Perry, 2004). Focus is commonly on management level and on the coordination between actors and organisation. *Full-scale exercises* are aimed at testing all crisis management functions, including those that represent the "boots on the ground" (Perry, 2004).

Learning

Learning is the process of acquiring knowledge, behaviours, skills, values and preferences, which can be seen as continually ongoing. Learning can be intentional or unintentional, and it can have a wanted or unwanted effect. The theory about learning is extensive, where different ideas and directions are promoted in different research fields, such as educational psychology, neuropsychology, experimental psychology, and pedagogy. In this section, some of the learning theories that are applicable for understanding learning in and from multi-agency, inter-organisational exercises are presented.

Organisational learning is regarded as individual experiences encoded into rules, roles and routines that guide the behaviour of the organisation (Levitt and March, 1988). In this way, knowledge and experiences are maintained in the organisation, even if individuals are replaced over time. Argyris (1977) described organisational learning as single and double loop learning. *Single loop learning* occurs when organisations upgrade their procedures, e.g. due to problems discovered during an exercise. *Double loop learning* occurs when organisations perform more fundamental changes, e.g. changing rules of engagement, business goals or policies.

Experiential learning is the process of learning through experience (Kolb, 1984). It is based on principles originating from ancient times, such as those of Aristotle. Later, Kolb (1984) developed a modern theory of experiential learning based on the work by John Dewey, Kurt Lewin and Jean Piaget. One idea of the theory is to make the participants more involved in their learning. Lewis and Williams (1994) stated that a simple form of experiential learning is *learning by doing*. Participants learn through their own perceived experience followed by reflection. This may result in new skills, new abilities or new ways of thinking. Experiential learning can be carried out as field-based experiences and classroom-based learning. It is held as a powerful and proven approach

for learning, based on the idea that people learn easier through experience. Experiential learning in the form of an exercise is claimed to be an effective tool for learning multiple competencies context (Silenas et al., 2008).

Situational learning takes place in the same context in which knowledge, skills and abilities are applied (Lave and Wenger, 1991). The learning process is ongoing and occurs among individuals engaged in social activities. The learning process is natural and knowledge cannot be separated from the situation.

According to Borodzicz and Van Haperen (2002) and Reime et al. (2016), hands-on experience is important for learning, but the learning outcomes in different roles of participation, for example, observing and teaching, vary. As one crisis is different from another, learning crisis management requires variation. Variation theory in learning implies that an individual could transfer learnings from one situation to another. Through variation in exercise scenarios, it is possible to learn generic skills that could be used no matter what kind of crisis needs to be handled. For example, types of crises are changing (e.g. forest fires and earthquakes), but crisis management systems need to be able to share information, coordinate actions, etc. (Borell and Eriksson, 2013).

Reflective process

Reflection is an important stage in the learning cycle for experiential learning and the ability to learn from exercises (Stainton et al., 2010). When participants have an opportunity to reflect on what happened during or after the exercise, experience transforms to learning. Furthermore, a participant or a team failing to solve a task provides a good opportunity for reflective learning. In these cases, a deeper learning and understanding could be achieved if the reflections focus on how the failure occurred (Stretch, 2000). The reflective process needs to be a critical examination of actions taken. It is easy to say what springs to mind, but the participants must question that thought or the actions that were taken during the crisis or exercise (Lalonde and Roux-Duford, 2013).

Reflection trough debriefing is common in crisis management exercises. The participants often perform this after the exercise. The debriefing process could be guided, video-based, or performed through questionnaires or panel discussions. It has been argued that a structured debriefing process with a significant discussion on what happened is effective for transforming experiences into learning (Borodzicz and Van Haperen, 2002; Kim, 2014).

Creativity

In crisis management, creative thinking is needed in order to apply routines in a different way (Borodzicz and Van Haperen, 2002). Further, creativity that drives innovations is vital for improving practices and organisation changes to better meet a changing environment and conditions (Amabile et al., 1996). Woodman et al., (1993) defined organisational creativity as "the creation of a valuable useful new product, service, idea, procedure, or process by individuals working together in a complex social system". According to Amabile (1998), creativity is based on the three components expertise, creative-thinking skills, and motivation. *Expertise* refers to what individuals know about the issue of interest, whereas *creative-thinking* requires releasing the potential of the mind to come up with new ideas. Creative thinking is based on individuals' attitude toward problems and solutions, together with their skills to amalgamate existing solutions into new combinations to provide new functionalities or capabilities.

METHOD

The present study was based on interviews with participants and observers in a series of crisis management exercises that took place in municipalities in the county of Östergötland, Sweden. Each crisis management exercise lasted for one day and included blocks of different scenarios that were performed as simulation exercises (Borodzicz and Van Haperen, 2002). The scenarios were separate and there was a restart for every scenario. Each scenario lasted for 60-90 minutes. The scenarios included a bus accident involving local students, a car hitting a crowd demonstrating in the centre of the municipality, and flooding in large parts of the municipality, leading to power failure. The exercise included a short period of time for reflections after the scenarios, albeit not in a structured manner. The aim of the exercise was to enhance the municipality's ability to work with crisis management in their organisation according to its assigned routines.

The respondents took part in the crisis management exercise, either as participants doing the training or as observers. For the participants, the exercise was performed in their own organisation. Their training involved functions in the crisis management staff. The observers came from another municipality than the one where the exercise was performed and their partaking was voluntary. They provided an observation protocol for support, the use of which was optional. As the exercise mainly took part in the same room, the observers could observe most parts.

The interviews were conducted by telephone and lasted for 15-30 minutes. As no individual learning goals had been provided for the exercises, the respondents were asked to make a self-assessment of their learning experience. Twelve interviews were performed with participants from six exercises, one to four respondents from each exercise. Of these, four were participants in the training and eight were observers. The interviews were performed in Swedish. Therefore, citations used in this study have been translated into English by the authors. The questions were divided into three sections (Table 1). The interviews started with questions about the participants' experiences, which were described in two ways. First, according to their present functions, if they had other functions in crisis management and how long they had been working with crisis management. Second, in what ways they had taken part in the crisis management exercises, that is, as participants, observers or another role. The second section included questions to the participants who done the training. The questions in this section were about the participants' expectations before the exercise and what they learnt from the exercise. The third section included questions to the observers. The semi-structured questions in this section were about what they had learnt from observing the exercise and if they would have acted differently from the participants. The interview responses were noted during the interview.

Table 1. Interview questions. The questions were asked in Swedish and translated into English by the authors.

Initial questions	Questions to the participants	Questions to the observers
Role in the exercise?	What were your expectations on the exercise and did you practice the things you expected?	What were your expectations as an observer during the exercise?
What is your present function in the municipality?	What did you learn from the exercise?	What did you learn from the exercise? Is there anything you did not learn?
Present experiences in the field of crisis management	What learnings do you bring to future work?	What did you learn that you can bring to your own organisation?
What is your experience of exercises? Participant doing the training, observer, evaluator, facilitator?	How do you expect that the results of the exercise will be used?	Would you have acted differently from those performing the exercise?
		Did you have more time for reflection as an observer than you would have as a participant?

The analysis started with the construction of interview questions to investigate the areas; (1) reflective capacity, (2) dimensions of learning (e.g. individually, team, organisation), (3) earlier experience from crisis management and (4) creativity to find new solutions. The questions were inspired by Borodzicz and Van Haperen (2002).

The analysis of the collected interview responses was performed by two of the paper's authors. Further, the analysis was carried out iteratively, where categories of similar responses were used to form themes. As more data was analyzed the themes were further refined and clarified, resulting in the final set of themes *described lessons*, *reflective capacity*, and *creativity*.

RESULT

The two respondent groups for this study were participants and observers. The participants were trained for their functions in the exercise as chief of staff. In their daily work, they held a position in the administration of the municipality, partly related to crisis management. Two of the observers had been recently employed at the municipality and observed the exercise to gain experience of how crisis management is carried out within municipalities. They had experience of crisis management and response through other organisations such as rescue services and insurance. All of the observers worked with crisis management development and strategies in their own organisations.

Experience from exercises varied, but overall, the respondents had taken part in an exercise more frequently as a participant doing the training rather than as an observer, facilitator or planner of an exercise. In general, those with more experience had both planned and trained in emergency exercises with less need for inter-organisational

collaboration to solve the assigned tasks. Six of the respondents mentioned that they had taken part as a planner or evaluator for their organisation in the most recent collaboration exercise held in Östergötland.

The results are presented according to the participants' and the observers' learning. Finally, the differences in learning between these roles are presented. Learning is described in the areas learning dimensions, reflective capacity, and creativity. Citations from the interviews are used to illustrate the responses.

Participants' learning

The participants in the exercise described their learning based on individual experience, for example, how they practised their own function and how they reacted to the pressure of performing crisis management tasks. One of the participants expressed the importance of feeling secure with the methods that are to be used: *"if you learn them and feel secure with them, you will not feel the same pressure and you can focus even in a stressful situation"*. Another participant wanted to test their learning from earlier education regarding how to act as chief of staff.

The participants had to solve problems during the exercise, which made it difficult to reflect at the same time since the start-up phase was intense. This meant that the participants saved their reflections until they knew the outcome of the scenario and the results of their acting. One observer expressed it as *"valuable to reflect when it is going on [the exercise]. As an active participant you do it afterwards if there is an opportunity, but in these cases it is not as easy"*. However, there were reflections that did not depend on the outcome of the crisis. One of the participants noted the importance of redundancy and replacement of personnel due to exhaustion and tiredness.

Creativity was described as the ability to apply existing procedures in new ways, which might lead to changes in how they are carried out. One example of creativity was described by a participant as *"We have cards that describe our functions in our organisation. I wanted to use them but realised that I chose to do differently to adjust to the situation we had"*.

Observers' learning

The observers described what they learnt from an overview perspective, for example, how to develop methods and train people in their own organisations. One observer described the learning as *"Their staff included decision-makers, which ours does not since it is a separate group. It is another way of working, which we could consider. It would be quicker to make decisions, but at the same time it might disturb the operational work"*. The overview perspective has advantages for organisational learning and development of an organisation.

The observers' reflections included identified differences. These were in some cases based on the observers' own experience. One of the observers stated:

> *I am probably more like the second person and therefore I learnt more from the first one [Referring to chief of staff in the scenarios]. An error that the second chief of staff made, and I realise I always make the same mistake, is to be too involved and take the task assignment from those who really should do them, so that I could have more time for the command and control function.*

Other reflections was made upon the differences that were discovered involved solutions to problems found by the participants and other possible ways of solving them. The solutions mentioned by the observers' mainly concerned internal issues, such as how to work with whiteboards and the allocation of work.

The observers mentioned that the role as an observer gave them more time to reflect on the cases as they did not have to handle the scenario themselves. One of the interviewed observers expressed it as *"If I am taking part in an exercise, I do not have time for reflection. I have to save that for afterwards"*. Instead, the observers had the opportunity to reflect before or in parallel with the progressing scenario. This means that the observers reflected before the outcome of decisions and acting were clear.

To be able to reflect during the crisis management exercises, the observers required knowledge of the system they observed. In their reflections, the observers often related to themselves or to their own organisation. One of the observers also expressed that *"it is important to have knowledge of their work to be able to reflect. It will probably be less valuable if you observe a completely different organisation"*.

Observers are not under the same pressure as participants to solve problems and issues in an exercise. For the participants the task at hand is more important than reflection on their actions, even if it is an exercise. The observers involved in this study could both reflect on how to act in the situation and compare this to how they themselves would have acted. This was expressed by one of the observers as *"the comparison to your own acting is made instantly, but you are not under pressure to act in the situation"*.

In two of the exercises, there was more than one person observing. In these cases, the observers also related their reflective process to the opportunity to discuss with others who made their observations in parallel with the scenario, which was described as positive by the observers.

There were opportunities for the observers to be creative by using an overview perspective to find other solutions to the problems that occurred in the exercise scenario. For instance, one of the interviewed observers pointed out the importance of viewing the situation from an external perspective and concluded that this is easier when observing and not having to focus on a more obvious task, as could be the case for those training. This was expressed as *"it was easier to think from a third person's perspective, for example, with the bus crash. The exercise participants started to act and plan. I could empathise with them and think about how I would have reacted if my son was on the bus"*. Another observer reflected on previous experiences from another crisis organisation, but at the same time concluded that those might not be relevant for crisis management in the observed context.

Differences in learning

The respondents' descriptions of what they learnt in the exercises imply that the participants focused on their own performance and capability to solve the tasks at hand. The observers focused on learnings and development for their organisation, but also their own learning (Table 2).

Table 2. Differences between participants and observers regarding *described lessons*.

Observers	Participants
How to train people in their own organisation	Practice their functions
Discover what types of equipment that could be used, such as whiteboards, maps, working space	Try things learnt from lectures or assessment reports in earlier exercises
Learn about another organisation	How they react under pressure
Roles and mandate of a municipality function	Using their organisation's routines
How they themselves would act in a certain function	
Discover what methods could be used to solve the assigned task	

Even if there is time for reflection after an exercise, there is a difference between when in time reflections are made; during an ongoing event or after the event (Table 3). As the observers in the present study had time to reflect on the situation in parallel with the scenario unfolding, they had opportunities to find alternative solutions to problems the participants did not find due to the pressure of handling the situation. At the same time, the observers had a clearer view of priorities in the scenario and what should be done first to solve the crisis as best as possible. The observers identified lessons applicable to the organisational perspective and lessons for upgrading organisational procedures. By obtaining an overview of the exercise scenario, it is easier to spot processes rather than tasks. Still, the participants' reflections on the applicability of the methods are useful in an evaluation.

Table 3. Differences between participants and observers regarding *reflective capacity.*

Observers	Participants
Make reflections in parallel with the scenario and reflect on different actions without knowing the outcome	Make reflections after the exercise when the outcome of the exercise is known
Make reflections and compare them to themselves or their organisation	Make reflections on their own performance (and in some cases relate these to their organisation)

It was difficult to discover creativity in the interviews and, consequently, differences between the roles (Table 4). Some of the answers indicate that the participants were creative in the way they used the organisations' routines. The observers, on the other hand, were creative in the sense that they found other solutions to the problems that the participants were too stressed to find.

Table 4. Differences between participants and observers regarding *creativity*.

Observers	Participants
Do not need to handle situations and can therefore identify other possible solutions of the problem	Opportunity to adapt the routines in new ways

DISCUSSION

Exercises are an important means to achieve experiential learning, in terms of acquiring knowledge, behaviours, skills, values and preferences (Kolb, 1984). Thereby, exercises can contribute to the development and maintenance of organisations' capabilities, which is also valid within the field of crisis management (Silenas et al., 2008). However, carrying out inter-organisational crisis management exercises is costly and time-consuming. Hence, it is vital to gain the most out of these exercises. One possibility is to explore if other roles than the participants could learn from the exercises. The objective of the study presented in this paper is to explore whether there are differences in learning between participants and observers in crisis management exercises.

The result of this study shows that both participants and observers learn, but that there are differences in their learning. The participants described what they learnt in terms of how they performed during the exercise. They also expected to practice hands-on skills. The participants' learning was experiential in that they were learning by doing. This theory of experimental learning points out the importance of reflecting on an experience to be able to develop new skills and new ways of thinking (Lewis and Williams, 1994). The observers described gaining new insight when relating the performance of others to how they would have acted. The participants raised questions on how they performed, whereas the observers raised questions on how they would perform to achieve an optimal outcome if they were exposed to the same situation. This double loop oriented learning did not give the observers hands-on practise, but prepared them for handling similar situations in the future (Argyris, 1977).

The observers' main lessons learnt were more related to theories about organisational learning (Levitt and March, 1988). This could be due to their purpose as observers, since they wished to develop their own organisation through good examples by others. The observers mainly described their lessons learnt in terms of a possible upgrade of routines and methods in their organisations, rather than learning individual skills. Still, learning individual skills and improving organisations are both important for developing crisis management systems and enhance their capabilities for solving future crises.

Furthermore, the participants reflected on their actions when they knew the outcome of the scenario, which might have hampered any attempts to discover alternative ways of acting. The observers, who made their reflections in parallel with the scenario, evaluated alternatives with a more open mind. Kim (2014) described debriefing as an opportunity to discuss what happened during an exercise and what lessons could be learnt from it. In the studied exercises, no structured debriefing was carried out. However, debriefing sessions could provide a deeper understanding among both participants and observers, i.e. enhance the effect of reflection, due to their different input in the debriefing discussion.

Few interview answers related explicitly to creativity. The exception was examples where participants were creative in applying their routines. Still, creativity is important to effectively solve crises by applying rules and procedures in different ways (Woodman et al., 1993). However, the opportunity to be creative could be limited by the purpose of the exercise, if the aim is to train established crisis management routines. For the observers, creativity might accrue when they initiate the process of applying what they learnt in their own organisation. Still, there are opportunities for creative thoughts even when observing the exercise.

This study had an explorative design. Aspects that might have affected the outcome of the study are, for example, the different purposes for the partaking participants and observers. The aim of the exercise was too test municipality routines. For the observers, the purpose was mainly to find good examples to bring back to their own organisations. However, the results show that there are differences in learning outcomes between participants and observers. The role as an observer provides greater opportunity for reflection and organisational learning. Still, it is important to learn one's own function and how to handle pressure, which the participants pointed out as their lessons learned. As one of the respondents expressed it: *"It is an advantage to observe, but you learn by training also. You learn in different ways"*.

CONCLUSION AND FUTURE WORK

Adequate inter-organisational exercises are challenging and costly to implement. It is, thereby, important to get the most out of exercises. The conclusion of this study is that both participants and observers learn from exercises. Hence, from a financial and time-consuming perspective, it is vital to make use of the fact that others than those

participating learn from exercises. Therefore, exercise management, needs to consider how to create the best learning opportunities for all attendants when planning an exercise. An additional conclusion is that participants and observers learn different things, and they have different possibilities to reflect on events during the exercises. Hence, individuals participating in exercises can learn additional aspects of crisis management and execution of exercises by adopting other roles. As learning through exercises differs between different roles, actors in crisis management exercises need to have the chance to take on different roles to fully grasp all aspects of crisis management. This study was only concerned with what the participants and observers learnt. Future work is needed regarding what other actors, i.e. facilitators and evaluators, can learn.

ACKNOWLEDGMENTS

This paper presents a study carried out within the research project KOMET, sponsored by the Swedish Contingencies Agency. To be able to perform the study the help from the county Östergötland has been invaluable. In addition, we would like to give a warm thankyou to the respondents from the municipalities.

ABSTRACT

This work in progress paper presents an initial evaluation of the observation protocol of the Team Resilience Assessment Method for Simulation (TRAMS) conducted in a crisis response simulation project. TRAMS is designed to assess the resilience of crisis response teams. The TRAMS observation protocol uses six core resilience functions from the Systemic Resilience Model as its theoretical foundation. Three independent observers used the protocol during a pilot study and six actual simulation games. Strategies relating to three out of six core resilience functions could be identified. The observations made were distributed similarly among the observers, indicating that the components of the TRAMS protocol are stable enough to continue developing the protocol. This study describes changes made to the protocol since the original design, and describes how the strategies relating to the six core resilience functions can be identified in the simulation games.

Keywords

Simulation games, training, Systemic Resilience Model, team resilience, assessment

INTRODUCTION

How should resilience in multi-organisational crisis response teams be assessed? The increasing complexity of society creates challenges as small disruptions in individual systems may propagate across other systems and create large disruptions. Multiple actors in the financial system provide different kinds of services that jointly create the pre-requisites for services we take for granted, such as credit card payment, online payment, billing, etc. A multi-disciplinary team must thus handle disruptions. The ability to uphold these services is often referred to as *business contingencies* or *resilience*. The payment system can be described as an "inverted pyramid". At the top of the inverted pyramid is the broad base of economic actors whose daily activity in the market economy gives rise to payment obligations. This base of economic actors consists of individuals utilizing retail payment services provided by banks, and a variety of business enterprises in the goods and service industries. The next level includes specialized firms, such as brokers and dealers, involved in the money, capital and commodities market, which also rely on bank payment services. (Blommstein & Summers, 1998, p. 27).

However, the payment system is vulnerable. A cyber-attack or even a bad software update of a common cash register system may cause a nation-wide disruption to the payment system. This issue is being addressed in a project called Creating Collaborative Resilience Awareness, Analysis and Action for Finance, Food and Fuel System in INteractive Games (CCRAAAFFFTING). Reliability in highly networked critical infrastructures has

been studied before, but mostly in the form of case studies (Schulman et al., 2004; Berthod et al., 2017). The goal for this project is to develop a simulation-gaming environment (combining table top role-playing exercises with computer simulation) to present a context where the payment system is represented and where dependencies between different actors in the food, fuel, and financial domains become evident. This approach allows for controlled studies of how resilience is achieved and maintained during disruptions to critical infrastructures (Laere, et al., 2017). The long-term objective of the project is to provide tools and methods for team-training of decision-makers that are responsible for handling crisis situations in multi-organisational contexts. The project will also increase knowledge of how multi-organisational networks manage crises, which is an area in need of further study as pointed out by for example Berthod et al. (2017).

A critical issue in simulation games is the question of how to evaluate them? This paper presents progress in the development of an assessment approach to evaluating resilience in crisis response teams called the *Team Resilience Assessment Method for Simulation* (TRAMS) (Johansson, Laere, & Berggren, 2018). TRAMS was developed for assessing team resilience in simulation games, based on the Systemic Resilience model (see below). The first version of TRAMS was presented at ISCRAM 2018 in Rochester, NY. Since then, a pilot study (with student participants) has been conducted, leading to some minor alterations to the protocol. After that, data has been collected using the TRAMS, which has led to a number of additional suggested changes to the method and the protocol.

The purpose of this work in progress paper is to present the initial evaluation of the Team Resilience Assessment Method for Simulation (TRAMS) based on data from six simulation games. The results will be used to improve the design of the TRAMS observation protocol and create some guidelines in how to use it in future data collections.

The paper begins with an overview of the problem domain (the financial system) and the theoretical basis of the paper, the Systemic Resilience Model. Then, it presents the TRAMS method, the data collection, and the evaluation. Finally, changes to the TRAMS as well as implications of the initial results are discussed.

THEORETICAL BACKGROUND

Resilience is used to describe how a system critical to society, such as industry, infrastructure, finance or ecology, can absorb changes or disturbances and still persist (Holling, 1973; Foster, 1993). Resilience is not to be confused with *robustness*, or stability, which describes how much stress something can take before it seizes to function. It is possible for a system to be robust and lack resilience (Holling, 1973). The financial system is robust when considered over a longer time-period, but also sensitive to local or short-term disruptions that can cause severe cascading effects that have impact even on a global level. It is therefore of great importance to society to improve resilience of the financial system. Resilience has however been interpreted in many different ways (Bergström, van Winsen, & Henriqsen, 2015), making it hard to operationalize resilience into useful strategies and measurable indicators. Lundberg and Johansson (2015) have proposed the Systemic Resilience Model (SyRes) model, in which they have made an effort to merge and compile different points of view in the field of disaster and crisis response resilience. The SyRes model is a way to describe the process, functions and strategies of resilience on a conceptual level in an effort to synthesize different theoretical models and frameworks. The model can be seen as a downward spiral activating certain basic resilience functions and their associated strategies. It is common to divide crisis into three phases: pre-event, event and recovery (before-during-after) (Shaluf, Ahmadyn, & Said, 2003) and the SyRes model applies a similar logic. There are four different sections in the SyRes model: *Event-based constrains, Functional Dependencies, Adjustment of capabilities* and *Strategy* (See Figure 1).

Event-based constraints refer to how the event is handled which put different constraints on the responding system during different phases of the event. Functional dependencies point to the core functions that must be maintained. *These core functions are realized in the form of strategies*, which are depicted on the lower side opposite of the functions in the model. Strategies are in practice the different ways of coping with an event that relate to the core functions. It is common that these strategies are visible in terms of actions taken to keep a system out of harms, for example constructing barriers (immunize) or creating response systems (control). The core resilience functions are: *Anticipating, Monitoring, Responding, Recovering, Learning, and Self Monitoring.*

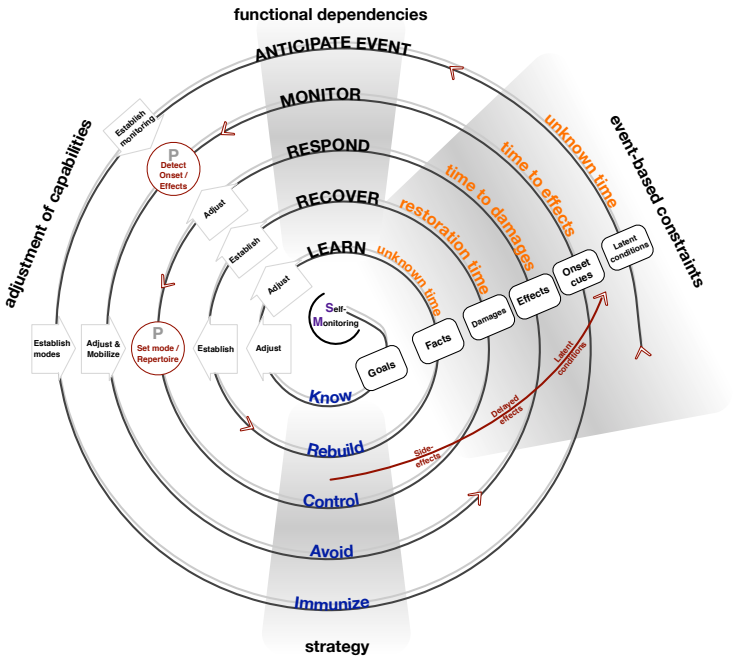

Figure 1. The systemic Resilience Model (Lundberg & Johansson, 2015. Used with permission from the authors).

Each function holds the potential to cope with an undesired development in the *before*, *during,* or *after* phases of a disturbance. For example, if a threat is *anticipated,* it can be mitigated or prevented from happening at all or if *monitoring* is directed in such a way that threats can be detected, harm can potentially be avoided. *Responding* is a consequence of anticipation or the detection of a threat, or even as a reaction to an event that is discovered first when it is already ongoing, and results in strategies for controlling the situation. *Control* is applied to minimize or avoid harm. *Recovery* comes into place when a system takes damage in some form and it needs to re-construct the system after the event. To avoid similar events and adapting ways of working in the future refers to the *learning* steps, which is an essential function to improve the resilience of the system. At last, *self-monitoring* is a continuous process to see if the current way of working is appropriate to maintain an acceptable level of safety and resilience in the system (Lundberg & Johansson, 2015). A lack of resilience manifests when there is a lack of strategies corresponding to the core resilience functions. The TRAMS instrument was created to capture the development of such strategies by teams participating in simulated, multi-domain, crisis response scenarios, hence assessing the capability of resilience of the teams.

Gaming simulation

The interconnected infrastructure in the payment system is experienced through simulation in the CCRAAAFFFTING project. Simulation generally aims at designing a model of a system in a complex problem area in order to perform various experiments (Grune-Yanoff & Weirich, 2010). In this case, the simulation includes a number of grocery stores (ranging from local convenience stores to mega-stores), petrol stations, banks and the flows of goods, fuel, and payments (both cash and by other transfers) that occur between these. The gaming approach is used to gain deeper insight into the behaviour of the participants by evaluating how various resilience strategies relating to the core resilience functions of SyRes (or the absence thereof) are displayed by team members (Laere et al., 2018). It also creates a learning opportunity since the participants are active participants in the simulation and are not just passive observers.

THE TEAM RESILIENT ASSESSMENT METHOD FOR SIMULATION (TRAMS)

As pointed out in the introduction to this paper, the initial TRAMS was presented at ISCRAM 2018. Since then, pilot studies as well as actual data collections have been conducted. **Figure 2**, describes the development process of the TRAMS protocol and method as up until this publication. The TRAMS method, and the process of updating it, is described in detail below.

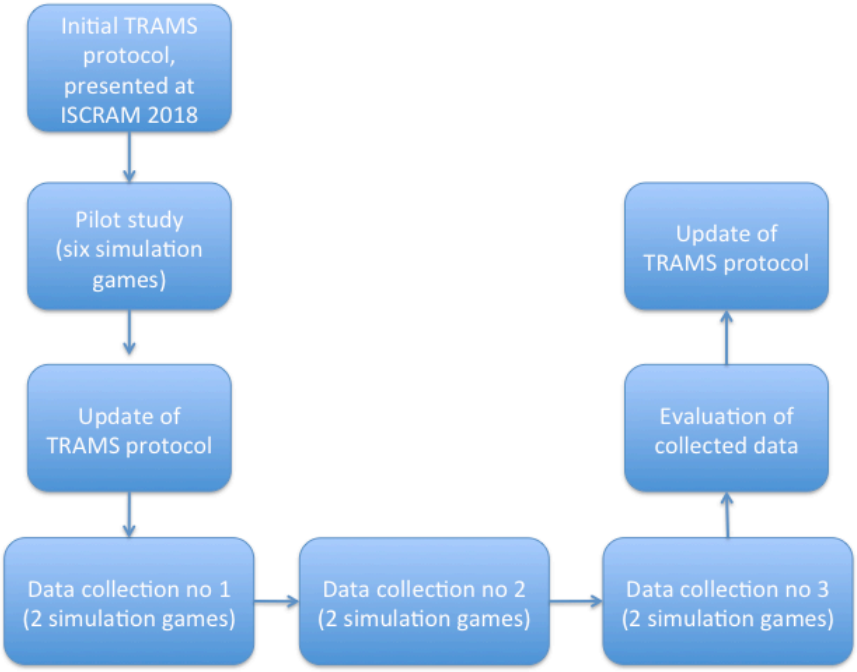

Figure 2. An outline of the TRAMS development process up until this publication.

The approach of the CCRAAAFFFTING project is founded on the premises that stake-holders in society and the financial system that normally don't work together work as a team to manage a disturbance in the payment system. TRAMS is developed evaluate if teams participating in the simulation games are resilient in the sense that they exhibit behaviors, in the form of strategies, that reflect the core resilience functions anticipating, monitoring, responding, recovering, learning, and self-monitoring. The TRAMS instrument comprises several assessments (Johansson, Laere, & Berggren, 2018), such as observations, workload (Helton, Funke, & Knott, 2014; Funke et al., 2012), team trust (cf. Willems, 2016; Seers, Petty, & Cashman, 1995), and shared understanding (Berggren, Johansson, & Baroutsi, 2017; MacMillan et al., 2005) (see **Figure 3**).

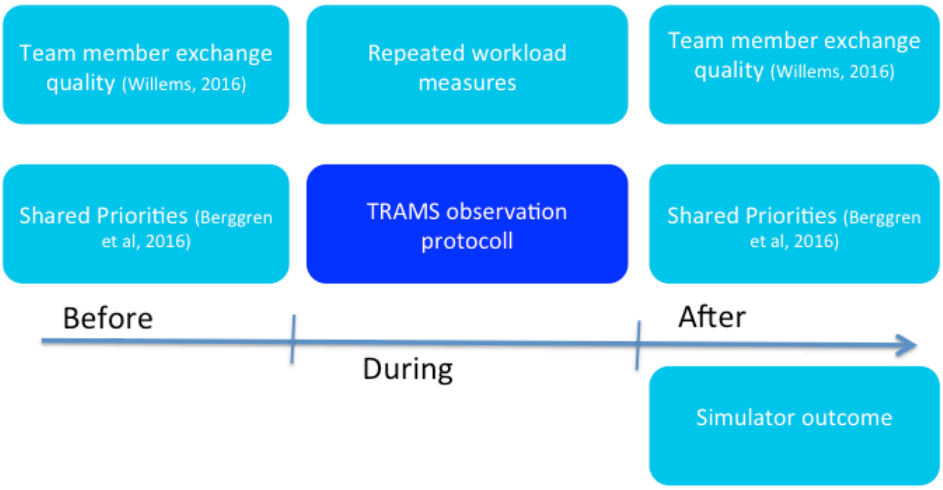

Figure 3. The various assessments of the TRAMS instrument as described in Johansson, Laere, and Berggren (2018). The focus of this paper is the TRAMS observation protocol.

While workload, team trust, and shared understanding are based on established methods, observations are supported by the TRAMS protocol, which is the focus of this paper. Henceforth, *when using TRAMS, and referring to alterations to TRAMS, it is the protocol that is meant*. The protocol, in its original design, consisted of an Excel sheet with the core resilience functions listed on the left-hand side (left column). The protocol is presented in **Figure** 4, followed by a more elaborate explanation of each column.

SyRes functions	Strategies in days 1---N	Developed by…	Core values	Involved actors	Expected effects	Implementation	Simulator outcome
Anticipating							
Monitoring							
Controlling							
Recovery							
Learning							
Self-Monitoring							

Figure 4. The TRAMS observation protocol as described by Johansson, Laere, and Berggren (2018).

SyRes functions

As pointed out, the core resilience functions of the SyRes model can be found in the first column to the left in the instrument. These functions are working as a guidance for identifying strategies that was used by the participants in the simulation during different simulated days of the simulation games. The strategy *anticipating* can take form such as brainstorming, consulting experts, discussing possible consequences of actions under consideration, etc. The strategy *monitoring* is based on earlier experience or actions in the gaming simulation. For example, checking resources or cash flow to understand the disturbance better. The strategy *controlling* is the coping of a disturbance and those actions that are implemented in the gaming simulation. *Recovery* can be based on what is anticipated, currently happening or after a disturbance has happened. For example, if a disturbance is expected in the card payment it can become less severe if all ATMs are prepared with enough cash to support such payments. Strategies relating to *learning* reflect that you learn from the disturbance. For example, creating reporting systems or assuring that experiences made during an event is incorporated in staff training. Strategies relating to *self-monitoring* takes on the form of self-criticism or reflection that alters the way the team works, for example re-organization of responsibilities within the team or changing decision mandates.

Strategies in days 1---N

The fictive days columns reflect the events in the gaming simulation. These are normally known to the researcher/training facilitator and can be described in the instrument. Strategies identified should be noted in the corresponding day. Doing so makes it possible to track what strategies that where developed in the different day. Note that several strategies may be developed in certain days while other days may include no strategies. This depends entirely on the participants and the outline of the scenario used in a particular gaming simulation.

Developed by

This column should be used to describe from whom a specific strategy originates. Was it a collective decision within the team, or did an individual participant suggest it? This information can be used to assess how well collaboration between the different participants work, who (what participant) is taking initiative, and if a certain organization is more prone to pushing strategies.

Core values

This column should reflect the core value that is affected by, or connected to, the strategy observed. This could, for example be revenue of a supermarket, or the well-being of citizens in a municipality. Core values are central to the SyRes model as they are key to the question *resilience of what*, i.e. what the strategies developed actually aims to protect.

Involved actors

The implementation of a strategy will normally involve several actors, both within the participating team and "external" (simulated) actors in the gaming simulation. If possible, these should be noted in this column.

Expected effects

Often, the participants express what kind of effects they believe the strategies they implement will have on the outcome of the gaming simulation. If this can be captured, it should be noted here. This information can be used to analyze what kind of understanding (mental model) the participants had of the scenario and their actions.

Implementation

This column is used to describe if a strategy actually was implemented and if so in what way? In this study it was very clear if the strategies were implemented since the participants needed to write down strategies they wanted to implement and hand these over to the game leader. This also makes is possible to fill in the column afterwards.

Simulator Outcome

The actual simulator outcome of the implemented strategies is noted in this column. This outcome can be used for analysis and the de-briefing session. According to Johansson, Laere, and Berggren (2018) three major performance areas are important, these are: 1) payment options, 2) goods flows, and 3) security.

METHOD

To evaluate, test, and further develop the TRAMS protocol, it was applied in a pilot study, using students as participants, and then on six actual simulation games (out of a planned set of 30 simulation games) with representatives from different stakeholders from society and businesses. In the latter case, three groups played two simulation games each. Three independent researchers applied the protocol when observing the games.

Pilot study

The pilot study was conducted in order to rehearse the procedure of the simulation games, verify that the computer simulation was working, and try the various data collection methods, such as the TRAMS protocol. The data collected was mainly used for verifying that everything worked as imagined. However, the experiences led to some alterations of the protocol. The design, instrumentation, and procedure of the simulation games were identical in both the pilot study and the actual data collection.

Participants

In the *pilot* study, three teams of students and colleagues played the roles of the crisis response teams. Each team consisted of 3-5 participants. The team members had no prior experience of the roles they were assigned to in the simulation games.

In the actual data collection, which is part of the planned 30 simulation games to be conducted, three teams of participants participate. Each team was composed of 6-8 participants from representative businesses, authorities

and public organizations. The *first team* consisted of seven members: one from the fuel distribution sector, two from food distribution (mega-store managers), one from the county administration board, one bank manager, one from the money distribution sector, and one journalist from a local radio station. The *second team* also consisted of seven persons: One from the municipality crisis management team, one from a local convenience store, one from a supermarket, one from the police, one from the money distribution sector, one bank manager, and one from the county administration board. The *third team* consisted of two members from the county administration board, one from the municipality crisis management unit, one grocery store owner, one police, one petrol station manager, one from the money distribution sector, and one bank manager.

As can be seen, the groups were not identical in their composition of competences, but sufficiently representative of the type of individuals that are likely to be involved in a crisis response during a failure of the credit card system.

Instrumentation

The simulation games were audio recorded with Zoom R8 with an Aston Spirit microphone to support note-taking with the TRAMS instrument.

The simulation is implemented and runs on the AnyLogic™ platform. The model uses a Geographic Information System (GIS) space to visualize the locations of food stores, gas stations and ATMs in a region that covers four municipalities (Lund, Malmö, Lomma, and Staffanstorp) in Skåne county, southern Sweden. The total population for the modeled region is 440,000 citizens. Typical shopping behavior is modelled based on available statistics from SCB Statistics Sweden and estimates made by the modeling team (Laere et al., 2018).

Scenario

The scenario describes a crisis in the payment system where card payments go down for ten days. In Sweden, almost all payments are made with cards and many shops even refuse to accept cash. Most people have no preparedness for a breakdown in the card payment system, and the amount of money available in ATMs is not sufficient to support a situation where all citizens needs to pay all their expenses with cash. As pointed out above, the simulation is based on a model of southern Sweden including both a large city and rural areas, is modeled in terms of stores (ranging from small convenience stores to mega-stores) and petrol stations (both manned and unmanned). All transactions, flow of goods, petrol etc. as well as customers and the amount of cash available in ATMs.

Procedure

All participants filled in a consent form and replied to a set of questions about their professional experience as well as experience from actual crisis response events. Then, the background to the CRRAAAFFTTING project was described, as well as the scenario outline for the simulation. After this, the simulation was started. During the simulation game, two researchers were available at all times, ready to answer any questions the participants had about the progress of the simulation or other concerns. The participants in the simulation game takes on the role as a crisis response council that need to suggest actions to handle the situation on days 1, 3, 6 & 9 in the simulation game. They are free to implement a number of things such as introducing new means for payment, providing information to the public, changing the number of security guards or police officers in stores and society, change opening hours of stores or petrol stations, or even close them, etc.

Three observers (denoted A, B, and C respectively) equipped with the TRAMS instrument sat adjacent to the participant team where they could see the participants and the simulation game output. There were no strict guidelines for the observers on how to use the instrument. During the simulation the observers tried utilize as many of the components of the TRAMS instrument as possible. After the simulation games, the observers compared their notes with each other and analyzed similarities and differences.

RESULTS

The pilot study provided valuable input, which led to alterations of both how the TRAMS protocol was used and the design of the protocol in itself. An important observation was that the observers should note only one strategy for each line used in the protocol to avoid mismatches in the number of strategies observed. Observers should also avoid chunking information, meaning that only one strategy should be noted at each occasion. For example, if the participants discussed monitoring sales figures for a specific store and the amount of cash available in the ATM outside the store, this should be noted as two separate observations, not one. Further, the days 1-n was replaced by individual columns in the TRAMS protocol sheet, where each column corresponds to

a decision event, i.e. days 1, 2, 3, 6, & 9.

Data from the actual data collection found strategies relating to three of the six core resilience functions; *anticipation, controlling,* and *self-monitoring*. The strategies *recovery* and *learning* were not observed during the game simulation.

The average distribution of observations over categories of strategies noted by the three observers A, B and C (percentage of the total amount of observations by each observer) from all six simulation games is found in **Table 1**. A criterion was used in order for a category of strategy to be included in the analysis: at least two observers would have to have noted the same strategy. Hence, learning is not included in the analysis as only observer B identified that. This is discussed further below.

Table 1. Average distribution of observed strategies in each category by each observer and the average total (in percent of the total amount of observations by each observer).

	Observer A	Observer B	Observer C	Total average
Anticipation	73.9%	64,2%	73,9%	70,7%
Monitoring	0,9%	7,4%	0,2%	2,8%
Controlling	25,3%	24,4%	25,2%	24,9%
Recovery	0%	0%	0%	0%
Learning	0%	0,3%	0%	0,1%
Self-Monitoring	0%	3,9%	0,6%	1,5%

On average, the observers made 109 observations per simulation game (Observer A=114, Observer B=111, Observer C=103). As can be seen in **Table 1**, and from the average number of observations conducted by the observers, the inter-observer consensus regarding what strategies were used in the simulation games is good. These numbers should be interpreted with some caution given the fact that they are based on only six simulation games.

Strategies relating *anticipation* were the most common of the observed strategies during the six simulation games. Strategy was identified during the game when the participants were talking about a potential development in the simulation, a consequence of the development, or the potential consequence of an action but did not go through with it. This type of reasoning was by far the most common during the simulation games. In essence, the participants were collectively discussing various hypotheses about what would happen during the simulation game and how their own action potentially could affect this development. It could for example be if they wanted to implement alternative means of payment early in the first day, but they never implemented it in the simulation. Other common topics were if customers would start hoarding products, whether there would be enough money in the ATM's, and the effects of information to the public – would it lead to increased attempts to buy things, or decrease them? Another example is when participants are worried about the stores' stock but did not check this against the simulation or did anything about it. In summary, the strategy anticipation is applied when the participants discuss and brainstorm potential actions and developments and think about important aspects to solve the disruption problems, but they don't implement them in the simulation game or check it in the game, at least not at the same game-day as the discussion takes place.

Strategies relating to *monitoring* were only classified a few times by the observers. On rare occasions, the participants in the simulation game asked the researchers running the simulation model about the state of specific parameters in the simulation game. In all such cases, they were given feedback. At some occasions, the participants also asked about the underlying logic in the model on which the simulation is based. Examples of monitoring are questions about the amount of money in ATMs, the number of citizens that are hoarding, or what kind of behavioral model that was used for customer behavior.

Strategies relating to *controlling* were the second most common in the observed simulation games (see **Table 1**). This is not surprising as the participants were asked to describe what actions they would like to have implemented on days 1, 3, 6, & 9 in the simulation game. Typically, they performed actions such as adjusting opening hours of stores, fill up the ATMs with cash, introduce alternative payment methods, and provide information to the public about the state of affairs and suggested actions to citizens. Controlling actions generally focused on minimizing the consequences of the payment disruptions, both in terms of lost incomes of business owners and from a community perspective.

Strategies relating to *recovering* were not observed during the simulation games. The main reason for this is

probably that the participants interpreted the task of the scenario as dealing with the foreseeable and immediate consequences of the disruption. Recovery as such was thus not yet necessary.

Strategies relating to *learning* were observed by only one of the observers (Observer B) and are therefore not counted in this assessment. The lack of strategies relating to learning can partly be explained by the fact that the simulation game was seen as an exercise, and learning may have been interpreted as something that will take place after rather than during the simulation game.

Strategies relating to *self-monitoring* were observed at a few occasions. Examples of this are when participants begin to discuss whether the way they are organizing their work or begin to question if the approaches they adapt are viable or not.

MODIFICATIONS TO THE TRAMS PROTOCOL AND METHOD

The data collection conducted resulted in some alterations to the initial TRAMS protocol and method. The TRAMS protocol was updated (see Figure 5) after the first simulation game. The new version of the protocol has some changes from the first version (Johansson, Laere, & Berggren, 2018) since it was noticed that it was not possible to use all components included in the original version. The most important change is that, *core values* no longer are used because it was hard to assess them during the observations. It is recommended to have at least two observers using the TRAMS protocol and have them compare the outcomes with each other. A single annotator will need to have experience in identifying the strategies and note taking. Furthermore, in some situations it is difficult to correctly assess what is happening, especially if the team enters parallel discussions. In such cases, it may be necessary to go back and listen to the audio recordings to capture what actually was discussed

DISCUSSION

Subjectivity of the involved observers obviously plays an important role as observations may be connected to the strategies differently. However, the results indicate a good coherence among the observers in this limited data collection, although the collected material was too small to calculate inter-rater reliability.

Only three of the six core resilience functions could be related to observed strategies, *anticipation, monitoring* and *controlling*. This may be due to the limitations of the game simulation, the participants or other factors. It is likely that it depends on that the participants have not had time to train enough. Alternatively, *learning* may not be visible during the games themselves. Hopefully, further studies can clarify this, because it does not mean that *controlling* and *learning* cannot be found just because it was not seen in this data collection. Also, the core values could not be assessed. The original version of the protocol had core values as an own column, but this study did not find these during the games and could not find any practical utility with it in the observation protocol.

As pointed out in the results section, it is at times hard to keep up the note taking during the gaming simulation and at least two observers are probably needed. An advantage of using two observers is also that it is possible to compare observations with each other after the game. Audio recording is also important, both as a support for verifying observations and as an important data set for retrospective analysis. Some cons are that we could not fill in the core values since our knowledge about the participants' core values was too low and it was difficult to use it during the game simulation.

The fact that only three categories of strategies relating to the six core resilience functions were found in the simulation games is interesting. Of these three categories, anticipation was clearly the most common, followed by controlling. Monitoring was only observed at a few occasions. Table 2. shows the distribution of the observations. It is not clear from the observations or experiences from the simulation games why the distribution looks in this way, but we have two main hypotheses: 1) that the teams get so engaged in their discussions about possible developments (anticipation) that they simply forget to ask the simulation managers about the actual state of affairs in the simulation (monitoring), and, 2) that the current game design, where the participants are asked to make decisions at certain points in time (simulation game days 1, 2, 3, 6, & 9) creates a situation where the participants believe that it isn't necessary to ask for additional information between these decision-points.

SyRes functions	Strategies days 1	Strategies days 2	Strategies days 3	Strategies days 6	Developed by…	Involved actors	Expected effects	Implementation	Simulator outcome
Anticipating	Put in security early?								
		Prepare billing opportunities and swish?			All	Banks, stores, transport		Yes	
			Lower the price of products that are going to go bad?		Store	Store			
Monitoring		Check how much money there are left in the stores			All	Store		Yes	Not that bad yet
				Check how it works with swish, invoice and money in the stores	All	Payments and disappointed costumers	Get an overview	Yes	Relatively good
Controlling	Inform the costumers that disruption is happening?				All	Costumers		Yes	Good effect
	Close the stores				All	Stores		Yes	Good effect
		Refill the ATMs with money			All	Banks		Yes	Small effect, but still not that bad yet
Recovery									
Learning									

Figure 5. Example of how the TRAMS protocol can be populated during a simulation game.

CONCLUSION

In conclusion, the TRAMS protocol has been modified to better support observations of resilience strategies used by the teams to cope with the disruption in the gaming simulation. The instrument is yet not fully developed and there are still columns that need to be added or deleted before it can be validated, but it is a first try to structure a data collection based on the SyRes model. The TRAMS method has so far been successfully applied to six out of a planned series of 30 simulation games. The result led to a guide and examples on the strategies *anticipation, monitoring* and *controlling.* Strategies relating to the core functions *recovery, learning* and *self-monitoring* were not found in this study. The discussion above suggests two hypothetical causes for this: 1. The style of the participants in the particular simulation games studied, and, 2.) that the design of the simulation game not encourage the formulation of strategies relating to these core resilience functions. The instrument will be continuously developed along with the simulation game approach during the following 24 simulation games. Experiences from these simulation games will help mature TRAMS until it is a validated and mature research instrument.

Design to Fit – Morphological Analysis as a Tool for Exercise Design

ABSTRACT

Exercises are considered as vital to develop and sustain crisis management capabilities. An exercise may have a role both as a provider of knowledge about the crisis management system, and its performance, and as a driver of change through training of individuals, groups and organizations. However, the relationship between the design and characteristics of a specific exercise, and the usability of its results in the development of the crisis management system is not well-understood. The objective of this paper is to explore if a morphological field can be used to investigate this relationship. Such a field was designed and evaluated. Even though this field was relatively simple, it was concluded that it provides results that deepen the understanding of how different types of exercises can contribute to the development of the crisis management system.

Keywords

Exercise design, morphological analysis, crisis management.

INTRODUCTION

A crisis is a situation where substantial values are at stake, characterized by severe urgency and a high degree of uncertainty (Boin, 2009; Sundelius, Stern and Bynander, 1997). Generally, crises are events that falls outside of the affected organizations' normal spectrum of challenges, something that distinguish crises from emergencies (Borodzicz and van Haperen, 2002; Lagadec, 2009; Wybo, 2004).

Examples of crises include natural disasters such as the tsunami in south-east Asia in 2004 and the forest fires in California and Greece in 2018, large-scale terrorism such as the ones in New York and Washington 2001 and in Paris 2015, and man-made environmental catastrophes such as the gas leak in Bhopal 1984 and the catastrophic nuclear accident in Chernobyl 1986. Crises, as opposed to emergencies, are rare and as a consequence there are relatively few relevant experiences available from actual events. However, their character and their consequences, as well as the strategies for handling them, are difficult to visualize in advance (Lagadec, 2009; OECD, 2015).

Crisis management generally involves a large number actors with different characteristics, roles and objectives (Comfort, 2007; Doyle, Paton and Johnston, 2015; Eriksson *et al*, 2017). The crisis management structures needs to be agile and adapt its configuration and response to fit a specific crisis (Boin, 2014; Comfort, 2007; Kim, 2014). Furthermore, as threats and vulnerabilities continuously change, so must the crisis management structures.

Exercises are considered vital to develop and sustain appropriate crisis management capabilities (Beerens and Tehler, 2016; Berlin and Carlström, 2015; Borrel and Eriksson, 2013; Kim, 2014, 851; MSB, 2016, OECD, 2015). Exercises have two overarching roles from this perspective: (1) to provide actors with new knowledge and competences or to validate existing knowledge, i.e. learning from exercises and (2) to be a driver of change through the training of actors, i.e. learning in exercises.

Multi-agency, inter-organizational exercises involve two or more organizations, possibly with some actors simulated, or one organization where the actions and reactions of all other organizations are simulated. These exercises may have different types of formats, such as table-top, functional or full-scale. Furthermore, they may also have different types of objectives, such as training, evaluating, or exploring. Training exercises aim at increasing the ability of individuals or organizations through the implementation and training of plans, procedures and methods, while evaluating exercises test current plans, procedures or methods or the ability to use them. Explorative exercises aim at finding new ways of handling challenges, e.g. through testing of new methods.

Multi-agency, inter-organizational exercises can be described using a number of different types of dimensions, such as the exercise format, the participants' level of experience, and the size and character of the exercised event. These exercise are furthermore complex and expensive endeavours, and the number of actors participating, with their different roles, their different types of organizations, and their different objectives represents a considerable challenge. It is therefore crucial to ensure that the exercises are designed so that resulting observations and conclusions are valid for the planned development process. However, the relationship between the design and characteristics of an exercise, and the usability of its results in different types of development efforts is not well studied. There is a need for developing ways to discuss this relationship in a structured way.

Morphological analysis can be used to investigate multidimensional problems with several possible solutions and different stakeholders (Ritchey 2006). The objective of this paper is to explore if a morphological field can be used to investigate the relationship between the characteristics a specific exercise and the usability of its results in different types of development efforts.

BACKGROUND

The crisis management structures could be regarded as a continuously developing system, having a configuration consisting of, for example components, goals, culture, rules, and procedures. This configuration is, using the terminology of Argyris and Schön (1996), the crisis management system's *theory-in-use*, i.e. a representation of the knowledge guiding an organization's activities and how these are performed.

If new knowledge leads to changes in the structure of the system's configuration, this is a change in the theory-in-use, or what Argyris and Schön (1996) call *double-loop learning*. Knowledge that instead leads to efforts for the incremental increase of the quality of existing parts of the configuration, is on the other hand called *single-loop learning*. Not all changes in the configuration are, however, double-loop learning. To exchange a system component with another one that does the same thing, albeit more efficiently, is single-loop learning, since the basic configuration remains the same and no change in the structure of theory-in-use has occurred.

Morphological analysis can be used to structure, and tame, so called wicked problems (Ritchey, 2006, 2011). Wicked problems are complex problems that involve several different stakeholders and perspectives, consist of several different dimensions that are interdependent in entangled manners, and include political and social complexities. Furthermore, these problems have no single correct answer, and what is seen as a good or acceptable solution will remain in the eye of the beholder. Wicked problems are genuinely difficult to define and every wicked problem is essentially unique. (Peters, 2017; Ritchey, 2011) Two examples of wicked problems are climate change and prioritization of communications infrastructure.

Although morphological analysis was proposed and used by Fritz Zwicky already in the 1940s, the use of manual calculations limited its usability. However, with the help of modern computers and software, also quite large morphological fields can be analysed (Ritchey, 2006).

The core idea in morphological analysis is to identify the relevant dimensions of the problem, and then assign mutually excluding and, in the context of the problem, exhaustive values to each dimension. The resulting morphological field can be used to explore different combinations of values from the different dimensions. As an illustrative example, a morphological field for choosing means of transportation when commuting to the city centre from a suburb, taking into account the dimensions of budget, commuting time, and environmental footprint, is presented in Figure 1.

Budget (per month, USD)	Acceptable commuting time (single journey)	Type of transportaton	Acceptable environmental footprint
<25	<20 min	Walk	Zero
<100	<60 min	Bike	Low
<1000	>60 min	Subway	Medium
		Car	High

Figure 1. A morphological field for the choice of transportation.

This morphological field contains 144 potential combinations of the values (rows) in the four dimensions (columns). Some of these combinations are feasible, for instance, the one highlighted in Figure 1. Others are not, for instance any combination of walking and less than 20 minutes of commuting time. In this simplified example it each potential combination can easily be manually examined. However, since a typical morphological field may consist of 10 000 potential combinations or more, manual analysis is not an option.

Instead software tools for morphological analysis are used to perform pairwise comparisons to decide which values

that can co-exist. Then the software identifies all combinations of values that are possible. If the original research question is well-defined and the morphological field is well-designed, the remaining number of combinations will be manageable.

In the commuting example, an environmental footprint that is zero can only co-exist with the values of walking or biking (Figure 1). Walking and biking are also the cheapest alternatives and can co-exist with all the values for the dimension budget. Instead of manually analysing the 144 different combinations of values to identify which ones are possible, the manual labour is reduced to do 73 pairwise comparisons, and then the software identifies the possible solutions. This difference in effort grows with increased complexity. Just adding one more dimension, with three values, would increase the number of combination that needs to be analysed to 432, but leave the number of pairwise comparisons at 109.

METHOD

To explore if a morphological field can be used to investigate the relationship between the characteristics a specific exercise and the usability of its results in different types of development efforts we used a tool for morphological analysis called CASPER (Computer Aided Scenario and Evaluation Routine) developed at the Swedish Defence Research Agency. The morphological field was developed in three phases: (1) setting a focus question, (2) developing a draft morphological field, and (3) conducting pairwise comparisons of values. In the first phase, the following focus question was chosen:

- What aspects of an exercise will affect how the results and lessons from the exercise can be used to change the crisis management system?

In the second phase, the morphological field consisting of dimensions and their values was developed. Normally this is done by using a group of subject area specialists, often practitioners (Ritchey, 2011). In this case, a draft field was first developed by the author. This draft field was then discussed, revised and improved by a group of six researchers and analysts with considerable experience from the areas of exercises and crisis management.

Designing a morphological field is often an iterative process (Ritchey, 2011). In this case, the field was further revised and developed during the pairwise comparisons. These revisions included both structural changes such as introduction of new values and removal of dimensions, and clarifications such as the inclusion of explanatory texts in some dimensions and values. However, for the sake of clarity the process is here described as linear rather than iterative.

The third phase was the pairwise comparisons, which were carried out using the same group of researchers and analysts that designed the morphological field. Normally the pairwise comparisons, like the design of the field, are carried out by a group of subject matter experts. However, as was the case with the design of the morphological field, it was decided that for the purpose of this study that the researchers and analysts had sufficient experience of planning, conducting and evaluating exercises.

The process of comparisons took about 10 hours of group work. Given that the group was quite homogenous, this was slightly more than had been expected. However, it was considered important to let the process run its course without forcing it, to ensure a reasonably stable result.

After developing the morphological field, it was tested in a series of analyses. In a first step the possible combinations of dimensional values related to each value in the output dimension were investigated. As a second and slightly more complex step, combinations of different values, representing features in common types of exercises, were tested against the output values.

RESULTS

The results of the process was the dimensions and values that constituted the morphological field, the outcome of the pairwise comparisons, and the conclusions from the evaluation of the field developed.

The Dimensions and Values in the Morphological Field

The morphological field consists of nine dimensions: (1) types of development efforts (in which to use the results from the exercise), (2) exercise format, (3) exercise objectives, (4) exercise planning logic, (5) exercise participants, (6) exercise focus (level), (7) exercise focus (content), (8) size and character of event and (9) frequency of exercises.

Types of development efforts (in which to use the results from the exercise)

The objective of the dimension *types of development efforts (in which to use the results from the exercise)* was to describe the output dimension of the morphological field, i.e. what types of system development efforts that the lessons and observations from the exercise should support. It was defined by four values: (1) develop exercise methodology, (2) increase the capability in the current crisis management system, (3) develop the current crisis management system and (4) transform the current crisis management system into something new, outside the current paradigm.

In the discussion, it was noted that the first value, to *develop exercise methodology*, was compatible with all the values in the other dimensions and consequently yielded no further information. Hence, in order to reduce the size of the morphological field, this value could have been deleted, without decreasing the model's analytical strength. Nevertheless, this value was kept in the field as a record since as it was concluded that in a future, more refined analysis it can have analytical significance.

The latter three values correspond to the different variants of single-loop and double-loop learning. *To increase the capability in the current crisis management system* is related to single-loop learning where the ability to use current methods, procedures or technologies is increased. *To develop the current crisis management system* is also related to single-loop learning, when single components are exchanged but the basic structure remain. *To transform the current crisis management system* is, on the other hand, related to double-loop learning, where exercise leads to changes in the structure of the system's configuration.

Exercise Format

The objective of the dimension *exercise format* was to describe the possible formats in inter-organizational exercise. It was defined by four values: (1) table-top exercises (2) functional exercises (3) full-scale exercises with one actor and the others simulated and (4) full-scale exercises with several actors.

The group defined the format *table-top exercises* to include a wide variety of discussion based exercises, from seminars where a group of participants meet and use a scenario to discuss a common problem to an exercise where all participants acts in their normal roles. Inter-organizational *functional exercises* were regarded as exercises involving one function, for instance crisis communication to the public or logistics, from several different organizations. *Full-scale exercises* were regarded as exercises where the actors participate also with operational resources. However, it was noted that, depending on the exercise objectives, a full-scale multi-agency inter-organizational exercise could consist of either several organizations or one organization and the others simulated.

This dimension could be further developed in future fields, for instance by using more detailed descriptions of the exercise formats. However, for the purpose of studying whether a morphological field could be used to describe the relationship between the type and character of an exercise and the usability of its results in the development of the crisis management system, the group decided that the chosen level of detail was good enough.

Exercise Objective

The objective of the dimension *exercise objective* was to describe the main purpose, implicit or explicit, of the exercise. It was defined by four values: (1) Train/educate, (2) test/evaluate, (3) explore/develop and (4) to signal capability internally or externally.

In the discussion it was noted that these values are not necessarily mutually excluding. For instance, there could be considerable training effects in an exercise primarily designed to test a system or its capabilities. Furthermore, many times two or more objectives need to co-exist, since there is a limited number of exercises. While the first three values are common in the literature, the fourth is more rarely found. However, from the experience of the group, this type of objective is present, explicitly or implicitly, in many exercises.

Exercise Planning Logic

The objective of the dimension *exercise planning logic* was to describe the underlying logic in the planning of the exercise. It was defined by two values: (1) scenario driven and (2) capability driven.

In the discussion, it was noted that a scenario driven exercise is when the scenario constitutes the starting point of the planning. Such exercises will focus on a specific chain of events. A capability driven exercise, on the other hand, is when the scenario is just a tool and the main focus is instead on the specific capabilities to be used. The basic difference between these two planning logics is the underlying principle. In the first case, you prepare the system to be able to handle specific scenarios that for one reason or another are seen as specifically probable, dangerous or interesting, and in the second case, you prepare the system's individual capabilities for any type of

crisis. The latter is sometimes called *zombie apocalypse planning*, alluding to the use of scenarios that, although highly unlikely, represents considerable challenges for the capabilities in focus.

Exercise Participants

The objective of the dimension *exercise participants* was to describe the level of experience among the exercise participants. It was defined by four values: (1) novice/beginner, (2) competent professional, (3) skilful/master professional and (4) experts/academics.

In the discussions, it was noted that most exercises include a mix of participants possessing different skill levels, from the novice to the master. However, the participants' level of experience was seen to affect not only how exercises can be designed and implemented, but also the validity of exercise results as well as their usability in different types of development processes.

It was decided to use a simplified version of the classification introduced by Dreyfus and Dreyfus (Dreyfus and Dreyfus, 1980; Tillberg and Tillberg, 2013) since it is based on a notion of the individual's competence and ability. The first value is *novice/beginner*. A *novice* is a professional who is completely new to the assigned task and a *beginner* is a professional with some, but limited, experience that is only able to follow simple instructions. The next value is *competent professional*, which is a professional who has gathered enough knowledge and experiences to be able to act independently and who may learn new similar tasks with instructions. The third value is *skilful/master professional*, which is able to act independently and, in the case of a master, almost intuitively making decisions simultaneously with assessing the situation. Finally, the group found that in some exercises *experts/academics* are used as participants to test and evaluate methods and plans from a scientific standpoint, and it was decided to add this as a fourth category to the ones defined by Dreyfus and Dreyfus. Although most exercises will have a mix of participant categories, for the purpose of this study it was deemed enough to choose the dominating one. In future studies, a more detailed approach can be tested.

Exercise Focus (Level)

The objective of the dimension *exercise focus (level)* is to describe *what decision-making level* that the exercise focuses on. It was defined by three values: (1) strategic, (2) tactical and (3) operational.

In the discussions this was the most complex dimension. Firstly, there are several different typologies for describing these levels (gold, silver, bronze; strategic, tactical, operational, etc) and they are not unequivocally described. Secondly, most inter-agency exercises involve multiple levels.

In the end, the above three values were used, as they are common among practitioners and to some extent are intuitive also for non-practitioners. The discussions concluded that the *strategic level* is the level where decisions are made regarding the overall objectives and prioritizations in the crisis, while the *tactical level* is the level where decisions are made regarding the choice of operational methods and prioritizations. Finally, the *operational level* was seen as the level where decisions are made to implement and lead the crisis management operation on the ground. In addition, a value of *multiple levels* was added for the case where no single level can be seen to dominate as this was found to be very common in multiagency inter-organizational exercises.

Exercise Focus (Content)

The objective of the dimension *exercise focus (content)* was to describe *what types of abilities* the exercise focuses on. It was defined by three values: (1) skills, (2) methods, plans and procedures and (3) concepts and generic capabilities.

This dimension generated a lot of discussions in the group, as the definitions of the values were all but straightforward. A complicating fact was that the values should be applicable on activities at different levels and, furthermore, be meaningful to different types of activities.

In the end, *skills* were seen as individual abilities, such as the ability to carry out a specific firefighting action or the ability to make a strategic decision. *Methods, plans, and procedures* were regarded as organizational rules and routines controlling the activities, for instance the existence and quality of procedures for handling a specific firefighting situation, or the existence and quality of a strategic plan for the handling of a flooding. Finally, the value *concepts and generic capabilities* was considered to represent the overall conceptual level that is definitions of the overarching priorities and choices, including the need for generic capabilities such as the capability to coordinate and the capability to communicate.

Size and Character of Event

The objective of the dimension *the size and character of crisis event* was to distinguish between exercises focusing on events that lie within the normal spectrum of events handled by the participating organizations (*emergencies*) and events that fall outside of this spectrum (*crisis*). This was the least complicated dimension, and generated little discussion.

Frequency of Exercises

The objective of the dimension *frequency of exercises* was to describe the recurring nature of an exercise. It was defined by four values: (1) *single exercise*, (2) *repeated exercises for one group*, (3) *repeated exercises for different groups* and (4) an *exercise series of increasing complexity*.

In the discussions, it was noted that many multi-agency inter-organizational exercises are indeed single exercises, that is, exercises that are neither repeated nor included in a series of exercises. This is also one of the major challenges. Firstly, the results from single exercises are subject to considerable uncertainties and has a low degree of validity. Secondly, there is often a tendency to try to include a large number of different objectives and elements in single exercises, with the risk of obscuring the main objectives. Single exercises can be used to test the system or to signal capacity.

The group identified three different variants of multiple exercises. The first one is an exercise that use the same exercise concept for a returning group of participants. This could be an exercise that regularly trains a specific ability, or collaboration or that is used to measure the development of a specific group's abilities. The second one is an exercise that use the same exercise concept for different groups. This could be an exercise that trains a number of groups in a specific ability, or collaboration, or that is used to measure the value of a specific method or specific procedures. Finally, the third type of multiple exercises is an exercise series with an increasing level of complexity. To be meaningful, it must generally be one and the same group that participate all through the exercise series. Such a series could be used to develop the overall ability of the system.

Resulting Morphological Field

The resulting morphological field is shown in Figure 2. It theoretically has 49 152 unique combinations of values.

Exercise Format	Exercise Objective	Exercise Planning Logic	Exercise Participants	Exercise Focus (Level)	Exercise Focus (Content)	Size and Character of Event	Frequency of Exercises	Types of Development Efforts
Table Top Exercise	Train/educate	Scenario driven	Novice/Beginner (professional)	Strategic	Skills	Emergency (event within the framework of the participating organisations' mandate)	Single exercise	Develop the exercise methodology
Functional Exercise	Test/evaluate	Capability driven	Competent (professional)	Tactical	Methods, Plans and Procedures	Crisis (event toutside the normal routines and processes of the participating organizations)	Repeated exercise (same exercise concept, same participants)	Increase the capability in the current crisis management system.
Full-scale (one actor, others are simulated)	Explore/develop		Skillful/Master (professional)	Operational	Concepts and Capabilities		Repeated exercise (same exercise concept, different participants)	Develop the crisis management system (within the current crisis management paradigm)
Full-scale (several actors)	Signal capability		Experts/academics	Multiple			Series of exercises, with gradually increased complexity	Transform the crisis management system (to something new, outside of today's paradigm.

Figure 2. The resulting morphological field.

Pairwise Comparisons

Overall, the field required that 424 individual comparisons were carried out. Some of these were relatively trivial. For instance, an exercise where most of the participants are *novices or beginners* co-exist poorly with the exercise objective of *signalling capability*.

Other comparisons were more complicated and the group had to revisit pairs several times to ensure consistency with other comparisons as their understanding of the morphological field increased. In some cases, the meaning of a dimension and its values was in the beginning blurred, and it took considerable time to reach a stable interpretation. One example of this was the field *Exercise Focus (content)*, where defining terms like *methods, plans and procedures* and *concepts and generic capabilities* required many iterations. The results of the pairwise comparisons are shown in Figure 3.

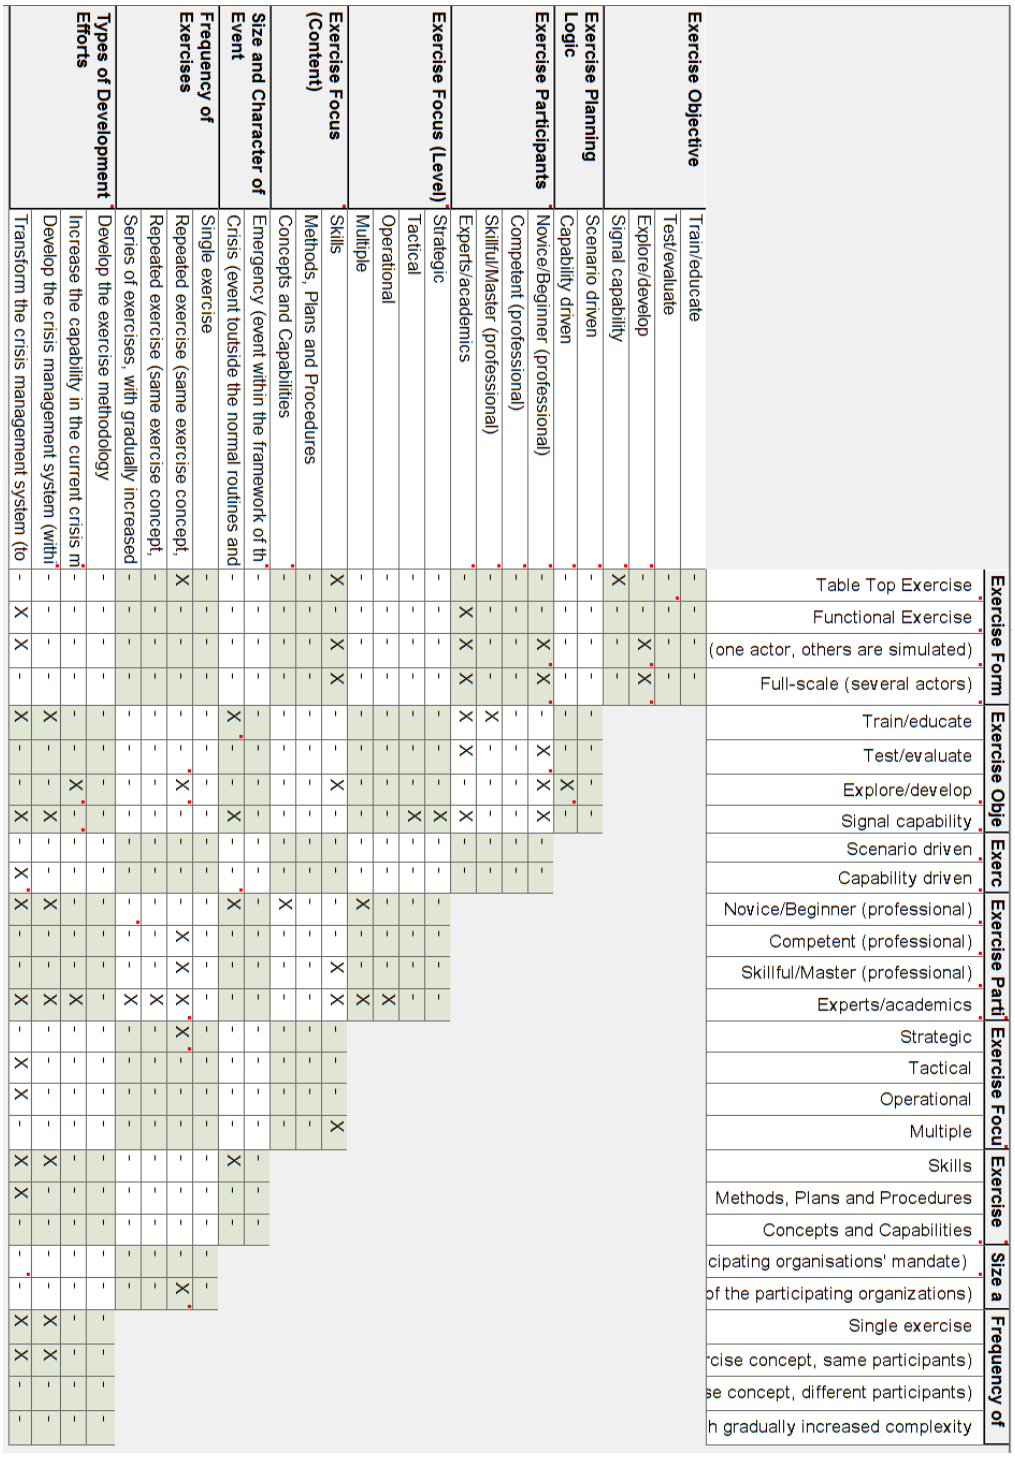

Figure 3. The results of the pairwise comparisons. X means that the values cannot co-exist.

Evaluation of the Field

The developed morphological field generated the expected results when focusing on the output dimension, i.e. the values in the dimension *types of development efforts (in which to use the results from the exercise)*. The value *develop the exercise methodology* was compatible with all the values in all the other dimensions, supporting the quite self-evident conclusion that whatever the type of exercise, it is possible to learn about how to design and implement exercises.

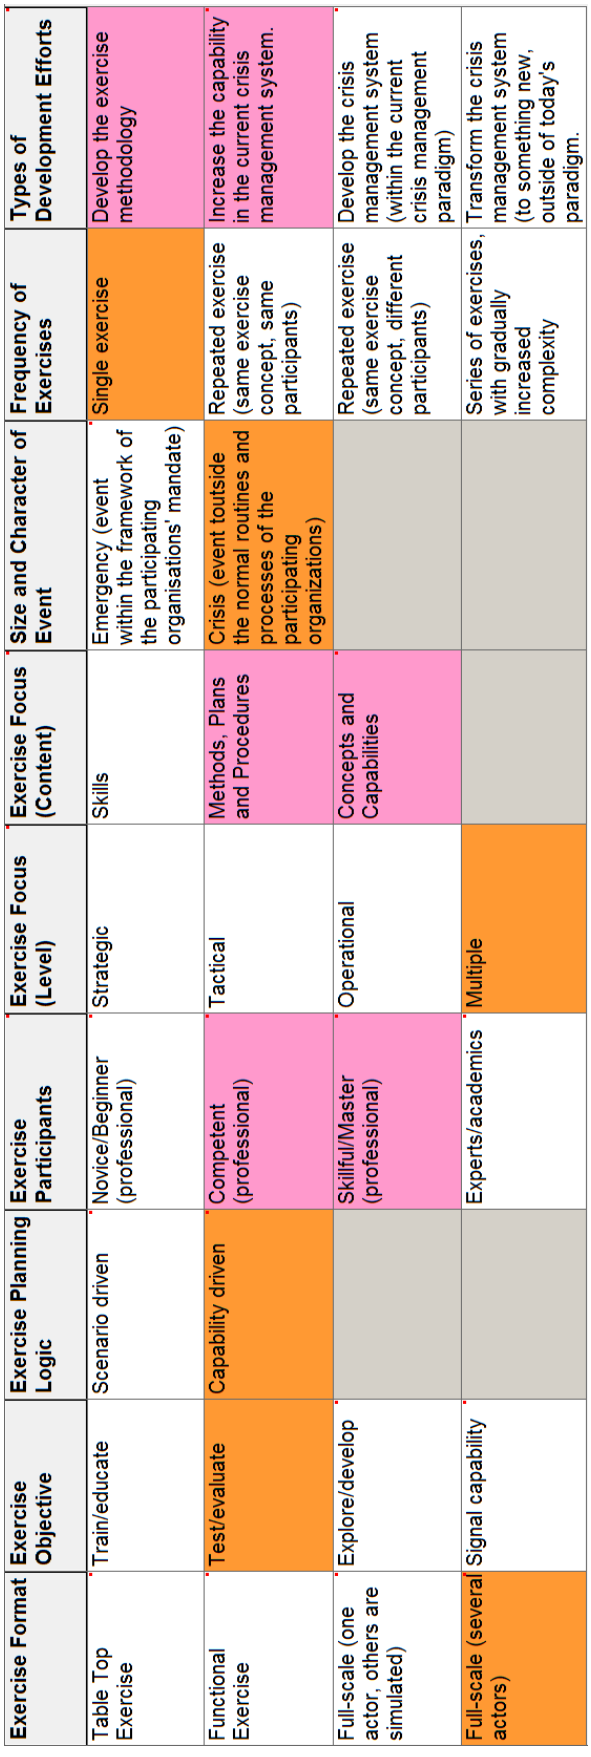
The next value in the output dimension, *increasing capability in the current crisis management system*, that is improving the quality of the system's components, is also compatible with most values of the other dimensions. This is no surprise, since most activities in any well-constructed exercise should have the potential to increase the capability of the current system in one way or another, for example training personnel and improving procedures. However, it is noticeable that this value is incompatible with explorative exercises. This may seem puzzling, but it is because of the inherent character of these exercises to explore beyond the current system paradigm. If a development need, for instance the need of extended training of personnel, is indicated by an explorative exercise, in most cases this needs be confirmed and validated through new exercises or through continued analysis to ensure its relevance also in the current system.

The third value, *develop the crisis management system within the limitations of the current paradigm*, that is developing different aspects in the system configuration without changing the configuration itself, is not compatible with exercises with the exercise objective to *train/educate*. Training/educating indicate that personnel are not fully skilled and thus any results regarding current system configuration's performance risk being flawed by the personnel's inadequate skill level. Similarly, this value is not compatible with exercises that focus on skills or participants that are novices/beginners. Furthermore, the model indicates that this type of development is only compatible with either several exercises using different groups or a series of exercises with successively increased complexity. A single exercise, or series of exercises with the same participants and without increasing complexity, will not yield the necessary knowledge to support the development of the system within the limitations of the current system. One exercise is not enough, and several exercises with the same participants will result in the participants learning to handle issues in the system, making these issues invisible and thus decreasing the value of the information that the exercise yields.

The final value in the output dimension, *transforming the crisis management system to something new outside the current paradigm*, that is changing the structure of the system's configuration, is incompatible with a number of different values in the other dimensions. For instance, it is incompatible with a capability driven exercise, mainly because a capability driven exercise presupposes the usage of a specific number of capabilities, leaving little room for exploring. Furthermore, the model indicates that this value is only compatible with an *exercise focus (level)* that involves the strategic decision-making level. This is because it is difficult to imagine that an exercise focusing on the tactical or operational would yield information implying that the whole paradigm must change.

When turning to specific combinations of exercise characteristics, to investigate compatible outputs, the field offers some interesting results. An exercise that has as its primary objective to *develop/explore*, cannot be combined with a planning logic that is *capability driven*, basically for the same reasons that capability driven exercises were incompatible with *transformation* in the dimension *types of development efforts*. Furthermore, if the value *explore*/*develop* is combined with *transformation*, the field indicates that this is only possible if a number of conditions are fulfilled. These are (1) that the exercise must be *scenario driven*, (2) that it should focus on the level *strategic decision-making* and (3) that it should focus on the content *concepts and capabilities*. Perhaps most noticeable, this combination of values is only compatible with the format *table-top*. This is a consequence of the fact that the exercise objective *explore/develop* cannot co-exist with any type of *full-scale exercise*, while the usage of results to *transform* the crisis management system excludes the format *functional exercises*. This does not, however, exclude that a functional exercise may have an *explore/develop* objective, for instance with the aim to generate results to develop the crisis management system.

A common combination of exercise characteristics, and perhaps the most expensive one, is the capability driven, full-scale exercise with the objective to test/evaluate the crisis management system and with a multiple-level focus. This type of exercise usually involves a crisis rather than an emergency and normally they are single events, although in some cases they may be part of a series of exercises (Figure 4).



Exercise Format	Exercise Objective	Exercise Planning Logic	Exercise Participants	Exercise Focus (Level)	Exercise Focus (Content)	Size and Character of Event	Frequency of Exercises	Types of Development Efforts
Table Top Exercise	Train/educate	Scenario driven	Novice/Beginner (professional)	Strategic	Skills	Emergency (event within the framework of the participating organisations' mandate)	Single exercise	Develop the exercise methodology
Functional Exercise	Test/evaluate	Capability driven	Competent (professional)	Tactical	Methods, Plans and Procedures	Crisis (event toutside the normal routines and processes of the participating organizations)	Repeated exercise (same exercise concept, same participants)	Increase the capability in the current crisis management system.
Full-scale (one actor, others are simulated)	Explore/develop		Skillful/Master (professional)	Operational	Concepts and Capabilities		Repeated exercise (same exercise concept, different participants)	Develop the crisis management system (within the current crisis management paradigm)
Full-scale (several actors)	Signal capability		Experts/academics	Multiple			Series of exercises, with gradually increased complexity	Transform the crisis management system (to something new, outside of today's paradigm.

Figur 4 The representation of a capability driven, full-scale exercise.

For this combination of values, the field indicates that the exercise's output is only useful for the development of exercise methodology and for the increase of capability in the current crisis management system. The reasons for

this are twofold. Single exercises cannot co-exist with neither the development within the current system, nor transformation of the crisis management system. Secondly, exercises with a capability driven planning logic cannot co-exist with transformation. In the Swedish context, the above characteristics are typical for the so-called SAMÖ-exercises, which are large scale, multi-agency inter-organizational exercises involving almost all sectors of the society. To use this type of expensive and complex exercise to try to find new ways of doing things is according to the model less productive unless the exercise is repeated or part of a series of exercises with gradually increased complexity.

DISCUSSION

Organizations within the crisis management domain invest extensive resources in exercises. Furthermore, multiagency inter-organizational exercises are expensive but also one of few opportunities, apart from real crisis, for sectors, organizations, and individuals to meet and interact with each other on crisis management issues. Although the ability of exercises to bring actors together in itself represent an important objective, other important objectives are to train, test, explore, and to produce knowledge for the development of the crisis management system.

Given the rarity of real crises, exercises are one of few sources of knowledge about crisis and crisis management. If the purpose is to provide knowledge for the development of the crisis management system, exercises need to be designed to fit this purpose.

The objective of this article was to explore if a morphological field can be used to investigate the relationship between the characteristics of a specific exercise and the usability of its results in different types of development efforts. The objective was not to determine the optimal morphological field for this cause. Still, we believe that most of the dimensions in the field presented in this article would be included by most groups, such as the dimensions format, participants and objectives. The validity of the field is also implied by the evaluation, generating both expected results for certain combinations of exercise characteristics and results that were somewhat more surprising but still could be explained from the underlying pairwise relationships in the field.

However, the morphological field presented in this article is not the only possible one to describe the relationship between the exercise design and the development of the crisis management system. Other groups may choose other dimensions or values. As an illustration of the non-absolute character of the morphological field, the group of experts at a late stage realized that an additional dimension could have been included: *type of evaluation*. Type of evaluation would affect what types of results that are yielded and how these results can be used. Examples of values for this dimension are *evaluation of goals*, *evaluation of processes* and *evaluation of effects*.

The next step in the research should be to involve a group of highly experienced practitioners to further validate the field, as well as to refine and expand it. The resulting field could be used as a tool for choosing and designing exercises that generate results with a high applicability for specific development efforts within the crisis management system.

CONCLUSIONS

This paper demonstrates that a morphological field can be used to investigate and understand the relationship between the exercise design and the usability of the exercise results in different types of development efforts. Even a quite simple morphological field offers results that deepen our understanding of this relationship. Further developed, we believe that a morphological field can be a powerful tool in designing exercises to fit the purpose of generating relevant knowledge for the development of the crisis management system.

ABSTRACT

It is commonly assumed that conducting exercises will contribute to better crisis management. However, the exact mechanisms of cause and effect are hard to isolate empirically. The objective of this paper is to compile and analyze the recommendations in the literature on inter-organizational exercises and learning. While not claiming to meet the strict scientific demand of empirical validation and general applicability, the compilation may nevertheless provide some guidance from research to practitioners. Forty-four papers about learning in inter-organizational exercises were analyzed. Out of the analyzed papers, 28 discussed obstacles or success factors. However, the recommendations applicable in one setting are not automatically valid in others, and some are even contradictory. The recommendations have therefore been categorized according to two criteria; when in the exercise cycle and for whom they apply. Several recommendations concern individual learning, but maximizing individual learning can sometimes hamper learning on the organizational level.

Keywords

Inter-organizational, exercise, learning, crisis management, collaboration

INTRODUCTION

Crises are major sudden events that affect many people. Regular resources and procedures are not enough for an unpredictable development, far- reaching consequences, and the need for a managed response from the society as a whole (Al-Dahash et al., 2016). This managed response requires collaboration between professionals in various organizations (Berlin and Carlström, 2014). Some of those organizations are used to inter-organizational collaboration and view it as a part of regular work, for instance the police and rescue services (Borodzicz and van Haperen 2002). However, in many crises, professionals and organizations that are not used to inter-organizational collaboration are needed in the response. Their main way of preparing themselves is through exercises.

It is commonly assumed that conducting crisis management exercises will contribute to better crisis management, but evidence suggests they often produce weak learning results (Borell and Eriksson, 2013). In addition, the exact cause and effect mechanisms are challenging to isolate and prove empirically (Wahl et al., 2015). Further, several researchers question the learning effect of exercises (e.g. Berlin and Carlström, 2015a; Beerens and Tehler, 2016;). As it is difficult to prove learning effects, let alone comparative effectiveness of various exercise designs, it is also difficult to decide on the best practice or guideline for crisis management exercises. One way to improve exercise practice is to compile recommendations in terms of what seems to work better or worse, even if no definitive answers can be provided.

There are a few compilations of do's and don'ts for exercises (e.g. van Laere et al., 2007, Berlin and Carlström, 2014; Grunnan and Fridheim, 2017). However, two of them are specific to format (role-playing exercise or simulation-games) (van Laere et al., 2007), and table-top (Grunnan and Fridheim, 2017), whereas one is limited to blue light services (Berlin and Carlström, 2014). None of them are specific for large scale inter-organizational exercises covering a whole of society response. However, there is reason to believe that the drawbacks as well as success factors identified in these studies can be valid for other kinds of exercises. Some of the exercises studied can be seen to be inter-organizational in nature.

The objective of this paper is to compile and analyze the recommendations in the research literature on the subject of inter-organizational exercises. The study is based on a scoping study covering learning in cross sectoral, inter-

organizational crisis management exercises.

BACKGROUND

Crisis management is aimed to prevent, protect against, respond to and recover from crises. These systems are inter-organizational by nature as crises are events that do not respect organizational boundaries. Furthermore, crises are not known beforehand and, therefore, the exact composition of a response organization cannot be narrowly defined in advance. Nor are crises frequent events, so the opportunity to learn, asses and evaluate the functioning of crisis management systems in real life are also rare. Therefore, exercises have a natural place within most crisis management systems (Bidinger et al., 2010). However, they can be used in different ways and for different purposes within a crisis management system.

One way of describing individual exercises and their role is to state the aim for conducting them, combined with a design description (e.g. table-top, full-scale, functional or simulation), and what kind of actors are part of it as well as a short scenario description. Aims for exercises are sometimes described as platforms for assessing capacities or validating plans and procedures (Bidinger et al., 2010). In addition, goals are often expressed in terms of capability building and/or learning (Berger et al., 2015). How learning or capability building actually takes place or how to measure it is less frequently discussed (Wahl et al., 2015; Berlin and Carlström, 2015b).

Inter-organizational exercises are different from many other types of crisis management exercises. In theory, they can use any format or kind of scenario and have many different objectives. They typically include several different organizations from different sectors of society and focus on collaboration in multi-agency responses fraught with conflicting objectives (Berlin and Carlström, 2014). They are often aimed at evaluating the crisis management response from a system perspective, rather than the individual's performance or the participating organizations. Therefore, there should be obstacles and success factors specific for this kind of exercises.

METHOD

According to Djikers (2016) the term scoping review has been used since 2001. It is used interchangeably with several other terms (e.g. scoping study, scoping report, evidence mapping, and systematic mapping). However, most researchers using the method use the one by Arksey and O´Malley (2005). This is also the case in the study presented in this paper.

The steps followed in this paper are the steps identified by Arksey and O´Malley (2005):

1. Identifying the research question
2. Identifying relevant studies
3. Study selection
4. Charting the data
5. Collating, summarizing and reporting the results

The research question in this study is: In terms of success factors and obstacles to successful learning, what recommendations does the literature offer concerning inter-organizational crisis management exercises? Relevant studies were identified through a search in the SCOPUS database using the search string: (learn*) AND (exercise*) AND (crisis OR emergency OR disaster). Only publications written in English were included. This generated a list of 744 papers. From the initial result relevant studies were selected in four steps; A title review, an abstract review, a quick full- length review and, finally, an in-depth full- length review.

In the title review, irrelevant papers were excluded. For instance, *emergency* might refer to individual psychological emergencies, the word *exercise* referred to workouts, or *crisis* was used to refer to a crisis of confidence. At this stage, 465 papers remained.

In the abstract review, three inclusion criteria were used. (i) The crisis/emergency/disaster described had to be of a magnitude that would require a large crisis management response from society, including several different organizations. (ii) The actual exercises presented must include several organizations from different sectors of society, or the exercise concepts presented must be relevant for organizations across different sectors of society. (iii) Some idea about how learning can be achieved through exercises must be stated, implicitly or explicitly. At this stage, 77 papers remained.

For the full- length review the same criteria as for the abstract review was used. After scanning through the papers, an additional 33 could be excluded on the grounds that they did not include any aspects of how learning can be achieved. Only statements indicating that something was indeed learned, typically in a topic or list. The remaining 44 papers formed the basis of the in- depth analysis

RESULTS

Forty-four articles about learning in inter-organizational exercises formed the basis for the analysis. Despite being about learning and inter-organizational crisis management exercises, not every paper discussed obstacles or success factors for learning. Out of the 44 analyzed papers, 28 discussed obstacles for learning and 26 success factors in some manner. In addition, in 13 papers the incentives for learning were mentioned. The success factors and obstacles identified in the literature were categorized and are presented in Table 1. However, the advice applicable in one circumstance is not automatically valid in other circumstances, and sometimes recommendations are contradictory. Therefore, the recommendations were categorized according to who (individuals, organizations or systems) is meant to learn, and when in the exercise cycle (planning, implementation, evaluation and dissemination) learning is meant to take place. There is no consensus about whose learning is the most important or if the learning is different in different phases, in terms of quality, quantity or effectiveness. Therefore, no grading of the recommendations are provided in the paper. However, it is clear that the focus of various papers is on different phases and entities of learning. By sorting them this way, seemingly contradictory recommendations can be reconciled.

Another effect of this tabular presentation is that it becomes clear that there is a lack of success factors identified in the literature when it comes to the dissemination phase as well as a systemic learning in general. This might be due to the scope of the study being too narrow. Perhaps these questions are dealt with more thoroughly under topics such as 'knowledge management and exercises', rather than learning and exercises.

Success factors

Four success factors were identified (Table 1).

Table 1. Success factors for learning in inter-organizational exercises

	Planning	Implementation	Evaluation	Dissemination
Individual level	Everyone learns	Variation Realism Everyone learns	Everyone learns	
Organizational level	Involve actors	Variation		
Systemic level	Involve actors			

Realism

Realism is the most frequently mentioned recommendation in the research literature (Meesters and Van de Walle, 2013). This primarily concerns the implementations phase of an exercise. According to Hills (2015), it is important that the scenario and format are realistic in order to expose the participants to a situation they find likely, so that they take it seriously and can experience the stress and pressure a real crisis would inflict on them. In this case, realism pertains to likelihood of the event as well as props. It is clearly aimed at learning opportunities for individuals by managing stressful situations. However, Borodzicz and van Haperen (2002) have claimed that too much focus on realism is bad as there is a risk that surprises and unlikely events are not taken into account on an organizational level and consequently not planned for, nor exercised. Crisis management is full of examples where the unforeseen and events deemed improbable have actually occurred.

Edzen (2014) has stressed that realistic means that there is no pre-established common understanding of what exactly the crisis consists of and how to respond properly. That is to say, the exercise must present a wicked problem. It is for the participants to define the crisis and find solutions through cooperation. Chen et al., (2008) claimed that exercises must be similar to the everyday workings of an organization in terms of the tools and support systems used. This is not always practiced; instead many exercises use alternative IT-support and computer aids not familiar to the participants. These kinds of exercises run the risk of teaching the participants the not in using tools, and not actual crisis management.

Variation

Variation is a recommendation thoroughly discussed in the literature. It also seems to be the most widely accepted one. The argument is that individuals need variation (in scenarios) in order to construct models of understanding

with general applicability (Borell and Eriksson, 2013). Variation can be understood as being important over a series of exercises such as slow or fast developments, different sectors, natural events or manmade ones (Chrichton et al., 2009). Another theme is variation within the same exercise, where "what if" scenarios can be developed (Macario et al., 2009). In both situations it is stressed that it is the possibility to compare and contrast different situations that enables the creation of general concepts and models. Borell and Eriksson (2013) adds that it is through dynamic scenarios, rich in variation, that facilitate unexpected meetings between individuals, combined with an openness for discoveries that constitute a good learning opportunity. Further, it could be argued that variation of format and design is important since they have the potential to generate qualitatively different results and conclusions.

Involve actors in the planning

This factor is about ownership of the results and willingness to learn from an exercise. Adult learning is sometimes different from traditional pedagogy, which is aimed at children. Adult learning (andragogy) demands a higher involvement of the learner in the planning processes with respect to what and how to learn (Tretsiakova-Mcnally, 2017). In a more practical sense, it is a fact that in inter-organisational exercises, no single organization controls all relevant factors. For instance, participating organisations often control what representative they send to an exercise. In order to select the right people, and the right format and content for the aims and purposes of an exercise, a great deal of coordination is needed in the planning process. It is also the case that a central organization does not always know what participating organizations need to exercise, nor what they want to exercise. This needs to be settled in the early planning stages and is best done through collaboration (Gleason, 2003). Many inter-organizational exercises focus on collaboration. To make sure that collaboration is actually needed during an exercise, the scenario and design need to be chosen with this is mind (Andersson, 2016). Constructing them together is a simple solution to this problem.

Everyone learns

When it comes to theories of learning, focus is often on the exercised individual. The rationale is that participation in exercises teaches the participant something. Through evaluation process, organizations and systems too are offered an opportunity to improve themselves by internalizing the results described in the evaluation report. However, this is too narrow a focus. Planners, observers, facilitators and evaluators could also learn from their involvement in the exercise. Borodzicz and Van Haperen (2002) suggested that participation in these functions constitutes a learning opportunity equally important as participation in the exercise, albeit a much less studied learning opportunity. Considering who is asked to plan, facilitate and evaluate exercises as well as consider who participates thus becomes important. Further, the evaluation should also take into account the experiences of others than the participants. This is rarely done in a structured way, for instance, hot washes are not meant for facilitators and observers (Borodzicz and Van Haperen, 2002).

Obstacles

Nine obstacles for learning were identified in the literature and are presented in Table 2.

Table 2. Obstacles for learning in inter-organizational exercises

	Planning	Implementation	Evaluation	Dissemination
Individual level	Manage expectations Complexity	Wrong participants Manage participants Wrong focus	Manage resources	
Organizational level	Manage resources Complexity	Wrong focus Lack of learning culture	Wrong participants Unfocused	Comparable documentation Lessons not shared
Systemic level	Manage expectations	Wrong participants Wrong focus Lack of learning culture	Manage expectations Wrong participants Unfocused	No incitement Comparable documentation

The wrong thing is exercised

In the field of crisis management, work is being done to analyze risks and vulnerabilities, to identify what preparations should be made and what needs to be exercised. Unfortunately, these are not always the things that are subsequently exercised. Often, exercises focus on decision- making processes and information management, and the exercise typically starts well into an ongoing scenario. At the same time, research has pointed out that the early phase before an event has been defined as a crisis situation that needs to be exercised (van Laere et al., 2007).

It should be noted that few of the exercises analyzed in this study concern typical inter-organizational aims and tasks. In fact, some of them could be described as organizational exercises running in parallel. Anderson et al. (2016) suggested that the focus for inter-organizational exercises should be the boundaries between exercising organisations. The purpose of inter-organizational as opposed to intra-organisational is to learn the specifics of coordination and collaborative work, rather than the regular procedures of one's own organization. Examples given are differences in vocabulary, priorities and overlapping responsibilities.

The wrong people are exercised

Who participates in an exercise is important, and failure to include the right people is pointed out as a frequent problem in the literature. The choice of who is to participate must be made early in the process, keeping in mind what level participants should be at and preparing them for the exercise at an early stage (Grunnan and Fridheim, 2017). Choosing the wrong participants can happen in several different ways. A great deal of crisis management is carried out by private actors who frequently do not participate in exercises conducted by government agencies. The public is also an important actor in crisis management. However, few exercises are aimed at the general public. A different mistake in choosing participants is that missing parties affect the realism of the exercise and cause great strain on facilitators who then have to simulate their participation. Therefore, it is often difficult to determine if the simulation was good enough (van Laere et al., 2007). Another problem is that participants sometimes are under-prepared and that more senior participants were needed. A frequent mistake in these circumstances is blaming the failure on plans and procedures instead of lack of preparation and selecting the right participants. An additional problem is that no one from the participating organizations has the mandate (in their own organization) to act on any identified measures for improvement (Macario et al., 2009).

Manage resources, participant and expectations

Different actors sometimes have different expectations and understandings of the purpose and goal of an exercise (Meesters and Van de Walle, 2013, Rutty and Rutty, 2012). This has consequences for who will participate in an exercise. For instance, one actor sends new member of staff to participate because the exercise is seen as an opportunity for them to learn. However, other actors understand the purpose to be a test of the system and therefore send their most experienced people. This mismatch is likely to cause friction and make evaluation more difficult. It is often the case that several purposes are adopted for an exercise without considering the consequences regarding participants and the exercise design.

Exercises are often designed with a focus on the intended participants. Participants in exercises often contribute to the design of the exercise both at the planning stage, as they often influence the scenario, and during the exercise when their estimates of time and effect of different actions are allowed to drive the exercise forward. Participants may refer to resources that are not actually available and overestimate the effects of their chosen actions while underestimating the timeframe (van Laere et al., 2007). The focus on the participants also has consequences for the evaluation work, hot-wash being a common example. In these, evaluators try to capture the participants' experiences (what they learned). It is equally important that observers and evaluators themselves participate and give their views, which often complement or even contradict the participants' experiences. Their view is important, both for feedback and for a broader context for the participants (Borodzicz and van Haperen, 2002).

Participants' efforts in hot-washes and other evaluation efforts are often inadequate. Gleason (2003) suggested that this may be because they are tired and want to go home. In many cases they have struggled through an intensive management simulation and were never given an opportunity to learn or reflect on alternatives. The latter can also be said about exercise managers. They focused on implementation and did not plan for the whole process. After the implementation, resources are drained and when the time comes for evaluation and experience management, there are no resources left (van Laere et al., 2007). For a successful exercise, planning must cover the whole process.

Choose complexity level carefully

Too many exercises are conducted in a vacuum in relation to other exercises. They are often planed and conducted as well as evaluated as a one of event and managed and financed as a project rather than as part of a continuous series of exercises. It is normally better to plan the complexity of an exercise progressively, where one exercise

build on a previous one (Kim, 2014). This makes it easier to view learning as a cumulative and ongoing process, leading to a focus beyond testing existing procedures and producing an accurate description of the current status.

Complex scenarios also make it difficult to exercise in inter-organizational settings, since there is a risk that a situation will be created where one organization has to wait for another for long periods during the exercise. Moreover, too much complexity can result in everyone waiting for someone else to take the lead (Berlin and Carlström, 2014).

The lack of a gradually increasing difficulty level makes it harder to match participants with a suitable level of difficulty. The complexity and difficulty level of an exercise is very important. If participants enter into an exercise that is too difficult their learning is compromised. On the other hand, if participants are too qualified there is nothing to learn (Rankin et al., 2012). They also risk jeopardizing the learning for the participants for whom the exercise is suitable. A common mistake in this respect is to simplify what should be a very complex exercise. It is better to choose a simpler scenario and format altogether, rather than simplifying a difficult one (Borodzicz and van Haperen, 2002). Another way of handling complexity levels far above the participants' capability is through active instructor participation (Rankin et al., 2012).

Unfocused Evaluation

An evaluation cannot capture everything. It has to be selective and focused on specific aims; otherwise it runs the risk of being superficial. Furthermore, there is often too high expectations on the observers' capability to see and hear and understand everything that is going on (Greenberg et al., 2017). Also evaluation is not just the report, it is the planning for and the actual organization for constructing, collecting and analyzing data during and after the exercise. This is often an organization with a limited budget and timeframe.

The exercise format and scenario do not match the goals of the evaluation. First, the format and scenario are chosen and only thereafter, ad hoc, the evaluation aims. The objectives must control the choice of format and scenario. Otherwise, there is a risk that the same mistakes reappear in later exercises (van Laere et al., 2007).

Lessons are not shared

A common mistake is that conclusions and recommendations are not allowed to spread outside the circle of those directly concerned. Chricton et al. (2009) believe that the threshold for learning from other actors and sectors of society may be high due to differences of contexts and terminology, differences that lead to greater resource utilization to adapt conclusions and recommendations. Furthermore, this may also be the case because the relevance is deemed to be low when conclusions are drawn by others outside one's own organization. One solution is to position exercises as part of a larger process of change. (Chricton et al., 2009) Lessons learned by other organizations and in exercises where the scope is broader than in one's own sector are often relevant. This is obvious as the same conclusions are often drawn in different exercises in different fields and, moreover, repeatedly over time for the same actors. This sometimes leads to frustration and scepticism towards exercises as a driver of change (Savoia et al., 2012). Epler and Hunt (1999) emphasized that the problem with exercises are that they often show the same result. Yet, participants often learn anyway, although the lessons are not translated into changed procedures or internalized on an organizational level. This risk is likely to be higher in inter-organizational exercises as no single organization can be said to fully own the results and responsibility for improvement.

Lack of learning culture

Some actors will try to distort results in evaluations or not share correct information during exercises. According to Upton (2009), both individuals and organizations, particularly in inter-organizational settings, feel that their reputation is at risk as the results may be seen as a comment on their plans and preparations. Further, a poor result may be used against them in the future by pressure groups or public opinion. Therefore, an unofficial goal of not looking bad tends to be a part of exercises. In addition, people can be afraid or uncertain and hide information or choose not to act in fear of mistakes (Hills, 2015). In organizations there is often a natural resistance to change. It is costly and admitting faults or failure can change power balances within organizations (Upton, 2009). It is difficult but important to foster a culture of learning in exercises (Kim, 2013).

Lack of comparable documentation

Lack of comparable documentation is about the fact that reporting about exercises is not very stringent. It mainly concerns the lack of a common reporting format and archiving of evaluation reports, for instance after action reports (AAR) (Savoia et al., 2012). Systems and archives for the documentation of exercises must be available in order to avoid making the same mistakes over and over, as well as create aggregated conclusions. However,

there is also a lack of common terminology for exercises between organizations, societal sectors and in research, which makes it difficult to use and learn from archive material (Upton, 2009).

Lack of clear incentives to learn

A possible obstacle not explicitly mentioned in the analyzed material, is the creation of clearer incentives for learning. By and large there seems to be a lack of incentives (Gleason, 2003). Upton (2009) pointed out that for market actors there are financial incentives, but for the crisis community the only incentive for individuals is personal enjoyment in participating in exercises and the idea of learning something new. This, however, is not the same thing as formal incentives. This lack of incentives to learn and, even more so, to change practices permanently might be a reason why many exercises seem to generate the same results over time (Meesters and van de Walle, 2013). Others have pointed out that gaining a better and more flexible organization is an incentive in itself (e.g. Hills, 2015; Chricton et al., 2013). Rutty and Rutty (2012) explored the reasons why participants want to learn, but also pointed out that their reasons do not have to align with planners' and organizations' reasons. On an organizational level there is a lack of incentive to change.

DISCUSSION

A few of the recommended success factors are contradictory, although some contradictions can be easily solved. They apply to different circumstances and can be valid both in their own situation and in relation to a specific purpose. However, the need for realism in order to increase individual learning while simultaneously running the risk of not exposing organizations for improbable, yet possible, scenarios is hard to reconcile within the framework of a single exercise. This must be a strategic choice in the planning process.

Many authors in the analyzed papers have an idea of who is meant to learn and when learning takes place. However, few have grounded this in a theory of learning. This idea most often consists of an activity within the framework of exercises that the author highlights as the most important learning opportunity. For instance, several authors (e.g. Epler and Hunt, 1999; Savoia et al., 2012; Upton, 2009) have pointed to the evaluation as the most important learning opportunity. This position tends to correlate with a focus on organizational learning, where findings in the evaluation report can lead to updates and changes in guidelines, divisions of responsibilities or mandate. Others focus more on individual learning (e.g. Berger et al., 2015; Chen, 2014), and therefore tend to highlight participation in an exercise as the prime learning opportunity. In addition to this, debriefing discussions after exercises are often highlighted as the main learning opportunity for the individuals (e.g. Biddinger et al., 2010; Gleason, 2003; Greenberg et al., 2017). Less common but still argued by a few is the view that the planning and observation of exercises constitute the best learning opportunities (Borodzics and Haperen, 2002). This view is based on the assumption that planning and observing an exercise provides a position where a more holistic understanding can be gained compared to participation, and that that is more important than enhancing individual skills.

Differences of opinion when it comes to what constitutes the best opportunities for learning can to a large extent be explained by different views on who should learn; is it the individual, the team, organizations or inter-organizational systems of crisis management? Another factor for explaining this is that there is a great variation in the views of what it is that is important to learn, for instance, personal knowledge (such as how to handle your own stress and how others respond to stress), or skills (everything from how to use IT support programs, operate heavy machinery or treat wounds), or capabilities (such as communication with the public, decision-making processes and prioritization). These capabilities are often conceptualized as the right configuration of a set of skills appropriate for the situation at hand. A select few of the papers analyzed also stressed that the most important thing to learn is a holistic understanding of crisis management rather than individual feelings and reactions, skills and capabilities.

Learning in inter-organizational exercises was the focus in the analyzed papers. It is, therefore, surprising that a large part of the material dealt primarily with individual learning and skills. There are individual skills that can only be learned in inter-organizational settings, e.g. collaboration between individuals from blue light organizations with different responsibilities on an emergency site (Berlin and Calström 2014). However, much of the skills and capabilities described in the literature is not inter-organizational in nature. For instance, learning the procedures and guidelines of one's organization can be done in an intra-organizational setting, which is often less costly. To adapt to conflicts of interest between different organizations' goals and procedures should be the focus of inter-organizational settings (Andersson, 2016). This suggests that the practicing of intra-organizational procedures should not be exercised together with others, only the specific aim of testing how they work in relation to other organizations' procedures. Hence, procedures in one's own organization should be well practiced before entering into inter-organizational exercises. This further highlights the need for the right participants.

The fact that no clear incentive for learning seems to exist is surprising and a likely cause for why few findings during exercises seem to be implemented. Further, little advice concerning dissemination of results from exercises is provided. This might be an effect of the focus on exercises in this paper rather than knowledge management or policy formulation. Nevertheless, it is interesting considering the fact that exercises are often expensive and that the aim of spreading lessons from an exercise in wider circles than the directly affected often is a part of crisis management exercises.

CONCLUSION

The main contribution of this paper is four factors that favor learning from exercises and nine obstacles that hampers learning from exercises. These factors can contribute to the planning and execution of inter-organizational exercises. Hence, making use of these factors may contribute to more successful inter-organizational exercises.

ACKNOWLEDGEMENT

ABSTRACT

To optimize the search for trapped victims after building collapses, the authors participated in the development of a localization system based on an unmanned aerial vehicle. The objective of this study is to evaluate an approach to implement this system into the command and control structures during the emergency response after a building collapse. For this purpose, a tabletop exercise, based on a gas explosion scenario in an apartment building, was carried out with emergency response managers of the fire department and the German federal agency of technical relief. Observers have documented the exercise. Additionally, audio and video recordings were used. Thus, statements could be made about the implementation approach and the tabletop exercise method. Based on the results, the implementation approach can be considered appropriate. In addition, knowledge was gained about the appropriateness of tabletop exercises for the purpose of scientific evaluation.

Keywords

Urban search and rescue, unmanned aerial vehicle, command and control structures, tabletop exercise, emergency management

INTRODUCTION

The successful search for trapped victims during urban search and rescue (USAR) operations is affected by different factors. Besides the successful localization of trapped victims, the safety of rescuers is of particular importance (Statheropoulos et al. 2015). The research project "Flying localization system for the rescue and recovery of trapped victims" (German acronym: FOUNT^2) takes up these issues and aims at optimizing the localization of trapped victims as well as at enhancing the safety of rescuers after a building collapse.

To enable a more efficient search for trapped victims after a building collapse, a semi-autonomous, unmanned aerial vehicle (UAV) equipped with automatic landing site detection as well as bioradar is being developed within FOUNT^2. Information about signs of life and the position of trapped victims are generated by the bioradar. The mission planning and the analysis of the bioradar data is carried out via a user interface. By integrating the bioradar into the UAV, trapped victims can be located without rescuers setting foot on the debris structures, thereby reducing the risk of rescuers becoming injured or buried by further building collapses. Furthermore, the UAV can provide a bird's eye overview of the collapse site to support mission planning.

The task of the Institute of Rescue Engineering and Civil Protection (German acronym: IRG) within the project

is, among other things, the development and evaluation of an approach for the implementation of the FOUNT² system in the command and control structures during USAR operations. Based on a gas explosion scenario that takes past incidents into account, several implementation approaches have been described by researchers of the IRG and evaluated by four emergency managers in expert interviews. All interviewed experts are full-time or voluntary emergency managers at German fire departments or in the field of civil protection. In addition, all of them are active in higher education for future emergency response managers at TH Köln. In Germany, primarily the fire departments are responsible for emergency response after building collapses. Therefore, all implementation approaches are based on the fire service regulation 100 "leadership and command in emergency operations" (German acronym: FwDV 100) as well as the guideline 03/01 "instructions for actions of the fire service and other emergency responders after building collapses" of the German Fire Protection Association (GFPA, German acronym: vfdb) (AFKzV 1999; vfdb 2005).

Figure 1 shows the final approach for implementing the FOUNT² system into the command and control structures that was considered appropriate by the interviewed experts. According to this, the FOUNT² system is assigned as a device for technical search to the search subsector, which is part of the search and rescue sector. In this subsector, the sole control of the system is located, which enables control/command input ("full access", marked in dark blue in Figure 1). Control/command input is carried out by the so-called "FOUNT² operator" using a tablet computer, which runs the FOUNT² user interface. In order to optimize the flow of information, further access options are provided to the command staff, the search and rescue sector commander, the scene protection and safety sector (hereinafter referred to as "safety sector") commander as well as the search subsector commander and the rescue subsector commander. Using these options, information access is available by other devices, but no control of the system is possible ("read-only access", marked in light blue in Figure 1).

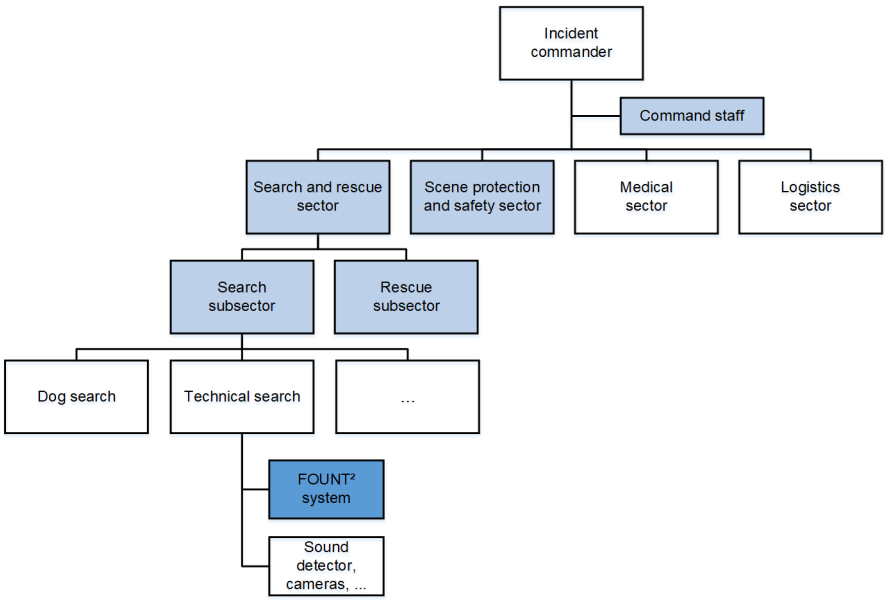

Figure 1. Approach to Implement the FOUNT² System into Command and Control Structures
(Own figure based on vfdb 2005)

To evaluate the implementation approach, the authors conducted a tabletop exercise with emergency management experts. Tabletop exercises are used in the field of emergency response for education and training of emergency response managers (Alexander 2002). These exercises provide the opportunity to bring various experts in the field of emergency response together to test coordination and response in a safe environment as well as to identify weaknesses of plans and procedures (Alexander 2002; Smith et al. 1999, qtd. in van Niekerk et al. 2015). In Germany, the command process defined in the FwDV 100 is used in emergency response missions and as basis for tabletop exercises in this field. The focus of tabletop exercises is the decision making of emergency managers. The medium used for the simulation usually is a diorama (shown in Figure 2), on which the incident situation is depicted in an abstract form using building and vehicle models. (Rempe et al. 2015) During the exercise, the participants verbalize relevant aspects of their decision making so that other participants can understand their actions. Additionally, the participants can enter into a dialogue with the exercise instructor.

Within the tabletop exercise conducted in this study, the following research questions were to be answered:

1. Which weaknesses/errors of the implementation approach can be identified?
2. Do the positions within the command and control structures that are addressed directly or indirectly by the FOUNT² system receive the information provided by FOUNT²? Is this information used and forwarded if necessary?

METHODS

The evaluation process was divided in three phases: preparation, conduct of the tabletop exercise as well as debriefing and data analysis.

Preparation

During the preparation phase, an exercises concept, a scenario description and an exercise script were developed. The exercise concept contained information about the objectives, the involved parties and the observation methods. The exercise script was based on the manual for strategic crisis management exercises of the Federal Office of Civil Protection and Disaster Assistance and contained the planned chronological order of the exercise as well as the information to be released during the exercise (BBK 2011). The detailed design of the exercise script also ensured the reproducibility of the tabletop exercise.

In preparation for the exercise, all participants received a presentation of the implementation approach and the emergency response units available in the exercise. Furthermore, information about the functions of the FOUNT^2 system as well as the tasks and procedures of their position according to the GFPA guideline 03/01 was provided to the participants. Additionally, a short presentation of those aspects took place at the day of the exercise.

Adjustments

The implementation approach shown in Figure 1 depicts the command and control structures in a real-life mission. However, the conditions of the exercise required some adjustments in order to realize this approach. The division of the search and rescue sector into two subsectors in the exercise would have been unreasonable and not necessary. Due to the physical proximity of the sector commander to the subsector commanders in the laboratory, everyone receives new information at the same time, although in reality this information must first be communicated from one person to another. For this reason, the subsector search and the subsector rescue are not displayed and the FOUNT^2 read-only access of the rescue subsector commander is transferred to the search and rescue sector commander. The documentation of the command and control structures was given to the participants, so that no alternative structures were used. This is comparable to the definition of a binding tactical standard procedure.

At the time of the exercise, the user interface of the FOUNT^2 system was not yet available in a functional scope that allowed complete interaction. Therefore, the information provided by the system (e.g. measurement diagrams of the bioradar) was released using printouts. Furthermore, a distraction of the participants by the operation of an unknown technical device during the simulation was to be avoided.

Scenario

To obtain a scenario that is both realistic and suitable for the evaluation, the requirements of the various actors in a rescue mission for trapped victims as well as the conditions necessary for the deployment of the FOUNT^2 system were considered during scenario development. An analysis of past real-life missions with trapped victims was carried out based on these criteria. The resulting exemplary scenario was a collapse of an apartment building in a residential area caused by a gas explosion. The scenario used in the tabletop exercise was based on a gas explosion that took place on March 31, 2017 in Dortmund (Germany). Table 1 lists the scenarios' boundary conditions derived from that incident.

To cope with the scenario, the participants had the tactical units listed in the GFPA guideline 03/01 at their disposal. The authors specified the compilation of tactical units, based on the generic terms in the guideline, with regard to the number and type of vehicles and personnel. Table 2 lists the units available in the exercise and their simulated time of arrival. Only emergency response managers who are represented in the exercise are listed. All other managers (e.g. subsector commander) are counted as operational personnel. The times of arrival are based on planning specifications from reality or on the experience of the authors. They were defined in such a way that the command and control structure envisaged in the implementation approach can be formed immediately and no alternative structure is established. For this reason, the incident commander and the search and rescue sector commander as well as the safety sector commander arrived at the same time.

Table 1. Boundary Conditions of the Gas Explosion Scenario

	Description
Localization of the incident	Residential area south of the city center in a town with about 600,000 residents.
Incident cause	Gas explosion intentionally caused by manipulation of the gas pipe
Development	Side street with multi-story terraced apartment buildings on both sides, sidewalks in front of the buildings
Description of the affected building	Partly collapsed, three-story residential building with several residential units Design: masonry with wooden ceilings Front: sidewalk Back: common courtyard with garden and a small playground
Access to the affected building	Front: access via side street, entrance through the front door Back: passage through the house into the courtyard, vehicle access via a passageway between the neighboring houses
Time, Weather	Thursday, May 3, 2018, sunny, clear sky, 22°C / 11°C
Number of trapped victims	5
Number of injured victims	5
Number of uninjured affected	15
Deployable localization means	Physical surface search (hailing) Rescue dogs Endoscopic camera Cell phone localization Bioradar / FOUNT[2] system
Deployable safety means	Site stability monitoring system Shoring system to stabilize adjacent buildings
Types of collapse involved	Lean-to collapse, pancake collapse, cantilever collapse

Table 2. Deployable Tactical Units
(Own figure based on vfdb 2005)

Vehicles	Personnel	Time of arrival
Fire and medical services		
1x command vehicle type 1	1x incident commander, 1x assistant	After 8 minutes
1x command vehicle type 2	1x logistics sector commander, 1x command staff	After 15 minutes
2x fire company[1]	1x search and rescue sector commander, 1x safety sector commander, 20x firefighter	After 8 minutes
1x rescue truck	2x firefighter	After 30 minutes
1x crane	2x firefighter	After 30 minutes
1x FOUNT[2] truck	1x FOUNT[2] operator	After 30 minutes
1x command vehicle	1x medical sector commander	After 15 minutes
3x rapid response car for physician response unit	3x physician, 3x paramedic	1x after 8 minutes 2x after 15 minutes
5x ambulance	10x paramedic	After 15 minutes

[1] A fire company consists of the following units: 1x command vehicle, 1x fire engine, 1x tanker, 1x ladder

1x equipment container for mass casualty incidents	2x firefighter	After 15 minutes
1x ambulance bus	2x firefighter	After 15 minutes
Federal agency of technical relief (THW)		
1x car	1x structural engineer / representative of THW	After 35 minutes
1x technical platoon[2]	22x THW volunteer	After 60 minutes
1x special unit search type A	9x THW volunteer, 4x rescue dog	After 60 minutes
1x special unit broaching	9x THW volunteer	After 60 minutes
Police service		
3x patrol car	6x police officer	After 8 minutes
Others		
1x energy supplier service truck	2x service personnel	After 30 minutes

Conduct of the Tabletop Exercise

The authors conducted the tabletop exercise on a diorama (1.20m x 2.00m) in the Laboratory for Major Emergency Incidents at TH Köln. The tabletop exercise diorama (shown in Figure 2) displayed a complex of several streets with residential and commercial buildings (scale 1:87). The incident site was visualized by a realistic debris model (shown in Figure 3), which had been prepared based on the scenario description from the exercise concept. Tactical units were represented in the simulation by model vehicles and figures.

Figure 2. Tabletop Exercise Diorama

Figure 3. Debris Model "Gas Explosion"

An experienced emergency response manager with brigade commander qualification from a fire department, who is also active in higher education for future emergency response managers at TH Köln, moderated the exercise (hereinafter referred to as "instructor"). This should increase the participants' acceptance of the exercise and make sure that the exercise was run according to its intended purpose. The instructor decided on his own on script adaptions necessary for continuing the exercise. To research information in the exercise script and document decisions deviating from the planned procedure, an assistant was available to the instructor. Furthermore, the assistant released information requested by the participants (e.g. results of a mobile phone location). Due to the amount of information provided by the FOUNT[2] system, an additional assistant was assigned for this purpose.

The focus of the exercise was on the activities in the search and rescue sector and the safety sector as well as on the activities of the incident commander and the FOUNT[2] operator. Two rounds of the exercise were performed with eight participants in total. In each round, the roles of incident commander, search and rescue sector commander, safety sector commander and FOUNT² operator were performed by different emergency response managers. The medical sector and the logistics sector as well as the tasks of the command staff were performed by participants, but only to enable the others to interact with them. The same people played these roles in each round. The tasks of the structural engineer and the representative of the federal agency of technical relief were combined

[2] The technical platoon consists of the following units: 1x personnel transporter, 2x rescue truck, 1x truck with wooden shoring system

and were also performed by one person in both rounds. A total of twelve participants were involved in the exercise.

Prior to the start of the exercise, all participants waited outside the laboratory so that they could not see the situation displayed on the diorama. The exercise began when the first participants entered the laboratory. The instructor first transmitted the information available at the time of the alarm that could not be displayed on the diorama (type of call, time, weather etc.). Then the participants approached the diorama. From this point on, the participants took over the incident response, discussed their reconnaissance results, decisions and measures, presented them on the diorama and received additional information from the instructor. At predefined times, further participants and simulated response units entered the exercise. Each round ended when all trapped victims had been located. At the end of a round, a debriefing was held with the participants.

Observation Procedure

To document the tabletop exercise and the debriefing, audio and video recordings as well as observers were used.

Observers

To reduce possible distractions during the exercise, four of the seven observers performed their task from a separate observation room. Three of the observers were deployed to the laboratory. The perspectives of all video recordings were transmitted live to the observation room and displayed with video projectors in front of the observers. The audio recording in stereo was transmitted as well. The coordination of the observers was carried out by the observation management, which was also based in the observation room. Arrangements between personnel in the observation room and in the laboratory were possible via telephone.

The task of the observers was to document the flow of information and the decisions being made by the participants. Four observers were assigned to positions in advance. One observer documented the search for trapped victims. Two other observers had no specific objective and documented the entire exercise. An objective could be assigned to them at any time during the simulation. Observations were documented by recording the time on a prepared observation sheet. Table 3 shows the location of the observers as well as their assignment to the position observed. The selection of observers was based on their personal experience in the field of emergency response. In addition, the observers were prepared for their task in the preparation phase of the exercise by participating in a trial run. During the trial run, each observer performed the position to be observed in order to become familiar with its tasks and procedures.

Table 3. Locations and Assignments of the Observers

	Position observed	**Location of the observer**
Observer 1	Incident commander	Observation room
Observer 2	Search and rescue sector commander	Observation room
Observer 3	Safety sector commander	Observation room
Observer 4	FOUNT² operator	Laboratory
Observer 5	Process of the search for trapped victims	Observation room
Observer 6 and 7	No specific mandate	Laboratory

Audio and Video Recording

Five cameras with wide-angle lenses were set up in the laboratory for audio and video documentation, recording the events from several perspectives synchronously. In the area in front of the diorama, two directional microphones were placed and aligned in such a way that the conversations of the participants could be recorded. To facilitate the observers' tasks in the observation room, a camera also recorded the frontal view on the participants. Figure 4 shows the positions of the cameras and microphones in the laboratory.

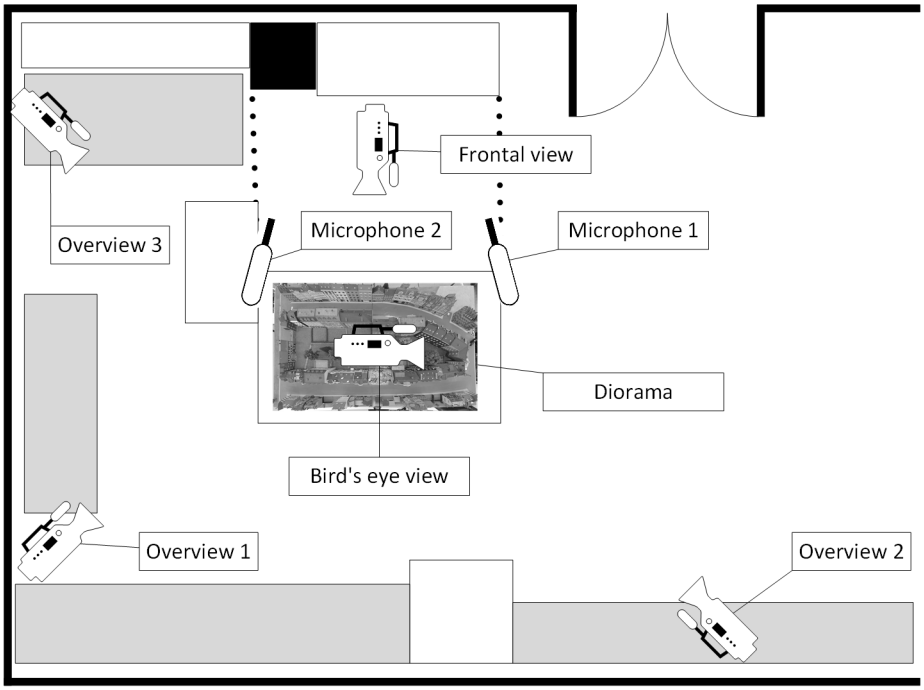

Figure 4. Positions of the Cameras and Microphones in the Laboratory

Debriefing and Data Analysis

In the aftermath of the exercise, the observers summarized their notes in the form of an observation report, which focuses on the main research questions. The authors reviewed those reports and compiled a summary. The audio and video recordings were evaluated and the chronological order of the participants' actions as well as the times at which information was released were documented. Orders, feedback and communicated information were recorded by specifying sender, recipient, time and content. In addition, the participants' debriefings were documented analogously. In a final step, the authors compared the summarized observations to the records.

RESULTS

The first round of the exercise took 1:11 hour, the second round 1:08 hour. Both rounds were carried out without interruption. In the following, the aspects most important for answering the research questions and for assessing the exercise as an evaluation method are listed.

Aspects for Answering the Research Questions

- During both rounds of the exercise, the proposed implementation approach was applied by the participants.
- In both rounds, a regular exchange and a joint discussion of information provided by the FOUNT^2 system (bird's eye overview, bioradar data) took place between the search and rescue sector commander and the FOUNT^2 operator.
- In the first round, the search and rescue sector commander asked the FOUNT^2 operator to independently coordinate his actions with the other search units.
- The FOUNT^2 operator communicated the results of the localization with FOUNT^2 to the incident commander in both rounds via the search and rescue sector commander.
- According to the participants, not all the information presented was relevant to the search and rescue sector commander and the safety sector commander. However, it is useful to be able to retrieve the information as needed.
- According to the participants, the information provided by FOUNT² can be interpreted by a single person who has received sufficient training to operate the system. Nevertheless, the use of several persons for this task can be helpful.
- In addition to the FOUNT^2 system, the participants used other search methods in both rounds.

- Errors or weaknesses in the implementation approach were not observed.

Aspects for the Assessment of the Exercise

- The FOUNT^2 operator had to re-sort the information printouts released in the first round. The labeling of the printouts was not sufficient.
- According to the participants of both rounds, the debris model displayed as well as the conditions on the diorama were authentic and realistic.
- The participants perceived the performance of the tasks of the structural engineer and the representative of THW by one person as problematic.
- In the debriefings of both rounds, the participants emphasized the good cooperation with one another.
- From the instructor's point of view, the participants achieved a comparably good incident response in both rounds.

DISCUSSION

Due to the exercise's boundary conditions, a statement regarding the suitability of the implementation approach can be made for the simulated scenario only. Since the assignment of the FOUNT² system to the technical search methods is scenario-independent, the applicability of the implementation approach to similar incidents with other causes can be assumed.

The assumption that the incident commander, the search and rescue sector commander as well as the safety sector commander arrive on scene at the same time, is fundamentally unrealistic. In reality, the complete establishment of the simulated command and control structure would be delayed. For the conduct of this simulation, however, a more realistic presentation would have had no benefit. Furthermore, this would have jeopardized the establishment of the command and control structure required for the evaluation, as the participants are not sufficiently familiar with the structure specified as the tactical standard. It is assumed that this is caused by the artificiality of this exercise.

The technical realization of the audio and video transmission into the observation room had negative effects on the observers' work. However, the number of microphones was too low. This made it difficult to differentiate between the individual contributions when several participants were talking at the same time. Furthermore, audio and video signals could not be synchronized. The observers perceived this time lag as distracting. This may have had a negative influence on the quality of the observation. In the aftermath of the exercise, however, the video recording could be synchronized with the audio track. Therefore, synchronized audio and video recordings were available for the evaluation. The information contained in the observation reports was verified during the follow-up process.

The representation of the user interface's information in paper form led to a large number of printouts, which had to be managed by the respective participants. It is assumed that the display of the information via the user interface itself will simplify the information management.

CONCLUSION, OUTLOOK AND FURTHER RESEARCH

Answering the Research Questions

1. Which weaknesses/errors of the implementation approach can be identified?

No errors could be identified in the implementation approach. However, it should be kept in mind that only the results of the evaluation of bioradar data should be displayed to managers with read-only access, so that the amount of information is kept manageable. Furthermore, it should be considered to have several persons operate the FOUNT^2 system, as evaluation, operating and communication tasks may have to be performed simultaneously. A crew commander for the FOUNT^2 system could facilitate the coordination with other units. Moreover, it is conceivable that he or she could act as an advisory function for superior commanders.

2. Do the positions within the command and control structures that are addressed directly or indirectly by the FOUNT² system receive the information provided by FOUNT²? Is this information used and forwarded if necessary?

In both rounds, the directly or indirectly addressed functions received the information provided by FOUNT^2. The information was discussed and used to cope with the mission. The information was passed on in joint briefings for all managers as well as in reports of the search and rescue sector commander to the incident commander.

Tabletop Exercise as Evaluation Method

The conduct of the exercise shows that it is possible to simulate a complex incident like a building collapse that requires an extensive command and control structure, using a tabletop exercise diorama. Also, the method used is suitable for testing an approach to implementing information gathering systems in an existing command and control structure.

Additionally, the realized observations show that it is possible to perceive observation orders in a separate observation room using audio and video transmission. Although, the technical realization used can still be improved. For example, the use of personal or position-related microphones could improve observations and expand the possibilities for the evaluation of the exercise.

Also, this study shows that in the context of using a tabletop exercise as an evaluation tool, the conduction of a trial run supports both the detailed exercise script and offers observers the opportunity to prepare for their observation objectives. However, carrying out a trial run requires that the observers have a basic tactical knowledge of the simulated incident response. This knowledge can also facilitate the classification of the perceived observations during the exercise.

Substituting digital devices with printouts appears mostly unsuitable. The excessive number of printouts caused a distraction in the exercise, so that the goal of avoiding a distraction by an unknown digital device could not be achieved completely. In the future, it will be necessary to investigate which form of information display is more suitable.

The participants' feedback also showed that the use of a realistic debris model in combination with an authentic scenario is appropriate to make it easier for the participants to immerse themselves. This could have a positive effect on the validity of the evaluation.

Summary and Outlook

The developed approach of implementing the FOUNT^2 system into the command and control structures in USAR operations can be considered suitable. During the validation of the research results, it has to be evaluated carefully whether the possibility of a read-only access to the FOUNT^2 user interface by the search and rescue sector commander and the safety sector commander offers a tactical added value. The instrument of a tabletop exercise seems to be useful for the simulation of complex incidents for research purposes.

For the further progress of the FOUNT^2 project, findings were obtained for the design of a tactical unit to operate the FOUNT^2 system. Also, new aspects for the optimization of the previous development steps could be identified. The next step is to test the FOUNT^2 system in a real-life exercise and to validate its benefits.

ABSTRACT

In a context of information overload, actors in disaster management are facing challenges to efficiently allocate critical information during a crisis. Based on the empirical experience of EMSC (Euro-Mediterranean Seismological Centre) with its application LastQuake, this paper explores ways to provide safety information in a timely manner, to the people who actually need it. First we introduce the method used to design and implement universally understandable visual safety tips, taking Ethical, Legal and Social Issues (ELSI) into consideration. Then, results on the effective use of the feature are presented. Findings demonstrate the importance of designing universal tools to limit the use of personal data as well as the necessity of developing a multichannel approach for efficient crisis information allocation.

Keywords

Earthquake, Risk reduction, Disaster app, Safety tips, ELSI.

INTRODUCTION

Earthquakes, one of the gravest natural hazards worldwide, annually cause a consequential number of injuries and death around the world. In 2018, over 4 000 casualities were recorded[1]. However, earthquakes *per se* do not harm or kill people; collapsing buildings and hazardous behaviours do (Johnston et al., 2014). Just as quake resistant buildings are necessary to reduce earthquake risk (Rahman, 2017), preventing risky behaviours also efficiently contributes to achieve this goal. Information before, during and after an earthquake has been found to reduce anxiety and increase resilience (Beatson et al., 2014; Bossu et al., 2018; Zhang, 2013). Furthermore, information sharing during every stage of the disaster cycle has been found to be a universal need, leading the Red Cross and Red Crescent Societies to declare that "people need information as much as water, food, medicine or shelter" (IFRC 2005). Thus, citizens must be informed about proper earthquake-related behaviours to adopt.

As earthquakes cannot (to date) be predicted, behavioural information must be sent once the event has occurred. Furthermore, as it usually takes time before trained professionals arrive on the ground, safety information about good behaviour should reach citizens in such a timely manner as to fill this gap (Milliken & Linton, 2016). Regarding information needs *during* a crisis, Ryan found that people expected to receive information about how they should behave and what they should do (Ryan, 2012). Hence, the messages should be sent right after the beginning of the crisis. Moreover, earthquakes occur all over the world, sometimes in border regions and due to

[1] https://www.unisdr.org/archive/63267

the massive development of global tourism, for a given earthquake, people with different cultures and risk culture can be impacted. Thus being able to provide safety tips to all witnesses right after the event regardless of their cultural background appears necessary. One ever more popular means of meeting this information need and reducing earthquake risk is through what are known as "disaster apps".The Euro-Mediterranean Seismological Centre (EMSC) has developped the lastQuake app to detect felt earthquakes and provide information about them. Based on the EMSC team experience,this article then examines the efforts of the Lastquake App to create and implement the sharing of behavioural information to earthquake eyewitnesses via "safety tips". It does so by first presenting a literature review on disaster smartphone applications (apps) and then describing the empirical methodology used by the EMSC, developer of LastQuake. It demonstrates how the "safety tips" were designed and implemented considering Ethical, Legal and Social Issues (ELSI). Then it examines the results of the monitoring system to draw conclusions upon the effective use of these "safety tips." Our findings show that EMSC safety tips were highly used during seismic events and help in educating citizens in general to adopt good behaviours after an earthquake.

DISASTER APPS

When a disaster strikes, people expect to find accurate and timely information on different channels and from a range of actors that they can trust[2]. Often this includes what used to be called "new technologies", aka social media, disaster apps, websites, etc. These tools have created opportunities to efficiently spread and collect information in case of disaster, including earthquakes (Aydin et al., 2016; Bachmann et al., 2015; Beatson et al., 2014; Tagliacozzo & Magni, 2016). While certain of these "new technologies" such as social media do enable one to circulate a large amount of messages to a large audience, they may also create communication challenges. As Hagar (2011) demonstrated, during a crisis, citizens on social media may be facing an information overload as the diverse actors and agencies involved in the response spread, each, an important number of messages. This adds to the difficulty of finding relevant and trustworthy information. In this context of information overload, how can actors in disaster management succeed in passing the right information to the right citizen, the one who needs it?

Disaster apps can be considered as a solution to the information overload problem. A wide range of emergency preparedness and disaster response smartphone apps now exist (Bachmann et al., 2015) and they provide opportunity to directly reach citizens in need. Indeed, smartphones present the strong advantage of enabling a precise localization of the user, through the GPS system (if enabled). Apps are thus efficient tools to directly reach citizens in the affected area, including tourists (Bachmann et al., 2015) who may not know the authoritative local source or may not be able to access information due to language barriers. They enable efficient warnings (Douvinet, 2018) and can be a practical tool to spread critical information about good behaviour to adopt and the ones to avoid, in a timely manner.

However when dealing with crisis information, one must not only think about how to reach the citizen in need but also about the technological and cultural suitability (Steelman et al., 2015). The question of suitability is especially important for disaster apps since a user must "opt-in", or download, the app. Thus, making the app attractive to the users is necessary.

If perceived usefulness and efficiency are key to effective use, trust is also decisive (van Velsen et al., 2013). This implies the need to take ELSI into account. For instance, when using users' localization to efficiently allocate safety instructions, institutions are collecting sensitive and personal data. This should be reflected upon and done in compliance with the law, such as, for instance, the General Data Protection Regulation (GDPR) enforced by the European Union (McDonald, 2016). A study lead by Adhikari et al. (2014) also showed that security and privacy issues can lead to great turnover in apps use. Privacy by design has thus become a key recommendation and even legal obligation, for apps in general, including disaster apps (Jasmontaite & Dimitrova, 2017; Kuner & Marelli, 2017; Kuner, 2018;).

Lastly, when managing a disaster app, it has been proven important to involve users in its development (Kouadio, 2016). It ensures a better understanding of needs and potential variations in use linked to cultural factors.

EMSC'S DISASTER APP: LASTQUAKE

The EMSC has developed a unique and innovative earthquake detection and multichannel information system. It is a perfect blend of crowdsourced data from eyewitnesses and data collected from seismic

[2] IMPROVER EU H2020 project, D4.1, Available at : http://improverproject.eu/2016/06/23/deliverable-4-1-social-resilience-criteria-for-critical-infrastructures-during-crises/

institutes. The system involves websites, social media and the app LastQuake (Bossu et al., 2015). The free and add-free app (available for Android and iOS) is now used in most countries around the world (

Figure 1) especially in all active seismic areas, by about 300 000 people[3]. The LastQuake users' community is composed of earthquake eyewitnesses, citizens with relatives living in seismic areas, as well as by scientists and emergency managers.

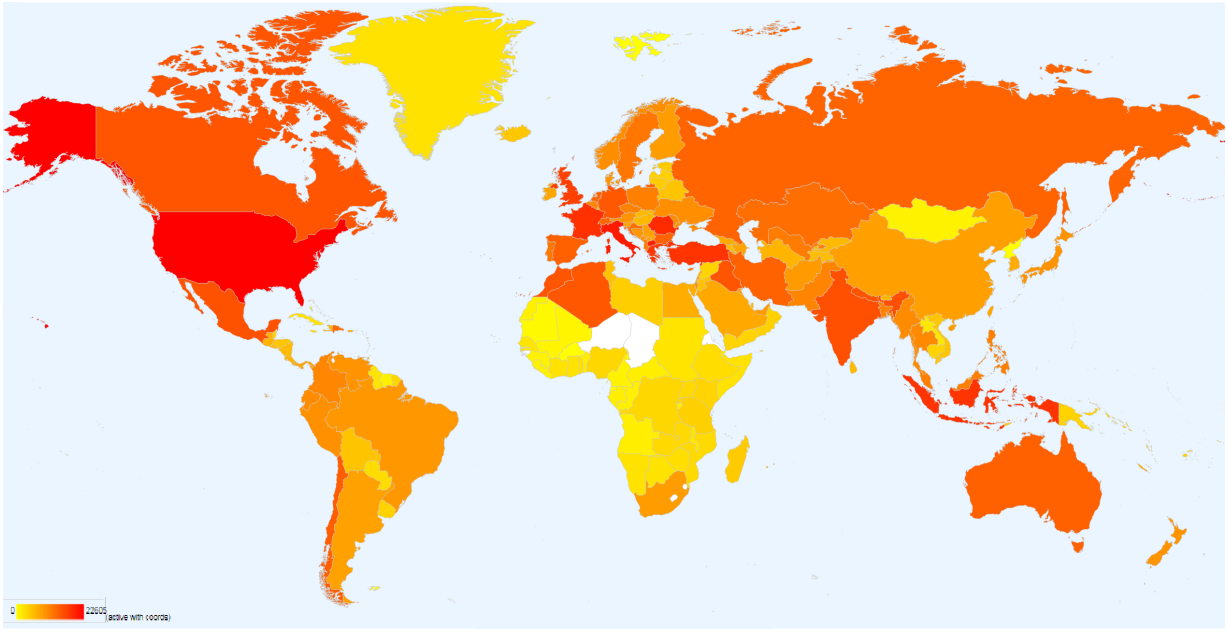

Figure 1. LastQuake users in the world

Through LastQuake, eyewitnesses can share their experience. Through 12 visual pictures, users can report the intensity of what they felt (Figure 2c). The visual thumbnail-based questionnaire has been proven to be more efficient than traditional online questionnaires and increase the number and speed of collected testimonies (Bossu et al., 2017). Users are provided with timely information about felt earthquakes[4] around the world and can read testimonies from those in the area (for a more detailed explanation, see Bossu et al., 2018). Providing information about the earthquake itself (such as the location and the magnitude) but also about its consequences (felt intensity, potential damages,…) actively contributes to reduce anxiety (Bossu et al., 2018).

When navigating through LastQuake, users are offered the possibility to (1) view a list of earthquakes (Figure 2a), (with a colour code corresponding to felt intensity and potential dangerousness), (2) get information on a specific event (Figure 2b), and (3) leave a testimony and even a comment or visual document about an earthquake they felt (Figure 2c and Figure 2d).

[3] The number of app users is in constant evolution due to downloads and uninstallations. However, it is quite stable with around 340 000 users.

[4] It is important to insist on the fact that EMSC focuses on felt earthquakes, as it is assumed that these are the ones that matter most for the public (Bossu, Steed, Mazet-roux, Roussel, & Etivant, 2015)

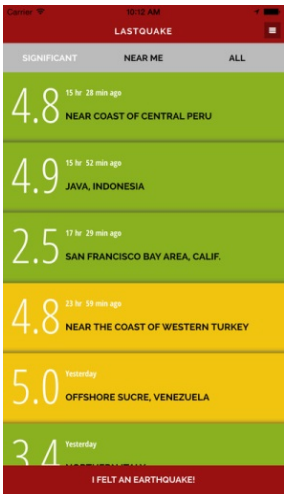

Figure 2a. List of significant earthquake in LastQuake

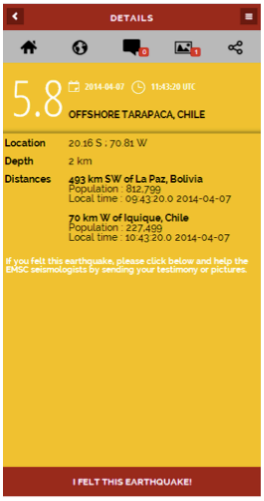

Figure 2b. Earthquake details page in LastQuake

Figure 2c. Felt reports page for testimonies in LastQuake

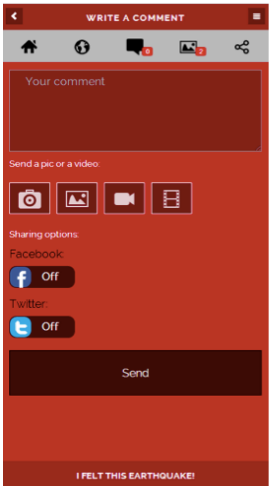

Figure 2d. Collection of open-ended comments, pictures and videos for testimonies in LastQuake

Using the GPS position of the smartphone, EMSC is able to determine the area where the earthquake was felt and thus, which app users may need safety information. A notification system alerts users in the area when a significant earthquake has occured. When a potentially damaging earthquake of global interest happens, a notification is issued for all LastQuake users around the world.

Since its launch in 2014,EMSC had to deal with ELSI when developping the app. Indeed, as a global information tool, it had to suit with various cultural information needs or technological cultures. The app also had to be designed to function even with low internet access. Along with overcome cultural and technological barriers, EMSC always paid attention to only collect necessary data in order to respect users' privacy. Having all stakeholders involved in the design of disaster-related tools has been proven efficient to adress ELSI (Liegl, et al. 2016). EMSC has thus paid attention to consult users regularly as part of the development process.

After the deadly 2015 earthquake in Nepal, EMSC launched an online survey among LastQuake users living in Nepal, India and Bangladesh, as part of a feedback process. For convenience reasons (cost and analysis), the questionnaire was written in English and disseminated through EMSC's Twitter and Facebook accounts, but also through a notification on LastQuake app. Data was collected between 8th and 15th of June 2015, less than two months after the main earthquake. Users were asked about the way they used the app during the crisis, but also about potential improvement. 667 users responded to the survey. 44% of them asked to be provided with "Dos and don'ts", so that they would know how to act after an earthquake. This was the most common request. To meet this need, EMSC developed a series of safety tips, following a methodology described in the next section. It is important to emphasize that this advice does not cover the duration of the shaking itself. Indeed, LastQuake is mostly used right *after* an earthquake.

METHODOLOGY

This paper follows a two steps methodology. First is presented the empirical approach followed by EMSC to develop and implement the "safety tips" through the disaster app LastQuake. In a second part the effective use of this feature is monitored and analysed.

DESIGN AND IMPLEMENTATION OF "SAFETY TIPS"

EMSC undertook the following steps:

1. Benchmark of safety rules for post-earthquake behaviours from key players
2. Develop a way to represent the chosen "safety tips" on a smartphone
3. Assess the understanding of the "safety tips" via an online survey and twitter conversation
4. Redesign the "safety tips" based on feedback
5. Implement them on the LastQuake app

Benchmark

Developing the safety tips required finding universal ones, which would be accurate in all areas of the world. Post-earthquake safety tips were identified through a benchmark of commonly agreed upon safety rules. The benchmark included advice from official seismic institute, NGOs, and some national disaster management agencies. The five most commonly used were selected: (1) Do not stay inside, (2) Stay away from buildings (3) Call emergency services only for serious injuries (4) When possible text your relatives rather than call them and (5) Stay informed.

Design

Because LastQuake is used in 191 countries, it was necessary to implement the advice in a way that transcended national, geographical, linguistic and cultural "borders" and could be understood regardless of literacy level. It was of prior importance to be able to reach also under-represented populations, including the poorest and people who have limited access to mainstream media (Akhgar et al., 2017). The messages had to be shared in a user-friendly way and thus shouldn't induce fear (Bean et al., 2016).

It was found out that in case of disaster, language-independent communication helps to improve the understanding and reduces the ambiguity of messages (especially those linked to semantic interpretation) (Fitrianie & Rothkrantz, 2007). Moreover, not all languages use the same space frame. For instance words like "up" "across" or "between" don't always have equivalents in Himalayan languages (Margetta & Fitzgerald, 2016). It has also been found that an Australian Aboriginal language does not use any egocentric coordinates (such as on the left), but only cardinal directions ("to the East" for instance) (Deutscher, 2010). Because language and geo-spatial perception are strongly linked, this makes safety instructions difficult to translate (Margetta & Fitzgerald, 2016). Moreover, with between 100 and 115 distinct languages spoken within Nepal's borders alone, it would be impossible for EMSC to translate a document into so many languages. Using visual communication is thus a good alternative to textual communication. Moreover, cartoons have been found to be an efficient way to communicate in the aftermath of a disaster (Chae et al., 2014) and to be understood in a quite universal way. For these reasons, added to the previous success of visual thumbnails to collect felt reports mentioned above, EMSC opted for designing visual, cartoon safety tips.

EMSC collaborated with an illustrator who turned these five principles into cartoons. Despite the universality constraint (inlcuding the representation of a building for instance), the design was also dependent on the average screen size of mobile device which is rather small. It required drawing cartoons with few details so that they could appear clearly on small mobile screens. To ease comprehension, the safety tips were created following a "do & don't" opposition. This was also, as previously stated, the desire of LastQuake users. However, creating a culturally indifferent do & don't system is not feasible, as ticks and checkmarks have been found to be highly cultural and linked to the education system[5]. Colours were also found to have different meaning. They are not understood the same way everywhere around the globe, depending on cultural factors. For example, in Japan, red is associated with blood, passion, self-sacrifice and strength whereas it is associated with "communism" in Russia or with "love" in western cultures (Bortoli & Maroto, 2001). Despite the difficulties in finding universally accepted codes for "dos" and "don'ts", it was decided to follow the ISO standard for no, a red circle with a slanted cross[6]. While no such standard exists for yes, a green check mark was seen as a good opposition to the no. Red and green were chosen based on the universality of traffic lights for "stop" and "go". The assertion was that combining both the marks and the colours will help the user to understand which picture is what should be done, and which one represents the behaviours to avoid.

Evaluation

Data Collection

In order to evaluate the understandability of the visual safety tips, EMSC launched an online survey. Overall, between the 5th of September and the 2nd of November 2016, 776 answers were collected. Respondents come from 79 different countries (11% from Italy and another 11% from the United States of America). 75% of them use LastQuake. Due to the sample size and dissemination method, the sample is not representative of the world population. 63% of the respondents are men, and 76% are highly educated (University, college or higher). 93% of respondents have already experienced an earthquake and 66% feel exposed or strongly exposed to seismic risk.

[5] https://separatedbyacommonlanguage.blogspot.fr/2007/03/ticks-and-checkmarks.html
[6] http://www.iso.org/iso/graphical-symbols_booklet.pdf

For each set of "do and don't" images (Figure 3), respondents were asked to choose among a list of sentences which one corresponded to their first understanding of the picture.

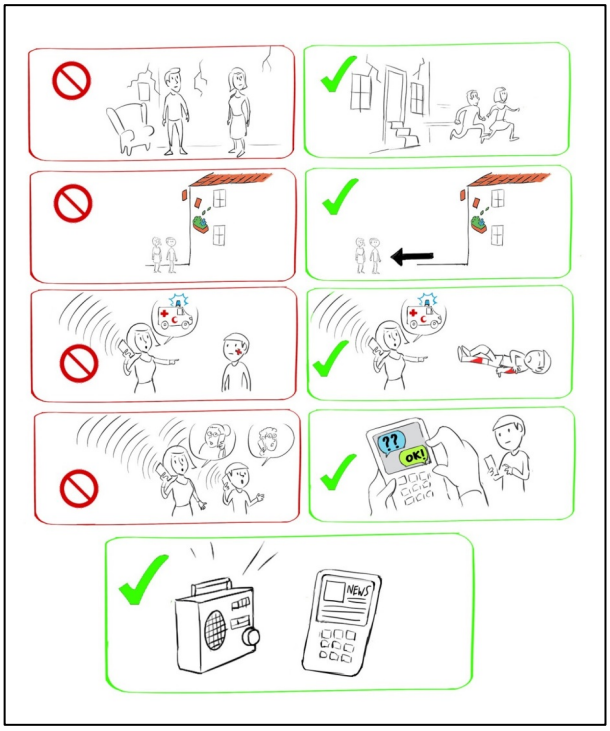

Figure 3. First version of LastQuake safety tips

Results

Overall the safety tips were highly understood by respondents, between 97% ("stay informed") and 85% ("Call emergency services only for serious injury").

Two elements can partly explain why understanding rates were so high. First of all the respondents had, in their majority, already experienced an earthquake. We can then suppose that they are, to a certain extent, aware of this advice. Moreover, in order to facilitate the data analysis EMSC chose to propose some meanings, which may help respondents and guide their understanding. The safety tips were found to be understood universally among the respondents, even if 79 nationalities as diverse as Afghans, Austrians or American were represented. Due to these high rates, no significant difference was found depending on nationality, gender, age, education level, or felt exposure to earthquakes.

Still, few misinterpretations were identified. For instance, for safety tip #1 (first pair of images on Figure3), some people thought they had to run out of the building, and for safety tip #3 (third pair of images on Figure3), 12% of the respondents understood "I should call emergency services for any injury" instead of "I should call emergency services only in cases of serious injury".

Redesign

Thanks to the misinterpretations as well as to comments left in the open questions, EMSC and the cartoonist were able to improve the images. Moreover some members of the community helped through a Twitter conversation and gave their opinion and picture drafts for improvement. This led to a co-constructed and validated final version of the safety tips presented below (Figure 4).

Figure 4. Final version of LastQuake safety tips

Implementation

Once designed in partnership with the cartoonist and LastQuake users, the safety tips had to be implemented in the app. The five safety tips are displayed one by one, with the associated do and don't on the screen (Figure 5) and the user can swipe the screen to see another safety tip. Displaying the safety tips one by one, gives a sense of priority and increases the reading comfort for the user as they can see bigger images. It also emphasizes the fact that there are five tips.

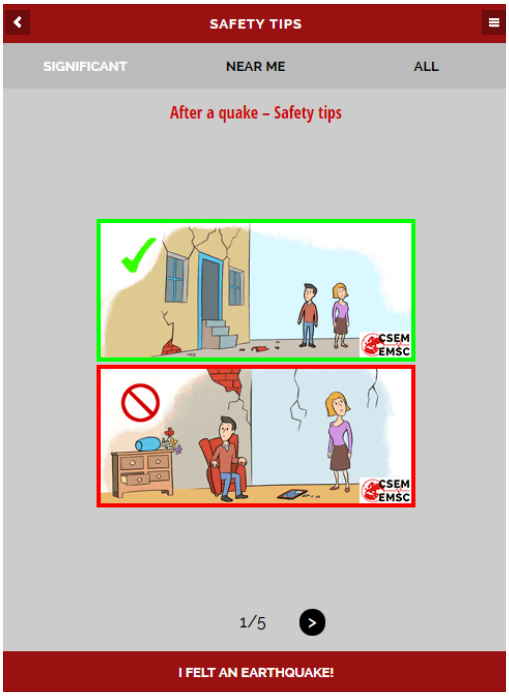

Figure 5. Screenshot of safety tips as displayed in LastQuake app

For preparedness purposes and in order to gain visibility, the safety tips are permanently available for consultation through the LastQuake main menu. However, the goal of this new feature in the app was also to efficiently provide safety tips to users in need when a significant quake strikes. This was made possible thanks to a notification system.

Indeed, for all earthquakes of magnitude 4.5 and above, EMSC determines the area where the expected peak ground acceleration (PGA) was high enough to frighten the inhabitants, i.e. where the shake was the most violent. We only consider LastQuake users whose geolocation falls within this area and then send them the specific safety notification. This safety notification is to be distinguished from the regular LastQuake notification that alerts users in a wider area about the earthquake. For instance, after the M5.7 in Central Italy (18/01/2017), 51237 users received the regular LastQuake notification about the earthquake (magnitude, location) and only 19 users received the safety notification which enabled them to directly consult the safety tips. Indeed only users who potentially felt a violent shake are targeted for the safety notification. The others still have the opportunity to consult the safety tips directly via the earthquake detail page or the main menu.

The underlying idea of the notification range is that citizens feel the immediate need for safety tips when they have felt an earthquake that scared them and/or generated damage. Providing safety tips for every earthquake and all users could thus be counter-productive and become in itself a source of anxiety. This could also lead to an excess of notifications which would decrease the visibility of truly essential information and bother the user, potentially leading to uninstallations.

Regarding ELSI, EMSC adopted the privacy by design approach, using as little personal data as necessary (only the GPS location) and only in the interest of users, namely their own safety. Moreover, no data is shared with any third party.

MONITORING THE EFFECTIVE USE OF THE SAFETY TIPS

In order to monitor the effective use of the safety tips, EMSC collected data to get a more comprehensive overview of how both seismological factors and socio-cultural ones, impact LastQuake use. All data are (and will be) collected with respect to the legislative framework and users' privacy. For instance, for each consultation of the safety tips, EMSC monitors if the user accessed them through the main menu, the notification or the earthquake detail page. EMSC monitored safety tips use between 15 February 2017 and 30 May 2018. Overall, they were consulted 73 874 times by 32 198 unique users from 175 different countries**.** This confirms a general and global interest for the feature.

The vast majority (97.4%) of users who consulted the safety tips found them through LastQuake main menu. 2.4% accessed them through the seismic events page and 0.2% have taken advantage of a safety notification to consult this timely advice. This is partly due to the fact that few earthquakes met the safety notification launch criteria. Moreover, a high shaking zone statistically has a relative small size leading to a slim chance to have users in this zone. During the studied period, 539 earthquakes met the criteria to initiate a safety check, but only 57 actually issued at least one safety notification due to the small size of the expected high shaking area, to the low number of LastQuake users in the region or to the low density of population. In 89% of the cases no notification was sent. This coincides with the idea that safety notifications are designed for rare, potentially frightening or destructive seismic events. Overall, 1 382 users have received a safety notification including a link to the safety tips. 7.8% of them have actually taken advantage of this feature to get advice on good behaviour to adopt.

The monitoring system also enabled to evaluate if users were consulting the five pieces of advice. We consider as complete a visit during which the user actually went through the 5 safety tips and didn't close the page before seeing the whole content. Results revealed that among all the views, only 33% are complete. Users who access the safety tips through an event page were found to be more interested in this advice. 39.5% of them consulted the safety in a complete way, against 33.4% when accessing via the main menu. We can assume that most users who access the safety tips through the event page are potential witnesses and thus directly concerned by the earthquake. They have an immediate interest for information about safe behaviours to adopt.

The number of visits on the safety tips page is to be compared with the total number of uses of the app in the given country. On average, 3.7% of the sessions on LastQuake include a visit on the safety tips page (whether or not the visit is triggered by a felt earthquake). However, significant and interesting differences can be noticed.

Countries such as Iran or Mexico for instance have a much higher safety tips consultation rate than Italy or the U.S.A. (Figure 6.). This goes along with the fact that the USA generates 10% of the total traffic on the app, but only 4% of the visits on the safety tips pages. On the contrary, Mexico issued nearly 18% of the safety tips visits but contributes only 4.8% of the total traffic.

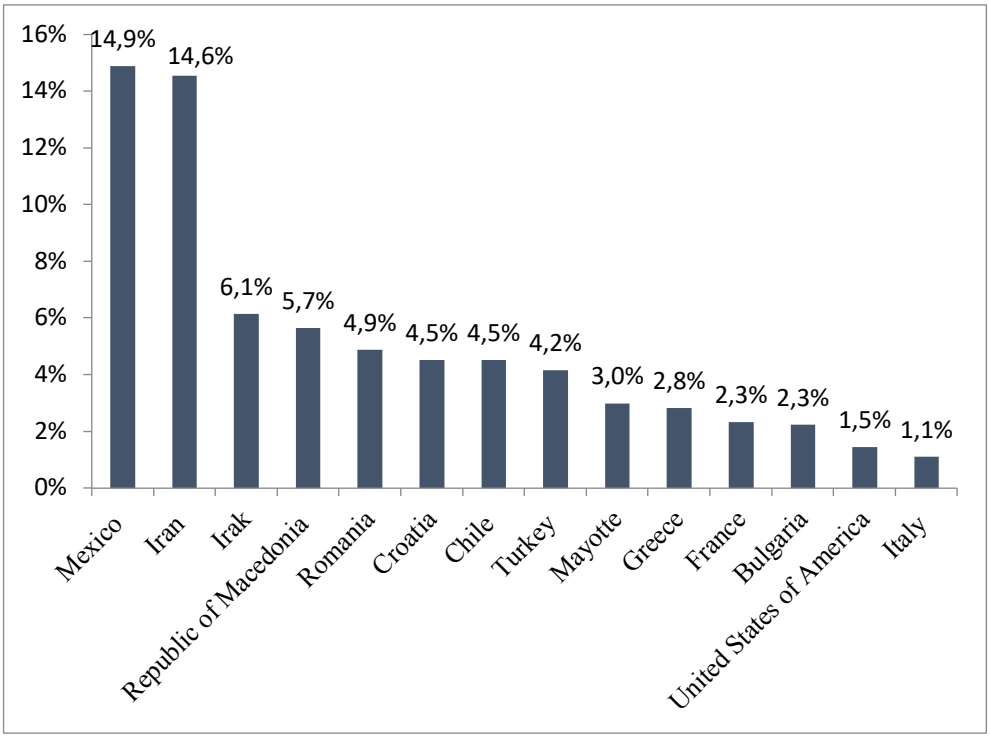

Figure 6. Percentage of connections to LastQuake which include a visit on the safety tips page, per country

DISCUSSION

The safety notification was designed to reach users located in the potentially affected area after a potentially damaging earthquake. Fortunately, few users are concerned by this type of alert. Nevertheless, during less frightening seismic events, many users still accessed the safety tips through the main menu and through the seismic event page. This proves that notifying users based on their localisation is useful but not sufficient to meet all users' needs and confirms that they should be accessible in various ways in the app.

Bossu et al. (2017) have already observed how LastQuake use varies along with seismic factors such as magnitude and felt intensity. Additional data would be necessary to study how these parameters impact on safety tips views. However, a cultural dimension can also explain these variations. Significant differences were found among the 23 countries with a high number of visits (500 minimum). Users from Iraq, Chile, Macedonia and Italy were found to proportionally visit more incompletely the safety tips, contrary to British, Bulgarians, Iranians, and French people living on the Island of Mayotte, found in the Indian Ocean. Mayotte and Great Britain are areas where seismic activity is rare, and thus where inhabitants are not used to earthquakes. This can explain a higher need for information. However, all the other countries are characterized by relatively frequently felt earthquakes. Risk culture and risk perception could thus explain variations of seriousness in the way people use this prevention tool. Depending not only on what other material of this type they can access in their language but also on general interest for risk prevention, users may not show the same involvement in their safety tips exploration.

The differences in the proportion of users' examining the safety tips in comparison to number of users' per country could also be linked to cultural factors, risk perception, and risk culture. For instance, perceived earthquake preparedness in Iran or Mexico may be lower than in Italy or Greece. Risk culture, may also vary between these countries and explain a different appeal for safety advice (Dressel, 2015). Moreover, nationality

has been found to influence expectations in regards to crisis communication (Petersen, et al. 2017). In countries where the needs for safety advice are high, EMSC safety tips help fill the expectation gap regarding prevention. Furthermore, Mexico and Iran, for which consultation rates are substantially higher, have both faced damaging and deadly earthquakes during the studied period. This may have raised the interest for safety tips more largely. More data is necessary to compare whether during earthquakes of this type, safety notifications are proportionally more used.

The fact that most users visit the page simply when navigating on the app implies that safety tips are also useful to raise preparedness. Results suggests that after a felt earthquake, there is a window for prevention, whether for locals who need timely information, or for other users who showed interest in the event. These teachable moments are strong opportunities for efficient prevention (Reynolds and Seeger, 2005; Tan and Maharjan, 2018). Indeed, after a destructive earthquake largely reported in the news or on social media, communities may experience what Gerome Truc calls *concernment* (Truc, 2017). This refers to the strong interest and emotional sharing that a person can experience after a disaster even if he or she wasn't directly involved into. During and after the event, concerned people focus their attention on disaster related news and are willing to get information and take action.

Overall, to better consider ELSI and technological cultures[7] but also the different phases of disaster management, a multichannel approach is necessary. Disaster apps must be considered as part of an ecosystem formed with other technologies such as social media, websites and messaging apps. Indeed, only a fraction of the local audience reached by EMSC launch LastQuake after an earthquake, and reach rates are higher on other tools such as the Twitter account and websites (Bossu et al., 2018). To efficiently address information allocation challenges, it is vital to spread information on various platforms, to push them through notifications when necessary, but also to have them available at all time for preparedness purposes. Thus, future work includes the expansion of the publication of safety tips on EMSC Twitter feed. The work undertaken by EMSC, along with the lessons learned, will also be carried on with the design and implementation of tsunami safety tips.

The example of the safety tips implementation illustrates that ELSI have to be adressed when conceptualizing and designing the tool. For instance, it enabled the EMSC to set up understandable visual advice. However, monitoring the use after the implementation is also essential in order to identify other ELSI linked to the effective cultural use. The challenges identified above will be reflected upon by the EMSC.

Limitations

True universality of EMSC's safety tips was not able to be determined due to limitations of questionnaire-based research. Indeed, when responding to a questionnaire, people often use snap judgement and may be influenced by emotional or contextual factors (Schwarz & Stack, 1999). It should also be noted that the use of Facebook, Twitter and the LastQuake app to distribute the questionnaire was likely to have skewed the sample in favour of those who used the Internet, social media and EMSC's app on a regular basis. EMSC does not collect demographics about its users, leading to a lack of knowledge about the typical user profile. However it is highly possible that users are not representative of the general population in terms of gender, age and social standing, adding to the questionnaire limitations. A qualitative survey on how users actually used the safety tips could help complement the analysis and give insights on how various factors such as education level, income level or quality of the internet access can influence the understanding and assimilation of this tool. Whether the user lives in a rural or dense urban area could also impact its perception of the advice relevance.

Finally, the efficiency of safety tips is complex to approach as inappropriate behaviors are hard to measure when they are avoided. Further, even if the safety tips have indeed been consulted, one cannot tell if lives were indeed spared or if the appropriate behaviors were taken.

CONCLUSION

In order to address both the safety information allocation problem, and a strong users' request, EMSC designed universal visual safety tips and implemented them in its mobile app LastQuake. The design process included a benchmark of safety rules for post-earthquake behaviours from key players, a reflection on how to convey this

[7] This is further developed in CARISMAND D3.1, available at : http://s.carismand.eu/p/c/a/carismand-d-03-01-ls2017-01-770.pdf

advice in a visual and culturally neutral way, and finally an assessment of the comprehension of the first version. Through this co-constructed material, EMSC took up the challenge to design totally understandable safety tips, using no words. They were then implemented in the app, carefully taking into consideration ELSI. Thanks to these safety tips, LastQuake efficiently allocates the right information to the right person at the right time. Users are reminded of the most important safety guidelines to be followed, in order to minimize additional damage and risky behaviours. Visual communication proved to be an efficient way to overcome language barriers, which is crucial in the era of mass tourism and especially for earthquakes, which strike without regard to geopolitical and cultural borders. In over a year, more than 32 000 users have been reached and educated about good practices.

Regarding ELSI, it demonstrates that it is possible to use as little personal information as GPS position to provide useful information to the person in need. By designing universally understood safety tips it prevents one from needing to collect additional personal data which would be necessary to have a more personal, adaptable message. However, after such earthquakes, there is also a window for prevention and it is not only affected citizens who are interested in safety advice. This, along with EMSC empirical experience with providing safety tips reveals the crucial necessity for a multichannel approach when providing critical information after an earthquake.

Overall, developing universal visual post-earthquake safety tips and efficiently allocating them to people in need actively contributes to risk reduction. But apps are not the panacea in terms of alerting and providing critical information. Lessons learnt from LastQuake experience about the multichannel system could be extended to other types of disasters and actors, including official institutions.

ACKNOWLEDGMENTS

Part of the results presented in this paper was developed within CARISMAND project. The CARISMAND project has received funding from the European Union's Horizon 2020 research and innovation program under grant agreement No 653748.

What can we learn from a crisis management exercise ?

Trusting social media in a french firefighters' department

Florent Castagnino

florent.castagnino@telecom-paristech.fr

ABSTRACT

This paper sets out the methodology and the temporary results of an ongoing research project on the use of social media in crisis management (in France). It discusses the benefits and limits to use an emergency crisis exercise for research purposes. It describes an observation protocol and a coding method that could be replicate to survey further exercises. Some possible processing of the observation data is exposed, and further visualizations of the data are still in progress. One of the first analytical results tackles the way Var's firefighters consider social media information. For now, social media seem to be regarded as questionable because they do not easily fit into the organizational routine. At the same time, the awareness of the need to use social media is quite strong. On the analytical level, the paper tries to use sociological concepts to describe and explain some results.

Keywords

Social Media, crisis management exercise, firefighters, methodology

INTRODUCTION

ISCRAM community is of course convinced by the usefulness of social media for EM (emergency management), and bunch of experiments and papers focus on how to really use them, integrate them and to make the most of it (especially with the help of computer-assisted methods). Yet, a lot needs to be done on "what information do emergency dispatchers and first responders really need" (Kropczynski et al. 2018, 2). Beyond the nature of the needed information, this paper focuses on how disturbing it can be for an emergency organization to concretely use new sources of information. All emergency managers are not still convinced that social media information is trustworthy ; even if social media trustworthiness strongly depends on the quality of the data (Tapia et al. 2013), we argue that in our case (a French firefighters' department) a questionable statute is still given to social media data. This un-trustworthiness relies as much on professionals doubt as on organizational routine.

Our research question fits into the agenda set by Elbanna et. al: "much of the research in the area has focused on public use of social media during an emergency as well as how emergency agencies benefit from the data and information generated by this process. However, there is little understanding of what are the operational implications of this public use on emergency management agencies and how does social media either positively or negatively impact these operations" (Elbanna et al. 2019, 112). Using a more sociological analytical framework, this paper tends to show that apart the quality of social media data and the efficiency of technical tools to process them, organizational features may also affect the propensity of emergency professionals to use social media. The paper builds on a collective observation of a crisis management exercise in France.

The paper consists of four sections. Section 1 frames the state of the art. Section 2 presents the exercise objectives and conditions: the exercise was organized by the Var's firefighters' department (France) and is part of a larger research project funded by the French Research Agency. Section 3 describes the observation protocol, building on previous observations made during the European Union Sequana exercise (for the 100-year flood). Section 4 puts forward some temporary results: data analysis is still on progress, as 2 more exercises, some workshops and interviews are to be made with other institutional partners. Section 5 discusses the methodological implications of the use of a simulation for research purposes and proposes to analyse social media as organizational resources. Section 6 draws some conclusions and perspectives that this ongoing project can offer.

STATE OF THE ART

A lot of research has been done on the potential use of social media for crises management (see for example the survey of ISCRAM proceedings from 2004 to 2011, (Grant and Jongejan 2011). Literature first focused on the use of social media by citizens to help each other and how social media could lead to "collective intelligence" , and then on organizational use of social media to communicate to the public , to use citizen-generated content as a new source of information (Denis and Hughes 2012; Starbird and Stamberger 2010) or to better communication between crisis professionals and organizations (Grant et al. 2013; Vieweg et al. 2010). We propose a non-exhaustive state of the art regarding the obstacles in the use of social media be emergency services in order to frame our observations and discuss our first results.

Organizational and professional grounds of social media trust

A positive attitude towards the use of social media has been observed by several studies, either the US (San et al. 2013) and Europe (Reuter et al. 2016; Rizza and Pereira 2014). Indeed, emergency professionals and citizens can use social media instead of traditional media when the latter not available, especially during the beginning of a crisis (Aupetit and Imran 2017). However, studies on the social media use in emergencies has also observed several obstacles: data quality (Tapia et al. 2011, 2013), the credibility of this kind of information (Castillo et al. 2011; Mendoza et al. 2010), the lack of training and guidelines (Hiltz et al. 2014) or the lack of organizational procedures to help managing such information (Kaufhold and Reuter 2017) or unintended consequences of such uses (Rizza et al. 2014). In accordance with those findings, the paper tries to use pragmatic sociological concepts to emphasize the organizational and professional features that can explain the lack of trust towards social media information. The concept of "interessement work" (Akrich et al. 1988; Latour 2005) – the fact that the interest of actors into a new device or procedure is the result of an organizational work that need to be cared of – and the concept of "trials" (Boltanski 2011; Dodier 2005) – which are moments where actors question the factuality of what they are facing to, moments where they mobilize their capacity to critic the reality – are used to describe the partial integration and use of social media information. They provide internalist explications of what is observed: the (lack of) trust is not what explain but is what need to be explained.

EXERCISE OBJECTIVES AND CONDITIONS

General objectives

The researchers team had two main objectives during the crisis management exercise. The first one was to observe how the Firefighters' crisis management integrate (or not) the citizen, both as an information source – especially through social media – and as stakeholders or participants into the management crisis (either as already reckoned volunteers and already organized and identified helpers, or as spontaneous helpers). Secondly, it was to prepare the second year of the research project (called MACIV -*Management of Citizens and Volunteers: social media in crisis situations*), bringing necessary elements to the realization of a new crisis management prototype in the R-IO-Suite software (Benaben et al. 2016)[1]. Indeed, exercises 2 and 3 will partly focus on the capacity of the prototype to improve the citizens integration into the crisis management by improving social media data computer-processing.

The observation was supposed to focus on three main elements: social media as information source, citizen initiatives during crisis, communication towards citizens. Actually, the exercise was organized in such a way that only the first element (social media as information source) was observable.

[1] Here is an online presentation of the R-IOSuite : https://research-gi.mines-albi.fr/display/riosuite/r-IOSuite+Home

Simulation configuration

The *SDIS 83* is the Var's firefighters' department and the simulation was based on a flood scenario in Sainte-Maxime area (south of France)[2]. This firefighters' department is one of the most involved and advanced in France into the use of social media and citizen-generated content for crisis management. The aim of the simulation was to perform their organizational line about social media. The exercise lasted 2 hours (with 2 hours debriefing), took place in several rooms on October 2018. Six researchers-observers were situated into those rooms (see figure 1):

- First there was the CRAU (Centre de Réception des Appels d'Urgence), which is the Department Call Centre, where emergency calls are treated: one observer was here at the beginning of the exercise.
- Then there was the CODIS (Centre Opérationnel Départemental d'Incendie et de Secours), which is the Department Crisis Room, the place where firefighters try to anticipate major interventions. They also give information to public authorities, and they monitor and advice the firefighters' field activity. In this crisis room, there was a special team (2 persons) dedicated to the monitoring of social media, called the MSGU team, (which is the French acronym for Social Media for Emergency Management, SMEM). One researcher was dedicated to observing the MSGU team while another one observed the whole crisis room.
- Firefighters' field activity was also simulated. This activity is supervised by a special officer, the COS, (Commandant des Opérations de secours), the Emergency Operations Commander. One observer was there too.
- Finally, there was the organization room where people simulated external roles (like the public authority, the VISOV – Volontaires Internationaux en Soutien Opérationnel Virtuel – which is the volunteer's association monitoring social media to help first respondents – like the VOST, Virtual Operation Support Team) and oversaw the scenario proceedings. Two researchers where here.

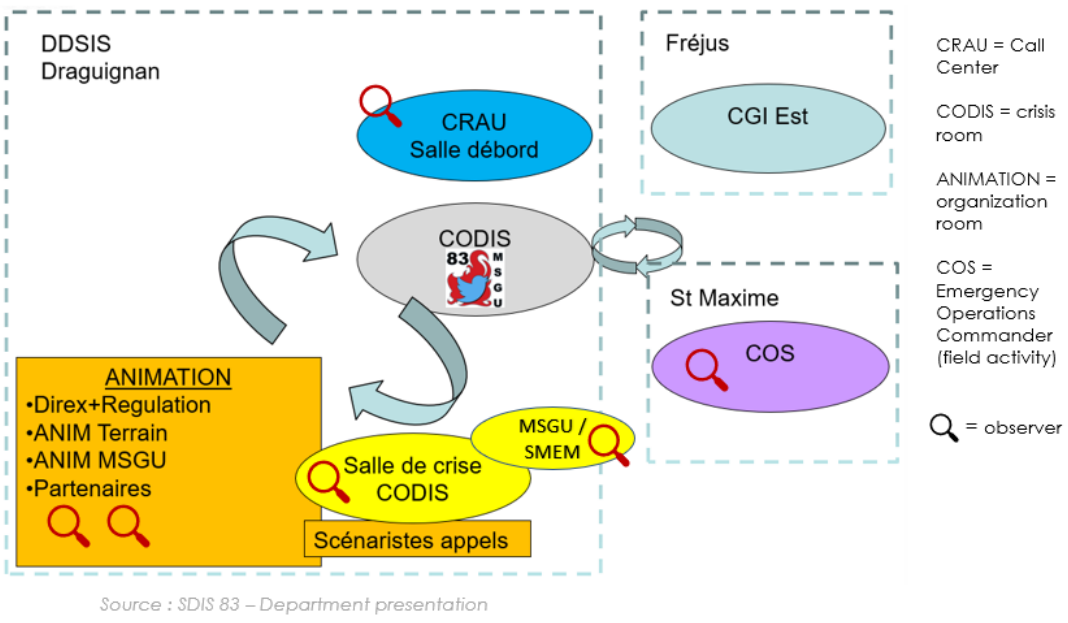

Figure 1. Var's firefighter's department and observers' position

As usual in this firefighter's department, simulation scenario was based on emergency phone calls to which the players must react (see figure 2). In this simulation, a specific social media scenario was added, consisting in a list of tweets (see figure 3): the social media team of the organization room (composed by one VISOV member and one social media analyst of the firefighters' department) "published" them. The Twitter platform was not used: simulated tweets were sent by WhatsApp to the MSGU/SMEM team located in the crisis room. Some tweets were fake or rumor and some contained information that no emergency phone calls could provide (according to the scenario).

[2] SDIS stands for *Service départemental d'Incendie et de Secours* (Local Fire and Emergency Department)

Figure 3. Tweets scenario

OBSERVATION PROTOCOL

Regarding the observation protocol, we used a method that was freely adapted from the observation made during the *Sequana Exercise* by the Euridice research Consortium (November and Créton-Cazanave 2017). The 6 researchers had the same observation grid, with a timesheet (in order to compile observation lines after the simulation) and a very simple codebook was used, in order to facilitate the data exploration. As the researcher team was interdisciplinary (3 social scientists, 3 computer scientists) and as each researcher had in own specific agenda (beyond the shared general objectives), the choice was made to adopt a descriptive codebook rather than an analytical one.

For each observation line, the observer had to code:

- Whether the observation concerned the players during the exercise, the organization team or the debriefing (*universe*)
- What where the protagonists involved in the interaction observed (*type*)
- If the interaction observed occurred through social media or not (*activity*)
- Whether the interaction was about an information coming from social media (*information nature*)

Observation was made during the simulation and during the debriefing. After the simulation, we made a compilation of each observer's data. To keep it readable, there is an *ad hoc* table sheet for each observer (Animation 1, Animation 2, CODIS, MSGU, CRAU, COS), as figure 4 shows. Further visualizations of the data (e. g., by a time line or by social media inputs) are still in progress.

	Description	Heure	Univers	Type	Activités	Nature de l'information
2	Mot de présentation de Pasquini : dans cet exercice 'ils associent 2 manœuvres CODIS et CGI. Ils parlent des chercheurs (MACIV) : pour lui, on cherche à aider avec des solutions informatiques et orga pour une meilleure prise en compte des initiatives citoyennes. Exemple : "inondation à sainte-maxime, imaginez qu'un mouvement citoyen appelle à venir avec des raclettes qui viennent aider". "on va avoir une crise dans la crise", il va falloir la gérer selon lui : détecter tous les petits signaux pour mieux gérer la suite. Il précise que la thèmatique MSGU est importante dans l'exercice. Il y a un VISOV (LMO), qui va faire arriver des inputs RSN en plus des canaux habituels. "On va mettre en pression le CODIS". "Merci de jouer le jeu, merci d'avoir monté l'exercice dans un temps reccord, pour la construction de tous les flux". "Jean-Luc, tu as la manoeuvre" (commandant qui gère la salle animation). L'ambiance semble sereine, tout le monde a l'air d'être très habitué à ce type d'exercice.	28/11/2018 09:06	Animation	Hors RSN	Pro-Pro	Non-MSGU
3	Premier appel du CODIS au COD : informe qu'on est passé en altere rouge. Le commandant demande si c'est Dragon 06 qui a appelé. Celui qui a répondu n'est pas sûr	28/11/2018 09:08	Exercice	Hors RSN	Institutionnels - Professionnels	Non-MSGU
4	Deuxieme appel : OPE (Laurent) dit :"Une inter qui tombe". commadant : s'ils vous demandent, les dragons restent sur leur base.	28/11/2018 09:08	Exercice	Animation	Pro-Pro	Non-MSGU
5	La Cadre MSGU (FAPA) dit à OPE (Laurent) "Dès que tu as la rue Michelet, tu me dis il y a un tweet de prévu"	28/11/2018 09:12	Animation	Hors RSN	Pro-Pro	MSGU
6	OPE (Laurent) à la salle : "j'ai un sauvetage qui tombe : 2 personnes à sauver dans une VL blanche, eau jusqu'aux portières"	28/11/2018 09:13	Animation	Hors RSN	Pro-Pro	Non-MSGU
7	OPE (Laurent) appelle le Commandant plusieurs qui ne répond pas tout de suite. Sur un des tableaux blancs, on note la première intervention et les moyens engagés	28/11/2018 09:14	Animation	Hors RSN	Pro-Pro	Non-MSGU
8	A priori il ont un logiciel pour faire des faux tweets (en fait, ce n'est pas d'eux, ils ont eu de l'aide extérieure, voir le debrief). Eux ils ont un faux compte tweet-exercice pour faire de la com' descendante. Ils jouent à la fois l'information au public + prise en compte (ou pas) des tweets des gens. Le VISov expliquent à un pompier comment ils fonctionnent : le système des classeurs et le fait qu'au-delà de transmettre les infos, ils font des points avec les pompiers via Whatsapp ou autre. Expliquent aussi comment ils se répartissent les missions entre VISOV en fonction du nombre de volontaires : c'est soit par type de RSN, soit par secteur, soit par inter.	28/11/2018 09:16	Animation	Hors RSN	Pro-Pro	Non-MSGU
9	OPE (Laurent) dit qu'il y a un inter qui vient de tomber, il l'imprime (j'ai par la suite arrêté de noter systématiquement l'annonce des inter, qui est récurrent pendant tout l'exercice, sauf quand un élément nouveau ou pertinent apparaissait). Cadre MSGU (FAPA), qui gère les input RSN, le note et regarde sur sa fiche excel si elle doit déclencher un tweet. Ils se répètent la priorité de l'événement pour être sûr d'en être au même point :"c'est ça c'est la PR".	28/11/2018 09:21	Animation	Hors RSN	Pro-Pro	MSGU
10	Sur les tableaux, ils suivent l'affectation des moyens engagés : tel camion, ou telle équipe là ou là, puis clôture d'une intervention et les moyens sont à nouveau mis à disposition.	28/11/2018 09:21	Exercice	Hors RSN	Pro-Pro	Non-MSGU
11	Autre inter qui tombe : 6613	28/11/2018 09:22	Exercice	Autre	Autre	Non-MSGU
12	La Cadre MSGU (FAPA) fait les inputs tweet-tableaux	28/11/2018 09:23	Animation	Hors RSN	Autre	MSGU
13	on en est à l'inter de 9h18 (selon le scenario)	28/11/2018 09:25	Exercice	Hors RSN	Pro-Pro	Non-MSGU

Figure 4. Observation grid

It important to note that players were aware that this exercise was meant to make observable their use of social media contents. Thus, it cannot be excluded that they had paid more attention than usual to social media information. Indeed, players were aware that some information could only be available on social media. We will discuss later the methodological implications of the use of a simulation for research purposes.

TEMPORARY RESULTS

As mentioned previously, the results presented here are temporary: possible data processing of the observation is presented, and some analytical perspectives are suggested. These feedbacks must be confirmed or disconfirmed with interviews with the players and the organizers involved in the simulation, and with a comparison with the two next exercises.

The main general conclusion that can be highlighted so far concerns the social media as a new information source for emergency managers. Even if the Var's firefighter's department is one of the most involved in the use of social media (only a few French departments, out of around a hundred, have a MSGU/SMEM team), this integration can be considered as *partial*. Indeed, the incorporation of social media into the organizational routine is not yet established or stabilized. This partial or proto-integration can be explained by three main elements. First, social media information is not yet considered as trustworthy as more classical information sources are. Information provided by social media still has a "questionable statute", especially compared to information coming from emergency phone calls or institutional partners. Secondly, this lack of trust can explain, to a high degree, moments of organizational hesitation, fuzziness or uncertainty observed during the simulation. However – and this is the

third point – all these moments are not explained by this questionable statute. Some institutional and professional dynamics, proper to the observed organization, that reinforce these organizational hesitation or uncertainty.

A questionable statute for information collected on social media

This questionable statute was obvious during the afternoon debriefing: players and organizers explained that they had to acculturate themselves to social media and that this acculturation was still an ongoing process (Azzouz 2012). For SDIS members, social media information is not trustworthy enough. This lack of trust is not unfounded: it is based on their everyday work and personal experience. Building on Giddens' work, one can say that social media for emergency management is not yet an "expert systems", i.e. a socio-technical or institutional system that people trust because "it works", but without fully understanding them – a trust backed by their everyday experience (Giddens 1990). In their everyday work, firefighters are confronted to social media information that does not "work" enough. They cannot rely on it without providing an extra task. Social media information is not good enough yet (and this goodness is determined by several factors, among them the fact that the information is actionable or not, Kropczynski et al. 2018), which can explain this untrustworthiness (Tapia et al. 2013).

Nevertheless, Var's firefighters are quite aware of the need to consider information coming from social media. Indeed, during the afternoon debriefing, they remind themselves that in a 2014 real crisis a very important information was only available on social media. This event seems to act like a trigger of this awareness. Following the Actor Network Theory, one could say that there is still a need for an "interessement work" (Akrich et al. 1988). The "interessement work" is a phase in an innovation process which strengthens the association between actors and a new tool or technique (leading to support the structure of the network they form). Actors need to be interested into using or adopting a new device or technology, and this process need to be cared of (Latour 2005). For now, the MSGU/SMEM team of the Var's firefighters' department seems to shoulder this work, with the support of the VISOV. A more systematic organization of this "interessment work" would be welcome to strengthen the awareness around the use of social media.A last hint regarding this social media questionable statute was the discussion –during the debriefing – on the necessity to precise, for each information, whether it is coming from social media. Of course, this would introduce an asymmetry between social media information and other sources of information. This would reinforce the questionable statute of social media information. It appeared to SDIS members that once checked, an information did not need to be tagged as coming from social media. One can interpret this decision as a normalization of the social media as a valuable information source.

…generating moments of hesitation and fuzziness

This questionable statute generated moments of hesitation and fuzziness during the simulation. These are moments where players weren't sure about an information, were wondering if it was accurate or not, etc. During these moments they try to reduce uncertainty, a process which can define risk management (Borraz 2007; Borraz et al. 2007). In these moments, actors mobilized their capacity to doubt or to criticise what they are confronting to (Boltanski 2011).

This result can be illustrated thank to the observation grid. Until now, the exploration of the observation data has been basic and needs to be more systematic. With the observation grid, it is possible to trace (more or less precisely due to a time artefact of the observation grid) the circulation process of a social media information : from the tweet-input by the organization room, to its processing by the crisis room (and especially the SMEM/MSGU team), to its operationalization (or not) on the "field" (= has the information lead to a ground intervention ? an exploratory mission ?). Several social media inputs can be studied. I will elaborate on one example about the "Belmondo's death case" which was a simulated tweet saying that Belmondo (a very famous French actor) died during the flood. According to the scenario this information was supposed to be false, but the players were not aware of it.

INPUT	ANIMATION 1		ANIMATION 2		CODIS		MSGU		COS	CRAU
Belmondo	FAPA et LMO se demandent si il faut envoyer la rumeur en disant que c'en est une. LMO décide de ne rien mettre (rumeur en question : Scoop - mort de JP Belmondo) LMO dit "C'est pas une rumeur c'est un fake" [Quelle différence y voit-il ? L'un plus évident que l'autre ? Après quelques discussions entre chercheurs, il semble que l'usage du terme "fake" soit destiné à une fausse information diffusée intentionnellement, là où une "rumeur" est une information incertaine, à vérifier, diffusée sans mauvaise intention. Distinction qu'il peut être intéressant de confirmer, mais qui semble en effet faite par les VISOV.]	28/11/2018 09:43	VISOV (LMO) : "j'injecte 4 d'affilé dont un sur la rumeur", en parlant d'input RSN, donc soit du tweet ici ou des commentaires dans la salle Whatsapp.	28/11/2018 09:38	pasquini demande au COS s'ils avaient des infos sur Belmondo et le cos a répondu "non vous pouvez contredire" Pasquini décide d'appeler directement la comm' de la prefecture pour l'affaire Belmondo. 'il devait pas jouer, mais il va jouer'	28/11/2018 09:56	Rumeur belmondo est mort dans l'inondation d'après les VISOV. Demande de confirmation sur WA de cette info par les VISOV, ça a l'air d'être une rumeur	28/11/2018 09:40		
	LMO et FAPA s'étonnent que Loic soit au taquet sur WA pour demander à vérifier la rumeur sur Belmondo	28/11/2018 09:44					Rumeur de belmondo mort retwitté également (Correspond sans doute à la propagation de la rumeur)	28/11/2018 09:41		
	Sur WA, indication par la cellule MSGU qu'ils ne traitent pas l'information pour Belmondo car pas + d'infos.	28/11/2018 10:01					"On ne parle pas de belmondo"	28/11/2018 09:59		
							Msg sur WA aux VISOV "Pas de réaction sur belmondo de notre part"	28/11/2018 10:02		
							Officier "Ca va ça se passe bien ?" -"On a toujours la rumeur sur belmondo et les gens descendent dans les caves". "Quelle drôle d'idée, pourquoi est-ce qu'ils descendent dans le caves, ils devraient monter au grenier "	28/11/2018 10:14		

Figure 5. Belmondo case and related observation lines

Figure 5 gives a compilation of the observation lines mentioning the "Belmondo's death case". In the table, column 1 gives the studied social media input, and the 6 other columns give the observation lines related to this input for each observer. Each observation line is stamped with the date and time. Thus, one can follow, approximately, the reaction time for considering the information, and how the information has been dealt with. Here only 2 minutes separate the input by the VISOV (ANIMATION 2; 9:38 am) from its observable consideration by the MSGU team (MSGU; 9:40 am). In that case, it is because no other source had confirmed or given more detail about this information that the decision is made to not react (CODIS; 9:56 am). The MSGU team lets the VISOV (played by the organizational team) know this decision (ANIMATION 1; 10:01). As no field action is undertaken, nothing appears in column COS. As this information was not foreseen by the phone calls scenario, nothing appears in column CRAU.

The same processing could be done for all the simulated tweets and for which the observations lines are precise enough (here is one of the drawbacks of the method). According to the first exploration of the data, the observation grid enables to follow the "checks and balances" process used by the players to validate or trust a social media information. A useful concept from the pragmatic sociology can be heuristic here: the "credibility trials" (a specific case of "trials", the explained concept in section 2). This concept is useful to describe the process and the steps to which an information is submitted to in order to be declared accurate. For instance, it was used to explain how and when a whistle-blower would be found reliable (Chateauraynaud and Torny 1999). It was also used to describe the checks a call taker makes before considering a phone call as serious (Boullier 1994). More recently, it was used to describe the steps a plaintiff (complaining for police violence) must face in order to be authorized to sue a policeman (Moreau de Bellaing 2016). At each step of the "credibility trials", the information, the whistle-blower, the plaintiff can be declared not reliable. The general principle is that there is a presumption of un-credibility: each trial must be positive to clear this presumption.

Thanks to the observation made at the Call Centre and the crisis room we can compare the processing of social media information and emergency phone calls information. One strong hypothesis suggested by the data so far is that the "credibility trials" are more complicated for social media information than for emergency calls information. Several facts tend to confirm this hypothesis.

Firstly, it seems that the MSGU/SMEM team (located inside the crisis room) only considered a social media information if it was also supported by a less questionable information source. For example, the same information (children stuck in a bus) reached to the crisis room both by an emergency phone call and a tweet. Nevertheless, the tweet came with a photo of a minibus, and not a bus, whereas the phone call mentioned a bus. For a while, credibility was given to the phone call, and the crisis room advised the firefighters to look for a bus first, and in a second time for a minibus (at that moment in the crisis room, whether the tweet and the phone call referred to the same event but with different descriptions of it, or if they respectively matched a specific event was not clear). Actually, the scenario talked about a minibus: the tweet was given credit only when another phone call clearly announced that it was a bus and not a minibus.

Secondly, in the organization room, people in charge of pushing tweets tended to "worsen" some information in order to prevent the MSGU/SMEM team from ignoring them. Another strategy was to post them a second time, to put some pressure on the MSGU/SMEM team. This was the case, for instance, for an information saying that water was entering some buildings cellars. According to the scenario, this information should have come from an

emergency phone call and from a tweet. But as the organization team had the feeling that social information was not considered enough, they decided to cancel the phone call and to only give this information through Twitter. They also decided to add a new information in order to make the firefighters react: the fact that some people were on site (and so hypothetically in danger).

Finally, observations of the firefighters' field activity tend also to support the hypothesis of stronger "credibility trials" for social media information. If the Emergency Operations Commander was to receive any information coming from the social media, he systematically sent a reconnaissance mission and not a direct mission (i.e. with specific means). The commander used another mission to check whether the social media information was correct before dedicating specifics resources to this information. This was the case for the flood cellars. Firefighters on ground explained that, during the simulation, the information they were given was only that "there were people on site". But whether they were in danger was not clearly said. And as there was already some firefighters in the area (for another case), the commander asked them to check the situation on their way back.

Thus, these initial elements enable to put forward the hypothesis of stronger "credibility trials" for social media information. More in-depth analysis must be done, notably with a systematic comparison with the processing of other information sources.

…reinforced by institutional and professional dynamics

Some institutional and professional dynamics, proper to this Firefighters' department, reinforced the moments of organizational hesitation or uncertainty due to the questionable statute of social media information. One can formulate the hypothesis that those more general dynamics could have limited the propensity of the players to take into account an information coming from social media. Two examples can be given here.

First, the organization team, during the simulation, was surprised because they thought – during the exercise – that social media information was not considered at all or very little by the MSGU/SMEM team. Apparently, this perception would come from the delay between a field intervention (once an information is checked) and its "creation" into the SDIS' information system (which was the only way, theoretically, for the organization team to know what action had been taken in response to an information). Actually, firefighters on the field explained that this delay was due to practical difficulties and not to the undervaluing of social media. They gave the example (during the debriefing) about a case with two boys on a zodiac boat: it was the social media input which have triggered a field intervention (not the re-posting of the information by the animation team), even if this intervention was computationally "created" later. Apparently, this delay is not due to the questionable statute of the social media. Indeed, it was also the case for other missions. It is a problem well known by the SDIS' members: operational staff gives priority to emergency actions and not to the "creation" of these actions into the information system.

The second example is also related to this "acknowledgment" issue. The acknowledgement is the action of confirming that an information is taken into account, well received. It concerned the communication between VISOV and the MSGU/SMEM team. The VISOV representative noticed that it was not possible for him to know whether the information he had gave to the MSGU team was really received (even if this information was not meant to trigger any action). This could explain some re-postings of an information which could eventually disturb the MSGU team. During the debriefing, the firefighters and the VISOV agreed that this "acknowledgment" could be a good practice.

DISCUSSION

Is a crisis management exercise a sociological experiment?

At this stage of the study, a temporary conclusion can be made about the consideration of social media information. In this French firefighters' department, a questionable statute is given to information coming from social media. Even if firefighters are quite aware about the benefits and the need to consider this new information source, they are reluctant to fully trust it. This lack of trust seems strongly determined by the variable quality of social media information (Kropczynski et al. 2018; Tapia et al. 2013). For now, these emergency managers are on an ongoing process of acculturation to social media. As Kaufhold and Reuter observed at the Frankfurt Fire Departement, "progressive organizational culture is required to enable a successful integration of social media" (Kaufhold and Reuter 2017, 607).

Nevertheless, one need to be careful about these temporary results. This was a crisis management exercise and if an observation was to be made during a real crisis, things would have probably happened in a different way. Maybe the consideration given to social media information would have been less important.

This leads to question the value of crisis management exercise for research purposes. Simulation cannot be a replication of the social reality. It cannot be easily a social laboratory as too many variables are excluded (Guggenheim 2012). Organizing a simulation specifically to make observable what the researcher would like to observe can lead to the misinterpretation of the data. This is not to say that what happens during an exercise is not real and senseless (both for researchers and professionals). As Katz showed, it is not because a situation is altered or even triggered by the researcher or the experiment that what is observed is not real or research relevant (Katz 1983). However, one needs to be careful, as researcher, to not over-interpret some results as many variables are flattened during an exercise. The MACIV research project has two forthcoming exercises to run. It could be a good opportunity to work more on the epistemological implications of crisis management exercise as research tool (and to propose some guidelines for further research).

Social Media: a new form of capital/resource for emergency professionals?

One could also learn more about the way that the consideration of social media information as new resource is going to re-shape (or not) the role of every entity of the emergency management. When one looks at the Var's SDIS, for instance, one can observe that there is a valuation of some members with what one may call a lower "firefighter capital/resources" but a stronger "social media capital/resources". Indeed, the MSGU/SMEM team mainly consists of firefighters situated at a low rank of the symbolic firefighter hierarchy. Their social media skills gave them the opportunity to be given a specific role (social media analyst) in the organization. As the sociology of organization shows, the adoption of a new technology or tool within an organization is the opportunity for some actors to gain prestige or to value under-estimated skills (Chiapello and Gilbert 2013).

More generally, into the emergency management field there is a new type of actor – VOST/VISOV – getting power by being in an intermediary position between citizens and institutional and professional actors. Like at the Frankfurt Fire Department, at the Var's firefighters' department, "spontaneous volunteers and social media communities are valued as important stakeholders in overcoming emergencies or large-scale-disasters, but due to limited resources, it is impossible to moderate them all" (Kaufhold and Reuter 2017, 609). Moreover, "additional research is required concerning the optimal implementation and evaluation of VOST (609). Can we describe them as a "sequential marginal actor" (Crozier and Friedberg 1977), a concept used to explain the power a person can get from belonging to two environments (here emergency field and social media) that usually do not meet ? Beyond the potential gain of power for this type of actor (individually or as a group), the effects of this in-between position are to be studied. Do the VOST/VISOV act as an "intermediary" or "mediator" actor as defined in the Actor Network Theory (Latour 2005) ? According to the ANT, an intermediary actor or entity does not alter what is exchanged between two entities whereas mediator do affect the exchange. Knowing whether virtual volunteers act like a simple filter – intermediary actor – or like an active filter – mediator – (and if so, what would be the nature and the effect of this alteration?) is a stimulating research track.

Thus, more investigations could be undertaken on to whom social media and citizen-generated content are beneficial. Because the integration of social media information within the emergency management does not simply and automatically lead to citizens empowerment. Like in every process or system where an agency is given to citizens, this agency is driven by professional or semi-professional actors who can use it as a new resource.

CONCLUSION

This paper sets out the methodology and the temporary results of an ongoing research project. It discusses the benefits and limits to use an emergency crisis exercise for research purposes. The described observation protocol, and the presented coding could be replicate to survey further exercises and simulations. Some possible processing of the observation data has been exposed and further visualizations of the data (e. g., by a time line or by social media inputs) are still in progress.

One the first analytical results tackles the way Var's firefighters consider (or not) social media information. For now, social media seem to be regarded as questionable because they do not easily fit into the organizational routine. The comparison between emergency phone calls processing and the social media processing should be pursued.

On the analytical level, the paper tries to use sociological concepts (from the Actor Network Theory and from sociology of organization) to describe and explain some results. The concept of "credibility trials" was used to describe the specific processing of social media information: as observed actors confer a questionable statute to social media, the "credibility trials" are more important than for the other information sources.

On the practical level, the location of the MSGU/SMEM team in the firefighter's crisis room and not in the Call Centre is an issue. This organizational feature contributes to distinguish social media information from more classical information sources. This spatial layout reinforces the cognitive distinction between social media and other information sources. The involved firefighters explained this choice by the double role they give to the MSGU/SMEM team : to report some emergency events (just like emergency phone calls) and to improve the situation awareness of the crisis room (Endsley 1995). Clearly, the situation awareness is for now favoured. Exercises 2 and 3 of the MACIV project (with other institutional partners) might give some useful comparison and feedbacks on that matter.

ACKNOWLEDGMENTS

This study is part of the MACIV project, funded by the French Research Agency. I thank all the players and the organizers of the crisis management exercise. The Var Firefighters' department was very helpful and a driving force to this stage of the research project. I also thank the other observers very much for the data collection: Robin Batard, Sandrine Bubendorff, Julien Coche, Aurélie Montarnal, Caroline Rizza. Finally, I would like to thank the three reviewers for their constructive comments.

ABSTRACT

As one of the most well-known social media platforms in China, Weibo provides an online public sphere. During the 2018 Shouguang flood, many people who were affected converged on the platform to discuss the disaster. The government – the highest emergency management authority – was accused of using censorship and other measures to suppress the coverage of the disaster. Based on an analysis of 34 qualitative interviews with Weibo users, of which nine directly address the Shouguang floods, this paper examines how three major actors contested facts and responsibilities during the disaster. Focusing on the state-censored, market-moderated social media context in China, our ongoing study provides new insights into a universal challenge of managing diverging interpretations and expectations in risk communication. We show that the establishing and framing of facts is inherently ethical and political. Time, time-space compression, liability and scales of risk responsibility emerge as critical points of friction. We draw on theories of risk governance, public discourse, computer supported collaborative work, and media studies for analysis and to articulate avenues for design.

INTRODUCTION

> *My parents are farmers in Shouguang, their farmland was flooded, … the crops yielded no harvest, their hard work this year has been wasted. In the two or three days after the flood, some villages, such as my parents' village, did not receive relief assistance and the serious situation was not reported on state media. … My parents do not use Weibo, so I had to send a weibo[1] to … let more people know the real situation in the disaster area, with a hope that people can donate rescue resources. My post was pushed on the trending list, I received a lot of emotional support, and some people also helped me forward the weibo to underscore the severity of the disaster. However, my post was quickly taken down. I wanted to access some disaster response information from the government Weibo [account], but I didn't see any information. I felt depressed and very helpless.'*

This story was told by Binqi (pseudonym), whose family were affected by the flood. Binqi was not alone, as many Weibo users posted information about the disaster on the platform. Their accounts differed from facts posted by the official Shandong provincial government Weibo account, and some of their posts were removed.

Our investigation takes the fact of conflicting accounts as its phenomenon. We are not on an investigative

[1] Sending a weibo is similar to sending a tweet.

mission to 'reveal' what was censored, but refer to literature on risk governance and urban environmental politics where the framing of disaster risk and disasters like Bhopal has been shown to be a social, political, and ethical process where capacities to contest facts are subject to power struggles (Jasanoff 2003, Fortun 2011, Swyngedouw 2015). There is no one truth about any disaster and our interest lies in the practices and 'infrastructures' for contestation that information systems can provide. Some are more suited to afford diverse information ecologies and democratic contestation than others (Jasanoff, 2003, Turner, Bowker, Gasser, and Zacklad, 2006; Baker and Bowker 2007; Karasti, Baker and Millerand, 2010). A deeper understanding of practices of contesting facts and responsibilities in disaster risk management can inform the design of information systems or infrastructures that can help the diverse parties involved to bring different perspectives into dialogue and develop a more democratic framing of risks, responsibilities and 'response-abilities'.

Sina Weibo is similar to Twitter in its design (Ramzy, 2011). As one of the most well-known social media platforms in China, it is used widely in emergency management by both the Chinese government and the public. Its features allow for the rapid spread of information. Therefore, Weibo provides a key platform for disaster relief and communication between the government and the public (Rigby, 2008; Ma, Zhang and Liu, 2014). The emergence and widespread adoption of Weibo also helped create an online public sphere (Xu, 2012), which enables civilians to debate social issues such as disasters by generating and posting evidence, examining and debating different versions of facts.

This paper draws on 34 qualitative interviews with people affected by disasters, of which nine directly discuss the Shouguang flood. Shouguang, an area famous for its fruit and vegetable produce in Shandong province, was hit by a serious flood from the Mi river between August 19 to 21, 2018. The flood caused thirteen deaths, three missing people, and an economic loss of 9.2 billion RMB (1.05 billion GBP), making it the worst flood Shouguang has seen since 1974 (Sina News, 2018). In this paper, we identify three major parties who constructed and contested facts around the disaster on Weibo:

(1) Official fact providers: The local Shandong government, the central government of China, disaster management agencies;

(2) Informal online fact providers: Weibo users who describe themselves as victims or who had family and friends affected by the disaster;

(3) Online onlookers: Weibo users who were interested in the Shouguang flood, but not directly or indirectly affected by the disaster. They participated by sending weibos, or commenting on posts.

A grounded theory analysis of the interviews has allowed us to draw out key practices of contesting facts. Asking 'what is the process of fact contestation of the public when a government version of disaster report is different from the public version?' and 'what is the impact of this process on future disaster response actions?', we aim to enable a deeper understanding of these practices and dimensions, supported by a discussion that draws on literature from risk governance, public discourse, computer supported collaborative work, and media studies. The aim is to inform the design of better disaster risk management sense-making practices and tools.

We found that the temporality of information release, the time-place nexus in witnessing and mediating the unfolding disaster, the liability and scales of responsibility are points of friction, which are contested by different actors on the Weibo platform. Overall, the paper not only demonstrates the process of fact contestation on Sina Weibo, it also suggests that the divergent constructions of facts could be a resource for better collective risk governance to promote a better cooperation between different disaster responders in the future.

BACKGROUND: THE RISE OF CHINESE SOCIAL MEDIA AS A STATE-CENSORED AND MARKET-BROKERED PUBLIC SPHERE IN DISASTERS

Thanks to the evolution of digital technologies, the public sphere has expanded into online space. This is a global phenomenon, and one that is highly contested. From Egypt's shut-down of the Internet during the Arab spring to concerns about voter manipulation during the 2016 US elections and UK Brexit Referendum, and debates about Internet control in Russia, governments, public safety services, commercial platform operators, regulators and citizens struggle over how common information spaces should be inhabited and governed (Millian, 2011; Bright, 2017; Ball, 2019). The online public sphere is a space in which a wide range of voices can be expressed due to the 'low barrier of entry' and interactivity (Edgerly, Vraga, Fung, Moon, and Yoo, 2010). In controlled information environments such as China, positive effects of social media on reducing state control of information and encouraging the development of civic engagement have been identified (Herold and Marolt, 2011; Tufekci and Wilson, 2012; Kaur, 2015), and a semi-managed online public sphere for Chinese citizens is emerging. However, the transformations and effects for crisis response and management are complex.

Writing in a Western European context, Habermas (1989, p.52) defined the public sphere as a 'society engaged

in critical public debate', which lies between the Private Realm (the personal domain) and the Sphere of Public Authority (the state, the police, the ruling classes). In this realm, private individuals assemble as a public body, and public opinion forms. In Habermas' theory, freedom of assembly and association, and freedom to express and publish their opinions, allows citizens to behave as a public body to discuss matters of general interest. In democratic societies, access to this domain is 'open in principle to all citizens' (Habermas, 1989, p.231).

Social media can be seen to open up an independent space online for individuals to engage in political communications (e.g. Yang, 2003). However, researchers are also observing opposing trends, such as the foreclosure of political debate through 'communicative capitalism' where online participants merely vent observations or views with no true dialogue (Dean, 2005). This interplay of contradictory forces also applies to China. Weibo is increasingly used by individuals 'as a new battlefield where the state and social groups fight for power and interest' (Wu, 2015, p.204). Following the 2011 train crash in China, Weibo users expressed concerns that the government had attempted to conceal evidence instead of supporting the rescue (Ma, Yuan, Zhang and Liu, 2012). In the 2015 Tianjin explosion, Weibo users believed that the Tianjin government shirked its responsibility and concealed the cause of the explosion and the accountability of local government. Weibo users succeeded in attracting the public's attention, which forced the government to respond to these perceptions of disaster response. By facilitating political debate and organising collective civic activities, the online public sphere that has emerged on Weibo enables the 'articulation of social problems and has shown some potential to play a supervisory role in Chinese politics' (Yang, 2003, p.474).

However, the model of the public sphere in Chinese society differs from Habermas' theory (Tong, 2015; Rauchfleisch and Schäfer, 2015). A number of factors undermine the applicability of classic public sphere theory in the Chinese context. The most significant factor is that the Chinese public sphere is not free from government control, as the Chinese government has devised a series of supervision and censorship mechanisms that restrict the communication of information and speech in certain topic areas by deleting weibos posted by individual users and by removing weibo threads from the Trending List.

Yet, although the government regulates, manages and limits communications, it also has to maintain 'the stability of the online public mood' (Li, 2010). The public can engage in debates online, but the topics they can discuss and the opinions they can express are severely restricted as a result of government censorship. At the same time, the social media public has the power to influence public opinion. This has led to a semi-managed online public sphere, which is a state-censored, market-moderated social media environment. In this paper we ask 'How is this organized and experienced?' and 'What are consequences and opportunities for disaster risk management?'. We proceed with a short discussion of our methodology and then turn to a presentation of qualitative data. From this, we draw out and discuss key themes and implications for the design of information systems for crisis response and management.

METHODS

The analysis is built on a case study of the 2018 Shouguang flood, which is part of a bigger ongoing study on the transformation of disaster communication in China via social media, focusing on Weibo. Qualitative methods were used to enable a deeper understanding of practices of disaster communications on Weibo. For the bigger project, 235 Weibo users were selected as potential candidates for interviews, the main criteria of recruitment being that different types of user candidates sent weibos during Chinese natural disasters to ensure their use of Weibo in a disaster. In addition, the type of Weibo user is further divided the sample into several subgroups. Weibo requires users to provide phone number, birth date, gender and location upon registration, and it enforces a hierarchy of 'unverified' and 'verified' users. The most common categories of 'verified users' are:

- Individual users
    - 'Red Verified Users' who have posted >20 articles/videos and earn >1,000,000 reads per month
    - 'Yellow Verified Users' who have >10,000 reads per month and support 2 Verified users
- Organisations who pay a fee or use the business license as the organisational identification, such as news organisations and government sectors.

For the ongoing research project, so far 37 interviews were conducted. These participants have been recruited through Sina Weibo private message (22) and snowball sampling (15). Three participants withdrew from the interview. Our research ethics means that they were not requested to provide a reason. The research overall is thus based on 34 interviews (5 Blue, 5 Yellow Verified Users, 24 Unverified Individual Users).

All interviews were conducted between October and December 2018. Before the interview, background information about participants was collected, including gender, age, employment status, disaster concerns and

reasons for concern. The 34 participants' reasons for engaging on Weibo during disasters fall into four categories: (1) interest in the disaster, including disputes over causes and the response of the government; (2) the affected area is the respondents' hometown; (3) personal exposure to the disaster; (4) engagement in rescue-related work.

Semi-structured interviews were conducted online, Questions started with an exploration of the participants' knowledge of the disaster, followed by questions about their use of Weibo, such as 1) How did you use Weibo in the disaster? 2) Why did you choose Weibo to find or send disaster information? 3) What kind of information did the government Weibos publish when you used Weibo during the disaster? 4) What kind of information on Weibo do you think is appropriate in a natural disaster? How do you define 'appropriate'? 5) Could you explain the advantages and disadvantages of Weibo? All interviews were conducted in Chinese, transcribed and translated. We have anonymised all data.

Nine of the interviewees directly discussed encountering the issue of fact contestation as they participated in communications around the Shouguang floods. Therefore, in this article, we focus on the interviews with these nine respondents. In exploring how they made sense of fact contestation, an open-ended interview design was used to allow the respondents the space to construct their narratives. For example, the interviews started with the question, "could you please describe what you know about the disaster and how you got to know about it?". If respondents referred to the governmental report, they were then asked about whether the governmental report concurred with the information they received from Weibo. If the respondents mentioned that they had posted about the disaster online, they were asked the questions, 'What did you post? Why on Sina Weibo?' Simple and short questions were used to enable the respondents to clearly and fully understand the questions.

DATA ANALYSIS

Table 1 below provides an overview of the respondents' role, behaviour, and uses of Weibo. After this, we discuss key findings.

Table 1. List of interviewees

Participant	Age	Gender	Occupation	Location	Role	Activities	Sina Weibo Uses
Yi	27	Female	New Media Editor	Nanjing, Jiangsu	Onlooker	Accessed information; Forwarded	Sharing disaster information; Calling for relief efforts; Expressing emotions
Penna	26	Male	Student	Chengdu, Sichuan	Onlooker	Accessed information; Forwarded	Sharing disaster information; Calling for relief efforts; Discussing causes and relief power
Stone	24	Female	Student	Osaka, Japan	Onlooker	Accessed information; Forwarded	Sharing disaster information; Calling for relief efforts; Expressing emotions
Weipin	25	Female	Student	Shouguang, Shandong	Online fact provider	Accessed information; Sent weibos; Forwarded	Reporting the disaster information; Sending rescue request; Calling for relief efforts; Discussing causes and relief power; Sharing disaster information
Binqi	26	Female	Lawyer Assistant	Nanjing, Jiangsu	Online fact provider	Accessed information; Sent weibos;	Reporting the disaster information; Sending rescue request; Calling for relief efforts;

						Forwarded	Discussing causes and relief power; Sharing disaster information
Clara	21	Female	Fashion Brand PR	Xiamen, Fujian	Onlooker	Accessed information; Forwarded	Sharing disaster information; Calling for relief efforts; Expressing emotions
Ming	19	Female	Student	Shouguang, Shandong	Online fact provider	Accessed information; Sent weibos; Forwarded	Reporting the disaster information; Sending rescue request; Calling for relief efforts; Discussing causes and relief power; Sharing disaster information
Yuhan	21	Male	Actor	Shouguang, Shandong	Online fact provider	Accessed information; Sent weibos; Forwarded	Reporting the disaster information; Calling for relief efforts; Sharing disaster information
Tian	23	Female	Student	Harbin, Heilongjiang	Onlooker	Accessed information; Forwarded	Sharing disaster information; Calling for relief efforts; Expressing emotions

KEY FINDINGS

In the age of social media, the gap of trust between the authorities and the public in China has been widening. Despite an increase in the presence of government on Weibo and the government's tightening regulation of social media platforms, Weibo still constitutes a relatively open online public sphere in which members of the public can discuss various social issues. During the Shouguang flood, government Weibo accounts and individual Weibo users' accounts — both those from the affected area and those whose families and friends were affected by the flood – diverged significantly. This led to heated contestation over the authenticity and trustworthiness of distinct versions of facts on Weibo. In this process, government Weibo accounts were perceived to be the official fact provider, while individual Weibo users with first-hand experiences of the flood either themselves or through their family members and friends assumed the role of online fact providers. As news of the flood spread, onlookers began to voice their opinions and partake in the process of fact contestation.

Multiple practices of generating and consuming 'facts' on Weibo

Platforming disaster 'facts', Weibo fulfils two major functions of social media, as identified by Ma and colleagues (2014): Weibo supports multiple practices of generating 'facts' about disasters, and it also provides an avenue for users to learn about, and moderate the 'facts', from within and outside the disaster-stricken areas.

With an aim to draw attention from emergency departments and Weibo users outside the affected areas, online fact providers such as Weipin, Bingqi, Ming and Yuhan began to post about the flood from within the flooded areas. Given the large number of active users, the online fact providers believed that the Sina Weibo would enable them to spread information in a rapid manner to reach a wide-ranging audience. To depict situations in the flood-stricken areas, the online fact providers posted textual descriptions, photos and short video clips. To justify the authenticity of such posts, geotags were used.

For example, Binqi posted about the flood on behalf of her parents who do not know how to use Weibo. Explaining why she chose to use Weibo as a platform to present her version of facts, she said, 'Sina Weibo is a very mainstream social media platform right now, for all to see, for all to search, for all to access information'. Weipin, another online fact provider, is a student who uses Weibo on a daily basis. After receiving a Weibo

notification of the flood from the local neighbourhood committee, she immediately searched 'Shouguang flood' on Weibo and participated in providing civil news coverage on the flood. As she explained why she '[relied] on Weibo to follow the latest developments of the flood', she said, 'There are so many active users on Weibo, which allows Weibo to provide more comprehensive information (than some other platforms)'. Notably, online fact providers often provided 'facts' that differed from those published by the government.

Weibo not only enabled some users to generate facts about the flood at close quarters, it also allowed other users to follow and interact with news on the flood from afar. Yuhan is a young actor, some of his followers are also actors with a large number of followers on Weibo. As a celebrity, he thought that posting about the flood on Weibo would facilitate rapid dissemination information his followers re-post the facts. As onlookers (Yi, Penna, Stone, Clara and Tian), individual Weibo users outside the affected areas considered Weibo as a readily accessible platform to obtain any latest news about the flood. Yi is a social media editor who uses Weibo for her everyday work and relies on the 'hot search' function on Weibo to access the latest news. She explained how she actively retrieved information on the Shouguang flood from Weibo:

> *I heard about the flood from my friends. Then I searched the flood on Weibo. Weibo is my daily source of information. I am used to following events on Weibo because I can get real-time information from multiple sources. In Shouguang flood, I saw a lot of Weibo posts sent by people from the flood-stricken areas. The posts showed the dangerous situations in the flood zone. I also saw some videos posted by Yellow V Weibo users providing descriptive accounts of the disasters, such as interviews with local farmers from the flooded areas.*

The use of Weibo in disasters is particularly prevalent among the younger generation. Tian, a 23-year-old student, indicated that almost all her peers relied on Weibo to consume news. She further noted that the interactive nature and diversified sources of information make Weibo a particularly attractive way of accessing the news. Tian compared Weibo with traditional media such as TV. She went on to criticise the latter as a slow and inefficient means to disseminate news. '*I use Sina Weibo frequently. Browsing Weibo has become an everyday leisure activity for me. I came across (the news of) the flood while I was browsing on Weibo. Then I kept searching and following updates on the flood*', Tian said. And, as a Chinese student studying in Japan, Stone noted that Weibo helps break down geographic barriers for her to learn about domestic news such as the Shouguang flood in China. Onlookers such as Clara and Tian noted that the information from Weibo raised the public awareness of the flood, which helped attract disaster relief resources and donations.

What are the contested facts?

Contestation of facts about the Shouguang flood centred on three issues, namely the causes and severity of the flood and the government's delivery of relief resources.

Description of the cause of the Shouguang floods and the situation

On August 20th, the CCTV released its official news of the Shouguang flood. Reporting from upper Mi river, the journalist stated that the flood situation was not serious. According to the news, the flood did not affect the villages downstream, and the local government had already dispatched rescue teams to the affected areas (CCTV, 2018). On August 23rd, the Weifang city government held the first flood control and relief news conference. Attributing the cause of flood to heavy rainfall, the spokesperson vaguely mentioned that Shouguang had been hit by a flood:

> *Under the influence of Typhoon Rumbia, heavy rain swept Weifang. Some cities and towns have been flooded…The heavy rainfall led to a rapid rise in the water level at three reservoirs. To prevent the dam from collapsing and for the safety of nearly one million people downstream, the municipal government released the floodwater downstream. However, Shouguang was still seriously flooded' (Global Times, 2018).*

At the news conference, no detail on the situation in Shouguang was released. The conference was covered by several news agencies on Sina Weibo, such as @Sina News and @Beijing News.

The CCTV news report was vehemently contested by Weibo users (CCTV, 2018). The online fact providers initially used Weibo to vent their anger at the journalist who was criticised for having misled the public to believe that the situation in Shouguang was not serious and that the area had received adequate rescue resources from the government.

Individual Weibo users such as Ming and Binqi provided a version of facts that is vastly different from the one included in CCTV report and the government's official press release. Weibo users believed that the cause of the

Shouguang flood was a complicated combination of human errors and natural causes.

Ming is a student who lived in a small town near Shouguang. As her town lies at the far side of Shouguang away from the Mi river, the town was not seriously affected by the flood. She saw the CCTV report on Weibo and noticed that the report failed to reflect the real situation based on what she had seen, what her relatives had told her, as well as some other information she had obtained on Sina Weibo. She recalled that 'the reporter said that the upstream flood had no impact on the downstream, we Shouguang people were outraged because the damage was really serious!'

Although a Shouguang local, Binqi was away from Shouguang during the flood. Although Bingqi was not able to participate in the disaster-relief herself, she contributed by drawing people's attention to the flood on Weibo. Dissatisfied with the CCTV report, she posted on Weibo: 'The CCTV misled the public by reporting that the upstream reservoir flood did not cause serious damages to the downstream areas. Due to the absence of rescue forces, villagers suffered heavy losses.' Binqi further explained how she first learnt about the 'facts' from her families and friends living in Shouguang:

> *Shouguang is my hometown. Although I don't live in Shouguang now, my parents and friends still live there. They told me that it rained heavily for several days in a row before the flood, which caused the upstream Qingzhou reservoir to overflow. This forced the local authority to discharge flood water from the reservoir, which flooded several villages on both sides of the river…The villagers suffered heavy losses. My parents' farmland was flooded. The flood swept away all crops that were about to be harvested.*

Weipin, an onlooker on Weibo, described that although the flood did not have a significant impact on her own life, she was upset to learn that such a severe disaster was not merely of a natural cause:

> *It is not just the heavy rain that caused such severe impact on Shouguang. The human error in mismanaging the upstream reservoir was also a main cause. Also, the villagers did not receive any notification from the reservoir team in time before they discharged water from the reservoir, which made the situation even worse...*

The government's rescue and relief delivery

Whether the government sent its rescue team and adequate relief resources to the flooded areas as claimed was another area of contestation on Weibo. In the news conference, the Weifang government announced that it had sent a relief team and relief goods to Shouguang. It was also explained that the Shandong party secretary had arrived in Shouguang in the evening of August 22nd, four days after the outbreak of the flood, to direct the disaster relief work.

The online fact providers accused the Shandong and central authorities of inaction. For example, Binqi and Yuhan posted on Weibo that the local firefighters and the police force in Shouguang rushed to the disaster area on the second day of the flood, which was far from sufficient. Other Weibo users, such as Ming, used the @ function to draw attention from government departments and state media outlets such as CCTV, pleading them to dispatch disaster relief and supplies. However, they did not receive any response from the official Weibo accounts at which they posted. Some other online fact providers also shared their first-hand experiences of the rescue situation on Sina Weibo. For example, Ming posted:

> *There are rescue teams in some of the worst-hit areas. However, I saw Weibo posts from many users with geotags in Shouguang saying that the disaster areas were "cordoned-off" and they were not allowed to contact the outside world. The rescue does not seem to go well either.*

As the online contestation developed further, '#Shouguang self-rescue' started to trend on Weibo and develop offline, according to Binqi. Using Weibo, local residents spontaneously self-organised to rescue people trapped in the flood and to deliver relief supplies to affected villages. Rescue teams from the provincial government only arrived in the affected areas a few days later.

Facts: Divergence and diversity

The fact contestations on Sina Weibo showcased divergence and diversity as the different actors assumed distinct social positions and responsibilities. Most government official Weibo accounts had remained silent in the first four days of the flood. Following the official news conference, facts about the flood were published not only via traditional media outlets but also via government Weibo accounts.

Shouguang natives and remote fact providers also occupied different positions as they took part in the fact contestation on Weibo. Weipin, a Shouguang native indicated that 'because this is where I live, this is my hometown, and when something like this happens, I definitely have to pay attention to it.' Some other online factor providers who did not live in Shouguang posted what they believed to be true based on reports from their friends and family members. In such cases, familial and friendship, and affective ties with intimate others played an important role in authenticating and validating the 'facts' for the remote fact providers.

Onlookers also participated in the fact contestation in diverse ways. For example, Stone defended the government departments, arguing that it is essential for the government to anticipate the public's response and consider whether any given facts may cause public panic and anger. Stone further explained that the official version of facts was necessarily constructed to maintain social stability and to mitigate negative social impacts arising from the flood. Unlike Stone, some other onlookers chose to trust online facts over government statements because they believe that the government may intend to cover up their negligence of responsibility, while others remained cautious for fear of misinformation.

In the aftermath of the disaster, many onlookers also acted upon the diverse facts in which they believe. One week after the flood, Tian accessed disaster-related information from the hashtag #Shouguang Flood. After reading about the dire disaster rescue situation, Tian donated relief supplies following the donation information posted on Weibo. She reflected that 'I didn't think about it too much, and then maybe I was just guided by the words posted by the affected people on Sina Weibo.' While some interview respondents expressed their doubts over the trustworthiness of donation appeals on Weibo, others believed that the government had already delivered sufficient rescue and relief resources.

DISCUSSION AND CONCLUSION: CONSTRUCTING FACTS, ACTORS, INTERACTIONS, INFRASTRUCTURES

Our analysis shows how the different users of Weibo construct the facts of the Shouguang floods differently. In and as part of these communicative struggles, actors, modes of interaction, infrastructures and practices of making sense of the disaster are shaped. Three key actors emerge:

(1) The Shandong Weifang/the Central government

(2) Sina Weibo users who were affected or whose families and friends were located in the affected area and who documented on the ground experiences of the Shouguang flood in near real time

(3) Sina Weibo users who participated as onlookers, who witnessed the contestation of facts, including the disappearance of posts and vented their dissatisfaction or anger, or adopted a 'wait and see' attitude.

Their experiences are shaped by many factors. Two are particularly powerful.

Firstly, the timing of information release and the temporalities of witnessing the mediation of the unfolding disaster are very different for the different actors. For government agencies, the speed of information provided by Weibo users on the ground and distributed across the country is hard to control and in arrhythmia with their necessarily slower fact-checking and paternalistic approaches to releasing information. For locally or remotely affected Sina Weibo users there is great urgency in those situation descriptions and it is difficult to understand why those in power do not provide 'adequate' immediate response. And for onlookers, the censorship and disappearance of Weibo reports is deeply unsettling. Lam (2018) describes how local members of a WeChat group who shared concerns over a potential spread of disease were arrested within 15 hours of posting their messages. This was unsettling in a different way, bringing divergent expectations on risk governance to the fore.

Secondly, the scales of responsibility are a source of friction. The government is responsible not only for managing the disaster at the local and national scale in terms of response efforts and financial long-term commitments, it must also manage public opinion. Moreover, the government is responsible for innovation and growth in regional productivity – a motivation for the engineering of the dams that are implicated in the floods. Their engineering of complex socio-technical systems increases the risk exposure in the area. At the same time as they benefit from these socio-technical systems, the local community suffer from their exposure from increased risks, they expects and are dependent on rapid emergency response and relief. Local responsibilities that may have contributed to increased exposure to risk, such as settlements and agricultural use of the river-banks are not part of the discussion on Weibo (although they do come into the slower paced debates on traditional media (see, e.g. Lam 2018).

We can use Jasanoff's concept of 'technologies of humility' to explore this challenge to design further. She argues that attempts at 'disciplining the incalculable through sophisticated forms of calculation' enact ill-advised hubris (2010: 19). To counteract it, she argues, a shift from disaster risk management to risk governance is

necessary. Jasanoff envisages public engagement as complementary to formal efforts, and designs such as Ma et al.'s joint official microblog platform to improve interactive communication with the public under a centralized system are beginning to support direct communication with the public in China (2014). But there is more to a shift to risk governance than shared platforms. Jasanoff shows that collective risk governance requires not only expert professionalism and broad-based engagement with local knowledge, but also flexible infrastructures. In Jasanoff's analysis, conflicts of interest and difficulties in the control of information are not problems that must be overcome *before* partnerships can function. Indeed, she shows that the idea that agreement requires erasure of conflict and difference is misleading. Instead, like Swyngedouw (2015), she argues that a political process of understanding risk, responsibilities for risk, and the injustices involved more fully is needed.

We therefore suggest that the construction of diverging facts is not a problem that must be eradicated, but a resource for better collective risk governance. With infrastructures that better support expression of temporal and scalar disjunctures between formal emergency response agencies and the communities they serve, better collaboration may be possible. In future work we will focus on the role played by Weibo as a platform in brokering information that is crucial to the construction of facts and trust.

The limitations of this study suggest a few important directions for future research. The interview data reported in this article is only collected from unverified individual users, which do not reflect the perspectives of verified individual users and verified organisational users. As these users have considerably large numbers of followers and occupy an influential symbolic status on Weibo, their views are often based on the social roles they play and assume on Weibo that may provide the view in the other direction. Secondly, the contributions of the nine interviewees provided the main data basis for this study, however, the data did not represent the larger Weibo user groups. We will include more types of Weibo users and samples in further research to keep diversity and quantity of data to analyse complex behaviour pattern of various perspectives in disaster response.

Managing Risk Across Borders: ethical implications of engaging information technology for transboundary disaster collaboration

Katrina Petersen
Trilateral Research
katrina.petersen@trilateralresearch.com

ABSTRACT

Disaster management is increasingly becoming a project in managing diversity, from cross-organisational collaboration to inclusivity of voices. This is particularly prevalent when dealing with transboundary risks. New information technologies support these transboundary interactions by compiling diverse information and sources to build collaborative insight beyond what any individual organisation can know. This paper explores the ethical concerns that planners and responders face as they work with these collaborative information technologies to engage with data from other organisations, based in different data frameworks, socio-political priorities, goals, and cultures of risk. It draws on the ethical impact assessment of a cross-border collaborative crisis planning platform currently under development in the H2020 project IN-PREP to examine ethical tensions around equity, inclusion, diversity, solidarity, accountability and transparency. It discusses the consequences of such design foci for an agency's ability to notice ethical risks that emerge from working in diversity.

Keywords

Ethics, Transboundary, Responsibility, Collaboration, Information Technology

INTRODUCTION

This paper explores what ethical issues get foregrounded when borders become a focus in the design of collaborative information sharing technologies for disaster management. Specifically, it examines the tensions and concerns that emerge when actors are brought together from different cultures of risk assessment and preparedness through an interactive data framework and insight tool. As borders – national, jurisdictional, or institutional – increasingly play a role in how disaster risk information is organised and understood, questions arise around how these tools influence the ability of diverse decision-makers to address and take responsibility towards equity, inclusion, diversity, solidarity, accountability, and transparency. It proposes that articulation mechanisms to build awareness around diversity and difference, not just pathways to consensus, are necessary to build trust between responders, the tools they use, and the broader society.

By considering how having "transboundary" as a specific design goal for disaster information technology influences the attention of those using it towards ethics and the risks they assess, this paper adds to literature around digital ethics and improves understandings of how these tools lead to better societal resilience as a whole. It also offers insights, though broad and high-level, into how the design and use of these tools can be approached to develop a clearer understanding and responsibility towards how they affect the way disaster managers work, care for those they serve, and make their communities safer and stronger.

ETHICS AND TRANSBOUNDARY COLLABORATIVE DISASTER IT

Transboundary crises are considered a primary societal challenge facing Europe (Cabane and Lodge 2018). To support better cross-border cooperation and understanding for disaster planning, information technology systems

(IT) are regularly being designed and implemented. These IT systems combine data and insights to provide the broader views of a situation for more efficient coordination and more effective collaborative planning and decision-making (Pottebaum et al., 2016; Jasmontaite et al., 2015). But in combining data in ways that are mutually accessible to a broad network of actors, the IT raise ethical tensions in relation to what kind of impact on disaster management practice they make possible. These tensions go beyond semantic inconsistencies. They are accentuated by the transboundary intention of the systems and become a necessary design focal point (Bharosa et al, 2012; Panten et al., 2018). If left unaddressed, these tensions can lead to results ranging from the further marginalisation of communities to decreased solidarity between response agencies.

These IT work by collecting and translating into comparable forms different types and sources of data. These can include data from satellites, drone, CCTV, alarm sensors in buildings, and GPS worn by responders at the scenes. They can blend in historical data and the results of models, like estimated plume rates, fire spread patterns, and person movements in order to enrich situational awareness and the ability for responders to anticipate their next steps and future needs. This work with the data makes it possible for disaster responders to see across agencies and regions: they can identify resources held by different organisations, understand how their agents are positioned in the field in relation to others, and anticipate when a hazard might move beyond their capacities to know to ask for to help. They fundamentally shift the role of IT from horizon-scanning with the aim of collecting information in one place to providing analytics that enrich information to help transboundary responders detect risk, support collaborative decision-making, understand each other's strengths or resource gaps, and improve joint sense-making (Backman and Rhinard, 2018). Moreover, by structuring collaborative interactions through the sharing of data, these IT also have potential to act as forms of accountability and as professional safeguards against making bad choices (Princen et al., 2016).

However, to work, these IT must bring together overlapping, but not identical, practices of risk assessment, perspectives and voices (Muhren and van de Walle, 2010). Interests may overlap, conform or conflict, differing in how they are translated and interpreted depending on the scale of activity (Williams et al., 2019). Combined with the complexity of the existing technological ecosystems, the diverse nature of the stakeholders they support, the potential needs of communities being served, what a good result should look like becomes more difficult to assess. While in some cases these are semantic (e.g. I define vulnerability in socio-economic terms, you define it in geographic terms), more consequentially they are about translating different valences, functions and expectations of that data that (Fiore-Gartland and Neff, 2015). In doing so, the IT piece together more than just information, but different conceptions of care and of what it means to take responsibility for the well-being of others (Baker and Karasti, 2018). As these combine, ethical tensions emerge.

In the most general sense, ethics around such collaborative IT asks questions about if a tool should be used, what acceptable results are of that use, and who is responsible for such use. For some scholars, this is a debate about what satisfactory results are for society, when the tools might be wrong, or to whom are designers and users accountable to and about what (Ananny, 2016). For others it is about considering the oughts and ought nots to determine what should and should not be designed and implemented (Floridi, 2018). Identifying ethical concerns is often approached by looking at different units of analysis, including examining the technology and the rules upon which it is constructed itself, looking at the processes and ends being sought, and addressing the responsibilities and liabilities of the persons or organisations doing the actions (Brey 2012; Ananny 2016; Floridi and Taddeo 2018). These framing questions and units of ethical analysis have the potential to act as a form of societal accountability, building into the tools forms of responsibility, and integrating societal concerns into the practices with these tools (Hijmans and Raab, 2018).

However, these frames rely on a basis of commonality to start with, and do not always anticipate the collaboration or necessary ad-hoc negotiations that make working over and through a border a benefit for all involved. They approach data and the digital in a way that assumes (even if just local to a given assessment) stability and lack of contestation about what the understandings of the world are, what is a good association, and what the hopes for making a world better are (Neff et al., 2017). Putting a border as a centre of focus complicates *shoulds* and *oughts* and *betters*, as the answers to these questions and what ethical concerns they evoke are not universally normative but culturally grounded and unstable over time and scale, and thus cannot be remedied via relativism or consensus (Leonelli, 2016; Fiore-Gartland and Neff, 2015). Approach these questions in a transboundary way requires taking into account how the tools can be used by end-users in the future and their potential human rights implications for the communities on either side of the line (Stahl, 2013). Ethics becomes about elaborating and encouraging dialogue around the tensions that arise in answers to the questions about if a tool should be used and if the results of this use are acceptable.

METHODS

This work is based upon an initial ethical impact assessment for a large-scale, 3-year long, ongoing EC funded research project to design a transboundary disaster planning and training platform, IN-PREP. This project team is made up of over twenty international and interdisciplinary partners (academia, industry, emergency management practioners and trainers, SMEs) from across the EU. This project intends to create an IT structure to connect a large quantity of complex and diverse data from disparate sources, from modeling of potential hazard outcomes and impacts (e.g. smoke plumes and infrastructural damage assessment) to the local resources available and deployed by collaborating agencies. It provides data analytics and data management frameworks to help process that data and provide realistic scenarios and insights to support all actors in improving their ability to coordinate and work together.

The ethical impact assessment is a process of critical scrutiny that aims to make it easier for designers and end-users to become more aware of the features and interactions that have ethical, moral, and societal implications (Brey 2000; Wright, 2015). In the process, they each learn more about the problem domain and potential of the technology, reflecting upon the potential impacts of different design moves, diverse user practices, and the ambiguities of real-world knowledge and experience (Carroll 2000). In doing so, it contributes towards the protection of societal values and the design of effective risk management strategy (Kloza et al. 2017).

The assessment is iterative throughout the project. This paper is drawn from the first stage, produced with the project's outset before design commitments have been made. The intention of this phase of the assessment is to identify what ethical concerns might arise at various scales of analysis, including technological, processual, and application (Brey 2012; Ananny 2016; Floridi and Taddeo 2018). It makes visible, early on, the potential dilemmas and tensions faced by end-users and stakeholders in the uptake of the new technology so that risks can be mitigated to the greatest extent possible and to support ethically aware future use. The results at this stage are thus more abstract and conceptual, describing little in concrete solutions.

The process began by developing an understanding of the IN-PREP technology by interviews with the technology partners and working with them to map high-level information flows, such as what information is collected and shared, how it will be used, and how quality is assessed. It proceeded with desk studies and participation in user requirements workshops to identify key ethical risks and related harms. It ended with stakeholder consultation, via an end-user workshop to validate these initial findings and to begin to identify mitigation measures and solutions that would be relevant to system design and organisational practice. The workshop included twenty-one participants, a mix of external stakeholder experts and IN-PREP's technology and end-user partners. The end-users included experts in Civil Protection, Fire & Rescue, Police, Crisis and Disaster Risk Management, Disaster Relief, and Public Crisis Management from eight different EU Member States. In addition, six technology partners participated to incorporate technical potential to better anticipate outcomes where tools and practices meet.

What follows are some of the initial tensions identified in the literature and these interactions around the mundane decisions that are necessary to make diverse data talk across borders and around making data mean when managing different cultures of risk.

MAKING DATA TALK ACROSS BORDERS

When building this IT, designers are able to combine a variety of data, manage their translations from one format to another, and map them together onto a common operating picture. These mundane design decisions about which data format to use or which terminology to adopt when describing data, decisions that are often made for practical and efficacy reasons, have the ability to both empower and disempower actors and communities as different data and practices with data are included and excluded from consideration (Leonelli, 2016). Choosing one classification scheme over another risks power struggles and exclusion (e.g. missing a race or ethnicity category). Choosing all schema for the sake of inclusion risks bringing communication between organisations into discord and confusion (e.g. so many different interpretations it is impossible to know which one is intended). Data needs structure, and coordination acts needs common reference points, but the answers are not to be found in the ability to share data itself.

When working with such IT, the end-users want to ask complex question of the data that go beyond layering and comparisons. Tensions starts to emerge around what they want to do with the data as they move from questions like 'what data might they need to know?' and 'what situations they might encounter?' towards questions like 'who could be the most vulnerable?' and 'what socio-economic elements could exacerbate a crisis?'. It is already well acknowledged among disaster practioners that what risk means is not the same on two sides of a border, and thus what data they use and how they use similar data to answer these questions differ (Abad et al., 2018). As a

result, for the data to talk together, design and use has to be able to navigate these ethical tensions in how they can be put to use towards answering these different questions in different risk contexts.

At the most basic level, for example: in Germany, responders will first attend to those in need of aid, then they will attend to the safety of the scene: the greater risk is the immediate lives lost. In France, it is the other way around, first the scene is secured, then those that are in need of aid: the greater risk is to the ability to provide service, if the first responders are injured, then no one will be helped. In England, the aim is to remove all victims from the scene so both scene and person can be treated separately. Differences in what is required of data can be similarly exacerbated by different organisational and role-based approaches to disaster management. While most European countries work with a command and control model that has three levels, strategic, operational, and tactical, the responsibilities at each level are not consistent. For examples, decisions taken by a tactical team in the Netherlands can be taken by an operational team in Italy. What keeps coming out when responders from different places engage with each other is the basic question "why are you doing it that way?". Each practice of risk management has different data that is immediately relevant and highest priority: data about the scene, context, broader picture; data about who is where and in what condition; data about who has the capacity to take victims. Each require the data to be able to be focused and organised depending on the goal of the actor. This does not imply that these goals are by their nature conflicting (they are not), but the different aims ask for different IT work with the data beyond the ability for them to be comparable. When responders engage with such a system, they need to know, for example, if relating their understanding of social vulnerability to another organisation's data on infrastructural instability is an accurate and relevant association to make and to understand how that association might need to be made differently in one locale to the next.

The manner in which data can be approached to answer these questions matters because, as previous studies have demonstrated, decisions taken during disasters can "reinforce, intensify and produce new and uneven stratifications" (Adey 2016: 42). But, as Mark Latonero notes, "the very introduction of data-centered technologies can both reveal and exacerbate power relations on the ground."[1] If a responder or a model they use assumes specific identifiers for vulnerability – such as poverty, lack of robust utility services, dense housing – but in a specific context vulnerability is exacerbated by disability and unique religious tensions, then the inequalities that already existed in these less well represented features start to have greater weight and impact on those living in that context. Yet, it is not always possible to see the details in even the most well-structured big data from across the border. Nor are actors always aware of their interests when they decide on how they structure and categorise data (Ackerman et al., 2013). Both the end-users and technology designers often have a "less-than-complete understanding of the assumptions and values shaping the data they are working with" (Neff et al., 2017: p. 88). And, users of the designed technologies will often have different expertise and priorities when handling the data. It does not help that it is also very hard to predict what information will be available and relevant at what time for which organisation (Ley et al., 2014).

When working at the intersection of multiple risk practices, the challenge becomes one of choosing what kind of knowledge gets included in a system of classification and standards to be able to support and enhance successful collaborative decision-making, without erasing all diversity and ambiguities for the sake of making things common enough for all. Thus, the ability to assign value to the data is not determined by the data itself but by ever-shifting contexts and situations of use (Leonelli, 2016). Identifying these perspectives and accommodating what various actors need to know versus what is nice to know, what tools they must have versus may have, requires careful and considered design (Radianti et al., 2018). Meta-data is a start but cannot provide for all these uncertainties nor can it anticipate the informational needs of other organisations in advance.

The reach of these technologies across socio-political, cultural, and organisational divides demands articulation mechanisms by which actors are able to be aware of others, express difference, and align activities (Doherty, 2012). This awareness can in part be achieved by including a diversity of data and localised sources in the design process to ensure the work done with the data (through algorithms, translations, layering) is generalisable in ways that produce collaborative environments (GFDRR, 2018). But reconciling this diversity, particularly in the face of unpredictability, sets out new forms of responsibilities. Understanding the diversity involved is a vital step in supporting equity and inclusion but does not in and of itself build solidarity or an understanding of responsibility within the collaborations being pursued through the system. Care fundamentally involves critical commitments not just in the acts with the data but the processes of curating the data for multiple audiences and situations of use and involves a unique responsibility to produce and maintain the awareness of where one stands in relations to others. It is necessary to understand how one's data and one's acts with data fit into the broader picture and how specific engagements with that data build trust (Baker and Karasti, 2018).

MAKING DATA MEAN ACROSS BORDERS

In order for the data to be technologically combined together, there needs to be an underlying ontology, grounded in some form of shared standards and classification system. But standards and classification systems for data sharing carry with them value systems, systems that guide behaviour, preferences, and implicit bias within a given society (Bowker et al., 2010). Data bias is not an ethical challenge unique to border situations. In fact, it is increasingly being accepted as inevitable and necessary; data systems and the categories upon which they function are just approximations of the world, helping those looking to pay attention in specific ways (GFDRR, 2018). All humans work with some form of implicit biases as ordering mechanisms to make sense of the world around them. And, not all bias or disparate impacts are bad. But putting borders between different entrenched cultures of bias together create new urgencies, such as avoiding mission creep or discrimination. It also presents new opportunities, through comparison, to make visible the otherwise tacit and implicit for interrogation.

The biases can be amplified in how community data, like the demographics of crime or who engages with specific public services, are known to often over- and under-represents communities. For example, low-income communities tend to be surveilled to a greater extent than high-income neighbourhoods, leading to disproportionate representation (Narayanan and MacDonald, 2019). While none of this data is inaccurate in and of themselves, inequalities emerge in how data becomes actionable information for specific actors, with the potential to make some segments of society better off or magnifying injustice for others (Powles and Nissembaum, 2018; Vallor et al., 2018). An added challenge with these transboundary tools is that there are so many actions being done with data and to the data in order to get different answers for different questions in different situations, that to design a system that can address these will be so complex that transparency becomes unrealistic for the users.

Yet, many disaster response agencies lack the technological and data skills and comparative capacities to ensure data and insights are accurate, credible, and not misleading for those they are sharing it with (Campo et al., 2018). When the quantity of data is so great that it is impossible for a person to process, actors need greater support in determining the proportionality and legitimacy of their actions with the data. To know if these systems are meeting specific needs and if their acts are accountable, actors need transparency: an understanding of what is being done with the data and why they received specific results with that data. But this is easier said than done, as exemplified in an exchange during one of the workshops:

> Responder: So when what we do changes, how do we make the models match?
> Designer: New rules would have to be able to be added to the system.
> Responder: How? Who would do that?
> Designer: You could tell us the new rules so we can add it in.
> Responder: But we don't understand what rules are there. How do we know how to make a rule?

The more accurate the algorithm is to transboundary interactions, the more complex it is and thus less able to be made transparent or intelligible by those making decisions with the systems. A lack of understanding in how the systems works means a greater reliance on this 'designed' foundation of action. It risks users being unaware of the limits of their view and experience of the data (House of Lords Select Committee on Artificial Intelligence 2018). Use of such systems require a level of data preparedness, technological knowledge, and knowledge on how to incorporate local and remote data activities into current practices (Baker and Karasti, 2018; Haak et al., 2018). This also magnifies bias discrimination and inequality, particularly in respect to underprivileged communities who have less access to such training and education (European Political Strategy Centre, 2018).

This puts actors in a difficult position of managing, without full information, the tension between using algorithms to make decisions more accurate in solidarity with others and ensuring fair treatment of those being served by making decisions that are locally relevant but potentially inaccurate for others (Whittlestone et al., 2019). With incomplete transparency or transparency that is full but too complex to be understood by a human, it is hard for users to understand when a model is insufficient for the required decisions or for the public to understand why certain groups get aid and others do not (GFDRR, 2018). This also makes trust problematic (Buscher et al., 2013). These are not simple decisions that can be tick-boxed away, but fundamentally part of understanding what is at stake in a collaboration, in a joint response, and when faced with simultaneously transboundary and local responsibilities.

Addressing bias is a social problem and not just a computational problem (Powles and Nissembaum, 2018). It involves envisioning the technical ecosystem, the full context, social forces, and purpose to which a technology is put to use (Vallor et al., 2018). While meta-data can help, it is difficult to produce the kind of background information useful to explain the data to help alleviate bias in advance of the information being exchanged. When

a responder learns how to engage with information, they learn it in a specific context -- national, cultural, institutional. This interpretive context helps people notice, determine, and improve the relevance, quality, timeliness, appropriateness, and compatibility of the data provided in the system (Bertelsen and Bødker, 2001). Understanding how categories were arrived at could help end-users see that a specific segment of the population would go unrepresented. It helps actors understand the 'how' and 'why' of information they are working with and avoid translating data inconsistencies into societal vulnerabilities (Dawes and Gharawi, 2018).

CONCLUSION

A focus on transboundary in disaster IT shows that for such systems to really work and support ethical decision-making and actions, they have to find ways to put that boundary forward. The IT becomes a starting point for a whole host of political engagements with ethical ramifications. Actors involved in the design and use need to learn how to be data allies, not just data sharers. Ethical standards are contextual and thus what is "good" in one context might not be in another and, as such, standards are not code-able or pre-definable in transboundary situations. As a result, the data, the structure of the systems it passes through, and the goals for its use need to become sites for deliberation (Neff et al., 2017). It might not be possible to take apart all the different classification systems to make sure they are ontologically representative (though they should still be, as much as possible). Nor it is possible to provide transparency of category, code, and algorithm. But, putting boundaries at the centre opens up opportunities to design for contextual awareness and articulation mechanisms that support actors in weighing local benefit with collaborative solidarity. It also makes visible new ethical responsibilities, not just about managing one's own data for the sake of liabilities, but about caring about its reuse by others.

The meaning and impact of codes and practices can only be understood in full in their relationship to others (Ananny, 2015). However, consistency and stability of meaning is exceedingly difficult in transboundary disaster management. Thus, ethics here is not about deciding right from wrong, but about providing the tools that enable actors engaged with these IT to produce the necessary descriptive context and interactional practices for an actor to understand where they stand in relation to others and how their actions affect diverse, and sometimes not well known, communities around them. Looking at ethical obligations with a sensitivity towards their context specificity can show that some data uses that may not be acceptable within one context may be permissible in another or to another purpose (Vayena et al., 2015). It is not enough to rely on context encoded as metadata or to open up code for inspection; while these steps are necessary, they are not enough to produce accountability towards the broader societal experience (Ananny, 2015). This kind of broader awareness is made in active and interactive the use of the system, as actors constantly renegotiate the distinctions between responder data and societal data (Neff et al., 2017). It is made through a better understanding of technological capabilities and limitations in different ethical contexts (Whittlestone et al., 2019).

Trust in the designers is not enough for trust in a system. Trust in a system is not enough for "good" collaborations that benefit society at all scales. Rather, mutual trust is built on shared context and coordination (Doherty, 2012). This comes from proactive engagement with the broader stakeholder and societal context, including activities to incorporate different kinds of knowledge, perspectives, and goals to inform innovation trajectories. In some respects, to understand the importance of different forms of interpretability in different situations, engagement with the system needs to reflect the interactive perspective and active participation often taken on by Liaisons or, as Princen et al. (2016) term it, Reginauts.

What is needed in the meantime is the ability to identify and see places where differences exist. Instead of aiming for an unreal transboundary ideal of no-bias and complete consensus in the abstract, the aim is then to use the diversity and discrepancies to make bias open for interrogation, in context. Maybe, then, though hopelessly idealistic, this kind of socio-technical work can become a starting point for understanding how to better address larger human rights challenges that increase societal resilience rather than merely act as amplifiers of bias and inequalities.

ACKNOWLEDGMENTS

The research presented here is part of the IN-PREP projects, funded by Horizon 2020 (H2020/2014-2020), the European Union's Programme for Research and Innovation under grant agreement n° 740627. I am grateful to my colleagues in this project for many inspiring conversations.

ABSTRACT

In this paper, we investigate how social media can be utilised to support the integration of emergency medical services (EMS) and crisis management activities. We explore the literature both on social media in crisis management and on EMS logistics to elaborate on their potential to support EMS logistics planning based on the experiences from crisis management. We then discuss how social media data can be used for tactical and strategic decision-making using location data to improve demand forecasting and planning for both routine emergencies and crises.

Keywords

Crisis Logistics, EMS Logistics, Social Media, Decision-Making.

INTRODUCTION

Recent statistics illustrate the continued relevance of research in crisis and disaster management. The United Nations Office for Disaster Risk Reduction finds that between 1998 and 2017, natural disasters caused 1.3 million fatalities and otherwise affected 4.4 million people (Wallemacq and House, 2018). While reports indicate an overall decline in the number of human-made catastrophes, the number of natural crises and disasters, such as hurricanes, wildfires, and earthquakes, continues to increase (Swiss Re Institute, 2018).

This sheds light on the crisis and humanitarian logistics required to attenuate the impacts of crisis events for people and communities that are affected (van Wassenhove, 2006). However, crisis and humanitarian supply chains, just like other systems involved in crisis response, often suffer from information flow impediments, including the unavailability and unreliability of information, with potentially serious implications for crisis response (Altay and Labonte, 2014; Day *et al.*, 2009; Maitland *et al.*, 2009). This is particularly evident when it comes to emergency medical services (EMS), which are expected to serve routine emergencies (e.g., traffic accidents and medical emergencies), but at the same time also to participate in crisis response activities.

In the crisis informatics field, the question of how information and communication technologies and particularly social media – Web 2.0 platforms such as content-sharing sites, microblogs, and online social networks that provide a forum for user-generated content and that are open to modification, participation, and collaboration by its users (Kaplan and Haenlein, 2010) – can assist in the coordination of crisis management efforts within and across different agencies has received much attention (Meum and Munkvold, 2013; Sarcevic *et al.*, 2012; Yates and Paquette, 2011). Taking up this question, we investigate how social media can specifically support the integration of routine EMS and crisis management activities.

Our research questions can be formulated as follows: *How can social media support decision-making in EMS logistics relating to crisis management activities? What is the potential of and opportunities for using social media as input for planning problems, and what are the limitations and risks?*

To answer these questions, we combine the existing literature on social media in crisis management and on EMS logistics. We draw on prior research on both crisis and humanitarian logistics, as both branches often face similar tasks and challenges (Zhang *et al.*, 2002). We then match the planning levels for EMS logistics with the crisis management phases to elaborate on the potential of social media to support EMS logistics planning based on the experiences from crisis management. We explain how social media data can be used at both the tactical and strategic decision levels – for example, using location data to improve demand forecasting and planning for both routine emergencies and crises.

The remainder of the paper is structured as follows. In the next section, we describe the research problem in detail. We then illustrate how social media might be used to support EMS and crisis logistics decision-making, considering operational as well as tactical and strategic decisions in crisis mitigation, preparedness, response, and recovery. Based on this, we present a use case for illustration and a research proposal at the strategic-tactical level. We conclude with a summary of our work and prospects for future research.

RESEARCH PROBLEM

Many different parties and service providers are needed to address a crisis event adequately, including EMS, firefighters, and police (van Borkulo *et al.*, 2005). The EMS system is designed to meet the requirements of everyday service, but also to be available during crises. Given that, it stands to reason that preparations for potential crises should take everyday EMS activities into account.

This is especially true for EMS logistics, which are an essential aspect of crisis management (Kovács and Spens, 2007). Decisions that relate to facility location, relief distribution, or casualty transportation – such as locating and relocating ambulances, setting up dispatching and routing policies, and coordinating with other actors involved in crisis management – are essential for dealing with a crisis (Caunhye *et al.*, 2012).

Thus, responding to a crisis inevitably requires EMS logistics planning, including decisions at the *operational, tactical, and strategic levels*, as Table 1 summarises (Reuter-Oppermann *et al.*, 2017).

Table 1: Overview of EMS logistics

Planning level	Time horizon	EMS planning problems
Strategic	Yearly or longer	Locating bases Determining the number of ambulances Hiring crew Long-term demand forecast
Tactical	Weekly or monthly	Locating ambulances Staff scheduling Scheduling emergency medical physicians
Operational	Daily	Relocating ambulances Assigning ambulances to calls Daily demand forecast Patient transport scheduling Handling unavailability of staff and vehicles

At the strategic level, much research on EMS logistics has focused on models and approaches for locating bases. Once opened, a base typically is in use for several years or even decades. Decisions about acquiring new ambulances are often made annually, but once purchased ambulances are expected to be in use for many years. However, as ambulances can be transferred easily between base locations, decisions on where to put them are made at the tactical level. Similarly, the schedules of emergency medical physicians, who are a constituent part of the EMS systems of several European countries, are determined tactically. At the operational level, planning addresses relocating and dispatching ambulances, as well as scheduling patient transports (Reuter-Oppermann *et al.*, 2017). EMS logistics decisions are thus an essential prerequisite of crisis management as they determine what resources can be mobilised when a crisis occurs (Bui *et al.*, 2000).

EMS logistics activities can be assigned to the four stages of crisis management (Altay and Green III, 2006; Galindo and Batta, 2013). They include: *crisis mitigation* and *crisis preparedness* activities aimed at preventing the occurrence of a crisis, limiting its impacts, and providing resources to respond to an event before it takes place; *crisis response* activities intended to minimise its acute impacts; and *crisis recovery* activities in the post-event stage, such as rebuilding physical infrastructures (Lindell, 2013).

The literature on EMS logistics in crisis mitigation and recovery has focused mainly on strategic decision-making, whereas the tactical and operational levels are considered more often in the context of crisis preparedness and response operations (Leiras *et al.*, 2014). In the pre-event stages, recruiting and training personnel, prepositioning ambulances and emergency supplies, and setting up long-term working relationships with other crisis responders is essential (Altay and Green III, 2006; Bui *et al.*, 2000; Goldschmidt and Kumar, 2016). During crisis response, EMS logistics often serve operational tasks, such as evacuating threatened populations, opening shelters, and providing mass emergency medical care (Altay and Green III, 2006). During crisis recovery, the focus of EMS logistics is on the tactical reduction of resources (Pettit and Beresford, 2005), but operational tasks, such as providing sustained mass care, and strategic activities surrounding the adjustment of existing tools and procedures are addressed as well (Altay and Green III, 2006; Bui *et al.*, 2000).

Demand prediction is a major challenge for EMS logistics in crisis management (Kovács and Spens, 2009). While rare, crisis are potentially catastrophic events associated with a high degree of uncertainty of occurrence, which means that the potential for crisis planning is limited (Boin and McConnell, 2007). Despite the occasional nature of events, sufficient EMS resources such as ambulances and paramedics must be available immediately at the onset of a crisis. This need competes with the fact that it is not feasible to install more resources than necessary for everyday service provision due to high cost pressures in many healthcare systems. Furthermore, even during a crisis, routine emergencies (e.g., traffic accidents and medical emergencies) still need to be served by EMS. It is thus unsurprising that the integration of EMS logistics and other systems is considered a prime challenge of crisis management (Gupta *et al.*, 2016).

To ensure the functionality of the crisis response system when it is needed, an efficient flow of information to and among all actors before, during, and after an event is essential (Day *et al.*, 2009; Maitland *et al.*, 2009). At the strategic level, incident data from previous years is a main input for EMS logistics planning and demand forecasting (e.g., of the expected locations and times of future emergencies [Ingolffson, 2013]). In addition, demographic information such as the number and ages of inhabitants in a district and the distribution of schools, nursing homes, and production sites can be taken into account. At the operational level, weather and current traffic are further data points. Beyond these inputs, social media and other sources of big data are expected to facilitate demand forecasting (Starr and van Wassenhove, 2014).

USING SOCIAL MEDIA TO SUPPORT EMS AND CRISIS LOGISTICS DECISION-MAKING

Prior research on social media in crisis management has emphasised the capability of platforms such as Facebook and Twitter to enhance decision-makers' *situational awareness*: by monitoring social media, they can learn about crisis events, including the location and extent of a hazard, newly developing threats and security risks, and the needs of affected communities (Eismann *et al.*, 2018). In addition, social media can assist decision-makers in obtaining contextual background knowledge to complement information from other sources. Thus, social media can support decision-makers in developing an overview of a crisis situation and establishing a sense of context (Ludwig *et al.*, 2015; Tapia and Moore, 2014).

We argue that social media can be considered *emergency response information systems* that enable EMS planners to collect information related to a crisis event (Turoff, 2002). In the following, we illustrate the promises and limitations of social media to enhance the flow of crisis-related information. Our assumption is that by supporting EMS planners in managing (i.e., collecting, processing, and sharing) information, social media can also enhance the integration of EMS logistics into crisis mitigation, preparedness, response, and recovery efforts (Maitland *et al.*, 2009; Saab *et al.*, 2008). Our argument is based on the premise that increased access to situational information can assist decision-makers in recognising decision problems (Bui *et al.*, 2000), while at the same time the actual relevance and meaning of this information depends on *environmental constraints*, such as the extent of situational uncertainty, complexity, and time pressure (Kapucu and Garayev, 2011), as well as the *time horizon* of a decision (Iakovou *et al.*, 1994).

Using Social Media to Support Operational EMS and Crisis Logistics Decision-Making

Operational EMS and crisis logistics decisions are often about routine tasks, such as the inspection and inventory of resources, but also include less-structured problems, such as monitoring potential information sources and coordinating assistance planning (Bui *et al.*, 2000). A key issue with such short-term decision-making is the lack of lead-time before decisions are made. *Timely access to relevant information* is generally not considered a problem for well-structured tasks (Thompson *et al.*, 2006), but operational decisions made during crisis response are known to suffer from a lack of timely and locally specific information, which cannot be provided by established sources of information because of the immediacy and unexpectedness of events and the lack or outage of local contacts and infrastructure (St. Denis *et al.*, 2014; van Gorp *et al.*, 2015). Yet under conditions of high situational complexity and uncertainty, decision-makers' need to consider a greater variety of

sources that provide general background information increases (Vakkari, 1999). By providing them with access to large amounts of near real-time information, social media can help fill these information gaps (Ludwig *et al.*, 2015; Sarcevic *et al.*, 2012; Tapia and Moore, 2014).

In addition, the *accuracy and representativeness of information* is essential for addressing short-term problems, which means that the evaluation and verification of data are major issues in decision-making (Fisher and Kingma, 2001; Thompson *et al.*, 2006). Using information from social media requires assessing the relevance and accuracy of that information under conditions of information overload and scarcity of time and other resources (Ludwig *et al.*, 2015). Moreover, operational – rather than strategic and tactical – crisis-response decisions are associated with high criticality, which means that trustworthiness of data is essential. Decision-makers may not, therefore, rely on available information to make decisions that have the potential to save or lose lives or that involve allocation of scarce resources, such as assigning vehicles and personnel for search and rescue operations. The findings of prior research suggest that social media data are usually at least triangulated with information from other, presumably more reliable sources (Tapia and Moore, 2014).

As regards operational decision-making, we observe that information from social media is likely of limited value for routine decision tasks for which alternative sources of relevant and high-quality information are available. For particularly urgent tasks, however, information overload and limited reliability of information can be problematic.

Using Social Media to Support Tactical and Strategic EMS and Crisis Logistics Decision-Making

Tactical and strategic EMS logistics decisions are most relevant during the pre- and post-event stages of a crisis, given that the acute impact phase of such events rarely lasts longer than a few days (Kumar and Havey, 2013) and decision-makers typically prefer making medium- and long-term decisions well in advance of a potential crisis (Danielsson and Ohlsson, 1999).

It is useful to distinguish between crises with a sudden onset, such as terrorist attacks, and events with a slow onset, such as droughts (Kumar and Havey, 2013): Whereas crisis preparedness is basically precluded for sudden-onset events, slow-onset events can be mitigated in the abstract and effective preparation is possible. In both cases, decisions made weeks or months before an event are likely to have ripple effects on crisis response activities because both the availability EMS capabilities and the flexibility of the EMS logistics system depend on prior planning (Thompson *et al.*, 2006).

Problems of timeliness and availability of relevant information are less severe at the strategic and tactical levels because a more extensive search for and vetting of potential information sources is feasible. Nonetheless, we find that there are still limitations to using social media to support medium- and long-term decision-making, as crisis planning involves many tasks that are well-specified in advance, such as defining roles and responsibilities and allocating materials and equipment, as well as activities that are restricted by organisational routines (Boin and McConnell, 2007).

Beyond that, evidence suggests that social media can provide decision-makers with *intelligence that is not available from other sources*, such as notifications about emerging security threats, newly developing crises, and other emergent conditions on the ground that could affect the safety of people and materials. If thoroughly vetted, such information can be useful for the tactical deployment of personnel and the location or relocation of vehicles and supplies, route choices, as well as strategic investment decisions regarding bases, local infrastructure, and alliances with other actors (Tapia and Moore, 2014). Furthermore, the literature suggests that information from social media can assist in long-term tasks aimed at increasing organisational and community resilience, such as reputation and community management (Anson *et al.*, 2017).

However, ambiguities in the interpretation of available information can hinder decision-makers from arriving at correct and consistent interpretations of a problem (Kowalski-Traklofer *et al.*, 2003). As the consequences of tactical and strategic decisions might not be observed until the actual occurrence of a crisis, which could be much later, this issue is particularly problematic for medium- and long-term EMS logistics decisions (Helsloot, 2005). Thus, reliability and especially the *accuracy, completeness, and consistency of available information* remain essential (Fisher and Kingma, 2001).

Overall, we are cautiously optimistic regarding the potential of social media to support EMS and crisis logistics integration in the medium and long runs. While many routine tasks might still not benefit from the additional information, social media can be used to obtain intelligence not available from other sources and to increase organisational and community resilience through timely engagement. The need for cross-validation is evident; the literature suggests that this can be done due to the extended planning horizon and the possibility to rely on crowdsourcing and interactive approaches to information collection and validation (Mehta *et al.*, 2017).

Summary

Figure 1 summarises our conclusions. Overall, it is unlikely for medium- and long-term decisions to be made while situational uncertainty and time pressure are high (Kumar and Havey, 2013). Due to the significant long-term impacts of such decisions, social media also do not recommend themselves as sources of information in such cases, given that baseline quality criteria might not be met and time pressures impede thorough validation of information.

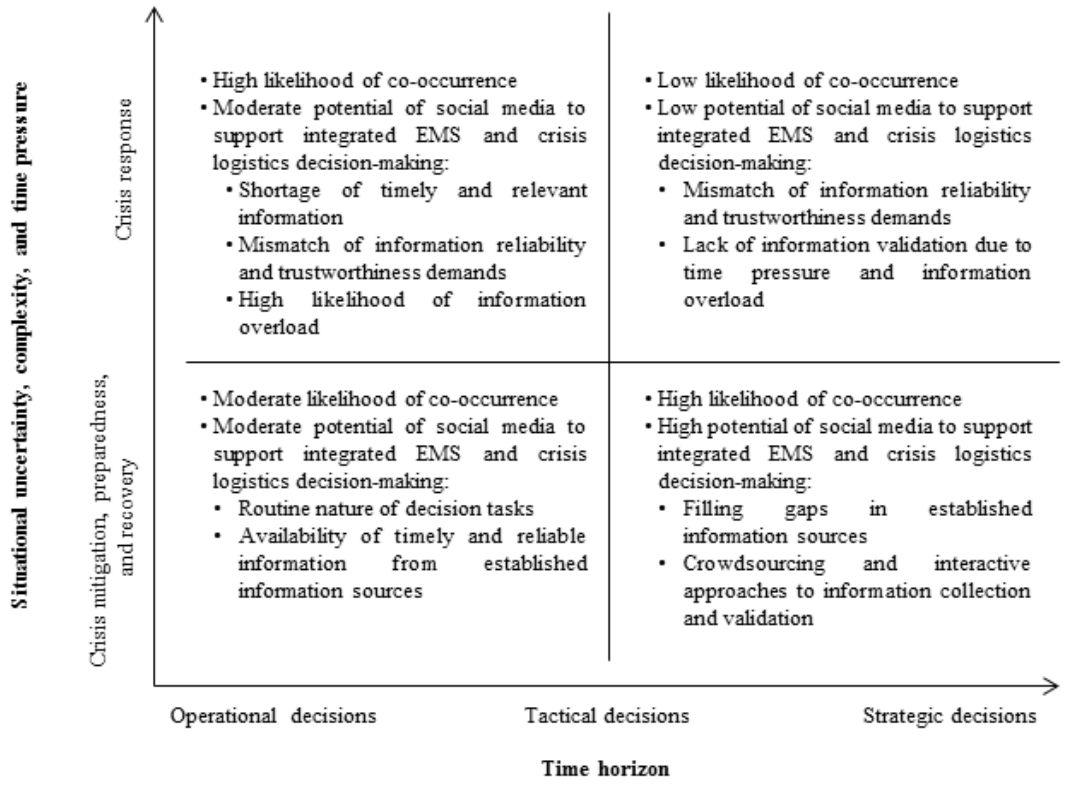

Figure 1 Potential of social media to support integrated EMS and crisis logistics decision-making

The less acute stages of a crisis are more similar to non-crisis EMS logistics (Holguín-Veras *et al.*, 2012). Based on the research literature, we conclude that operational decisions before or after the crisis impact phase are often subject to established EMS routines and can be made using regular sources of information, which diminishes the potential of social media to contribute to these tasks.

We believe, however, that both tactical and strategic EMS logistics decision-making can benefit from incorporating social media, especially during crisis mitigation, preparedness, and recovery. Although the need to cross-validate information is evident for medium- and long-term decisions, too, the environmental conditions allow for more rigorous data collection and verification using more time-consuming methods. In particular, social media can support decisions that are not overly regulated by organisational norms and routines, such as those regarding investments in infrastructures, personnel, and networks of responders and potentially affected communities.

Contrary to our insights, prior research on social media in EMS and crisis and humanitarian logistics has mostly focused on operational decisions made in the response phase (Kirac and Milburn, 2018). Therefore, we suggest a use case for illustration and a research design to investigate further how social media can enhance EMS and crisis logistics integration based on strategic and tactical decisions, especially in mitigating and preparing for a sudden crisis event.

RESEARCH SCENARIO

Although prior literature has mostly focused on the use of social media for operational decision-making during crisis response, our insights demonstrate that it can also be used for tactical and strategic planning problems. On

the strategic level, decisions regarding where EMS ambulance and bases should be located are frequently investigated. In line with earlier approaches (van Essen *et al.*, 2013), we consider the planning problem of locating ambulances and bases both strategically and tactically.

Locating ambulances and bases serves several objectives that may, depending on the decisions made, lead to outcomes that are at odds with one another. These include, for example, maximising the coverage of the region or population, minimising driving times to emergency calls, maximising response time fulfilment, minimising costs for installing ambulances and bases, and maximising the survival probability of patients in case of an emergency (Reuter-Oppermann *et al.*, 2017). When deciding on locations for ambulances and bases, it is typical to take only everyday EMS demand into account (Steins *et al.*, 2019). Crisis mitigation and preparedness activities thus must be handled separately, using the locations of EMS vehicles as input. Nevertheless, these EMS decisions are likely to have ripple effects on how a crisis is dealt with in the acute response phase, which means that it is most promising to investigate the potential effects of integrating novel sources of information for integrated EMS and crisis logistics decision-making prior to an event. Our research proposal thus aims at integrating EMS and crisis logistics planning by considering the potential of information from social media to facilitate strategic and tactical decision-making in crisis mitigation and preparedness.

The research question of the proposed study is: *How does integrating social media into tactical and strategic EMS logistics decision-making for base and ambulance locations influence crisis response?*

The expected demand is the most important input parameter for this planning problem. Unfortunately, the occurrence of future emergencies is, by nature, uncertain. Based on historical data on the times and locations of past emergencies, future demands can be predicted with a certain probability using statistical and machine learning techniques (Steins *et al.*, 2019). Predictions could also benefit, potentially highly, from integrating novel sources of (big) data and information, such as social media (Starr and van Wassenhove, 2014).

The assumption is that significantly improved predictions cannot be obtained using currently available data; additional data are necessary for that (Steins *et al.*, 2019). It is obvious that emergencies can occur only where there are people, but it is not easy to determine with certainty where they may be at any given time of a given day. Census data can provide a zone's population, but we cannot know for certain when people are actually at home. We do not know generally where individuals within a population work, when they work, and where they spend their free time. We also do not have anywhere near precise knowledge about how many people go to shopping areas, city centres, and other public or private facilities, which routes they take, and which means of transportation they rely on. The planning problem is aggravated when having to account for a sudden crisis event, such as a terrorist attack or a major fire. In such cases, ambulances that would otherwise serve routine emergencies (e.g., traffic accidents, medical emergencies, and patient transport) are needed to respond to the events.

Social media can help EMS planners approach this challenge, using, for instance, location data from posts and tweets collected in advance (Hasan *et al.*, 2013), which could be beneficial in better estimating the actual number of people in an area for different months, weekdays, and also times of day. Combined with the actual number of emergencies in a zone and data obtained from other information sources, such as the density of active mobile phones in an area, such information could be used to estimate the relationship between the number of emergencies and the location of people to arrive at better forecasts of emergency events. Furthermore, social media data collected during a crisis event (de Longueville *et al.*, 2009), along with potentially available data from historical events in the same region, could be integrated into crisis mitigation and preparedness planning for future events.

POTENTIAL STUDY DESIGN

Our aim is to investigate how using location data from social media for strategic and tactical decision-making regarding the location of ambulances and bases influences crisis response activities. In particular, we want to investigate its effects on the estimated distances and driving times to expected emergency calls during a sudden crisis event (e.g., a terrorist attack) in a given zone.

We adopt a qualitative research approach based on the critical incident technique, which is a flexible method for investigating goal-directed behaviour in specific types of situations (Flanagan, 1954). Initially, a set of vignettes of the research scenario outlined in the previous section will be compiled. The vignettes will provide descriptions of the situation (i.e., responding to emergency calls during a sudden crisis event in a given zone) and the general aim of activity in that situation (i.e., minimising expected driving times and distances to emergency calls during crisis response). Using a vignette-based approach allows us to gain an in-depth understanding of the cognitive processes that guide respondents' decisions (Jenkins *et al.*, 2010).

We intend to compile a set of three vignettes to illustrate the critical incident. The first vignette will present the problem of locating ambulances and bases based on established data inputs, such as census and demographic data, historical incident data, and outputs of frequently used decision-support systems (Ingolffson, 2013). It will contain a description of the underlying planning problem in a fictive response zone, enriched by materials that further illustrate the zone, especially maps of the area, potential vehicle locations, and data inputs. The second vignette will introduce simulated location data from social media for the respective area to complement the first vignette by additional data input. The third vignette will enrich the scenario by the occurrence of a sudden crisis event. Again, supplementary materials to indicate the location and magnitude of the event will be displayed.

We then plan to use the vignettes to conduct semi-structured, qualitative, face-to-face interviews with EMS planners from rescue operation centres in Germany. All interviewees will be presented the vignettes in the order delineated above. For each vignette, interviewees will be asked to describe how they perceive the situation, how they would respond to it to achieve the stated aims, and what criteria would be relevant to their decision-making (Flanagan, 1954). Interviews will be recorded and transcribed to identify emergent themes, using the constant comparative method (Boeije, 2002). The number of interviewees is to be determined based on the theoretical saturation in an iterative data collection and analysis process (Bowen, 2008). To ensure the credibility and trustworthiness of results, the scenarios and vignettes will be discussed with at least two experienced EMS planners in advance. The outcomes of the study will be validated through discussions with domain experts and participant cross-checking (Butterfield *et al.*, 2005).

The results of the proposed study will demonstrate the potential of social media to support integrated EMS and crisis logistics decision-making in the tactical and strategic domain, which can serve as an input for future model development and testing.

CONCLUSION

Our goal is to evaluate the potential of social media as a complementary source of information to assist in the integration of EMS and crisis logistics decision-making. In this paper, we have investigated what prior research on social media in crisis management reveals about their capabilities to enhance the integration of EMS and crisis logistics. We find that social media are most likely to assist in that task for tactical and strategic decision-making – for instance, determining the location of ambulances and bases. The outcomes of these decisions can be used, in turn, as input in crisis mitigation and preparedness.

Based on our findings, we propose a research scenario and a potential study design to investigate how social media can be used to enhance tactical and strategic EMS logistics decision-making, and the implications of using social media in the pre-crisis stage for achieving crisis response outcomes. In our research proposal, we compare the outcomes of tactical and strategic ambulance and base location planning using established information sources (e.g., census and demographic data, historical incident data, and outputs of existing decision-support systems) with location data obtained from social media. We rely on vignette-based qualitative interviews using simulated data and a fictive area of operations in which a sudden crisis event (e.g., a terrorist attack) is imagined to take place. Apart from the potential of social media to support EMS and crisis management integration, the outcomes of the proposed study will also shed light on the limitations and trade-offs of social media with respect to information collection, forecasting, and (automated) information processing.

Future research might expand this approach by collecting social media data for a specific EMS region that can be used to update the expected demand for future EMS. Furthermore, decision models that take such data into account for strategic and tactical planning problems, such as locating ambulances and bases, or for operational tasks such as dispatching and relocating ambulances and scheduling patient transports to, from, or between hospitals, can be developed and integrated into decision-support tools for EMS planning based on the prospective results of our work.

ABSTRACT

Expertise-based intuition plays a key role in decision making, especially in complex environments as those involved with crisis and emergency domains where decisions often need to be made on the basis of dynamic, incomplete, and/ or contradictory information. In such environments, a deliberative analysis is often impossible or inefficient. Using teams to make collaborative decisions in complex environments can bring benefits to organizations, but the complexity of supporting this scenario also increases. The present work proposes a solution based on graphs to support the sharing of the intuition rationale in teams aiming at an accelerated expertise. The development of the proposal is part of a methodological context of design science research. In this paper we report the execution of one of the expected cycles that explores the use of generated artifacts in practice that then produced insights for the proposed computational support.

Keywords

Knowledge sharing, intuitive teams, collaborative intuitions.

INTRODUCTION

Experts make decisions heavily based on intuition (Klein, 2013). Expertise-based intuition can be understood as the translation of experience into action and plays a key role in decision making, especially in complex situations such as crises and emergency environments (Salas et al., 2010). In emergency situations, experts perform complex decisions characterized by high risk, time pressure, dynamic environment, multiples actors involved, goals poorly defined, and problems badly structured (Quesada et al., 2017; Hutchins and Kendall, 2011; Orasanu and Connolly, 1993). In these environments, a deliberative analysis is often impossible or inefficient, for example, due to time constraints (Okoli et al., 2018). In contrast to deliberative analysis, intuition is based on the identification of subconscious patterns accessed very quickly by experts (Ross et al., 2004).

Considering that organizations are increasingly globalized and working in increasingly complex environments, collaborative teams gain strength and adopt different network models, with their members often distributed across the globe and possessing different expertise and cultural contexts. An organization should consider that experts eventually leave and take with them tacit knowledge. Considering that organizations should be prepared to face these risks, it is important that not only technical capabilities be shared but also the capability of intuitive decision making.Using teams to make collaborative decisions can bring benefits to organizations, but the complexity of management also increases compared to the use of a single individual. In teams, knowledge is not contained in just one individual, but sliced through several members. Often, collaborative teams perform better than individuals in both quality and quantity decision-making. During decision-making, collaborative teams can more easily parallel tasks and leverage the redundancy of team knowledge and enrichment provided by different views (Huang et al., 2014). The research question is: How to support collaborative decision making in complex environments through a computational solution regarding a perspective of expertise-based intuition? Imagine that an organization has to decide whether or how to send doctors to provide lifesaving medical care in a challenging area that suffered with a natural disaster such as the earthquake in Haiti that created a tremendous coordination challenge for the humanitarian relief agencies (Van de Walle and Dugdale, 2012). A team working in this organization, made up of members with different perspectives, should articulate the different intuitions about that agreement and then collaboratively make the decision.

In this way, this paper consider expert-based intuition a kind of knowledge that should be managed and shared. The expert making a decision based in intuition can be compared, for example, to the most swimmers that cannot explain, in coherent prose, how they manage to keep themselves afloat but, besides that, they might learn and teach to do so, or to a pianist that even while it may be difficult to pay attention to the music and the movements of his fingers at the same time, it does not exclude that the pianist, at another time, can give an account of how he was using his fingers (Schmidt, 2012, apud Harré, 1977).

As the work space has undergone intense changes in the last decades, the organizations have become more knowledge-based and the use of pervasive technologies have shaped the current cognitive complexity of work performed in organizations (Hoffman et al., 2013). As a consequence, the task of sharing expertise-based intuition from the experts has become even more complex. However, it is not feasible for organizations, especially in emergency domains, that sharing this expertise takes the same amount of time as the expert has acquired. In this way, it is essential to take the notion of knowledge sharing to other levels. Knowledge sharing should be accelerated within organizations and the consideration of the use of complex systems for this should be taken into account (Hoffman et al., 2013).

As argued in (de Carvalho et al., 2018) if one accepts that certain kinds of knowledge have different qualities (e.g. expertise-based intuition rationale), as discussed before with the swimmer or pianist examples, then methodologies for making it explicit and formal are needed. Collaborative decision making considering the use of expertise-based intuition is a new proposal that raises new challenges with regard to computer-supported cooperative work point of view. The main objective of this project is to propose and implement a computational solution to support collaborative decision making in complex domains through a perspective of intuition based on expertise.

The methodological approach followed to develop this proposal was the design science research (DSR) and an evaluation of the artifacts was conducted to gather insights and evidence in order to elicit requirements to the computational solution presented in this paper. Based on the evaluation results we proposed a solution based on graphs to support the sharing of the intuition rationale in teams aiming at an accelerated expertise. More discussion about the methodological approach and evaluation was conducted along the paper.

In the remainder of this paper, the next section presents works related to expertise, intuition and decision making. The Section entitled ‘Sharing Gut Feelings to Support Collaborative Decision Making’ describes and discusses artifacts designed to support expertise-based intuition sharing. In the Research Model Section, an experiment to explore the artifacts feasibility and gather new insights is presented. Then, in the following Section a graph based solution developed considering the insights and data collected in the experiment is proposed. The final section concludes the paper and recommends directions for future work.

RELATED WORK

The literature provides some strategies to deal with the management of a decision making process (Orasanu and Connolly, 1993; Klein, 2004), and most of them can be applied to complex decisions. However, to execute these strategies it is necessary time and available resources that are not ever possible in an emergency scenario (Quesada et al., 2017; França et al., 2017). In this sense, expertise-based intuition has been identified as an important factor to decision-making in researches conducted with military, police, firefighters, doctors (Klein, 2004). Intuition is based on the identification of subconscious patterns (Adolph and Kretch, 2015; Ross et al., 2004). When experts make intuitive decisions, these patterns are accessed very quickly, unconsciously.

In this paper, intuition is considered a mental faculty (van Riel and Horváth, 2014) that can be measured and developed. Intuition can be used for different purposes and in different contexts. There is a consensus that it is an important result of experiential knowledge. The quality of people's intuitive judgment can be as good as the experience upon which it was built. In this way, expertise-based intuition can be defined as experience translated into action (Adolph and Kretch, 2015).

In a general sense, as stated in (Okoli et al., 2016), intuition is fast and requires unconscious processing of information (minimal mental effort). Intuition is alogical (i.e. neither contradicts nor follows the rules of logic) and the intuitive process involves tacit knowledge (i.e. intuitors find it difficult to describe how they arrived at their judgment). The outcome is holistic and information is processed based on the analysis of unconnected elements that are integrated to generate more meaningful insights (Okoli et al., 2016).

The model proposed in (Nonaka and Takeuchi, 1995) discusses the way knowledge is created, transferred, enriched and incorporated into organizational processes. For (Nonaka and Takeuchi, 1995) the existing knowledge in organizations can be identified in two forms, explicit or tacit. These two forms of knowledge interact and in the dynamic processes of organizations are transformed.

The Recognition-Primed Decision (RPD) model (Ross et al., 2004) was constructed based on observations made by decision-makers in operational situations. The RPD describes how decision-makers use pattern recognition to achieve decision objectives. For the recognition of patterns, the model considers four aspects, the goals to be achieved, the identified cues, that is, the identified pieces of segmented information, the expectations to be met and, finally, the actions to be taken. The RPD foresees in its structure the resources of situation awareness in order to generate a common plan of action and the use of mental simulation to predict and evaluate the strategy that will be covered in the decision. There are evidences that this model works well in complex situations, for example in conditions with time pressure and scattered information.

It is important to state that as discussed in (Schmidt, 2012), the term 'tacit knowledge' has been used, in a way that we also do not stand for, as a way for vaguely talking about practical knowledge as intuition, insights, heuristics, procedures, etc. The studies conducted by (de Carvalho et al., 2018) indicate that much so-called 'tacit' knowledge is not tacit at all and is regularly articulated in conversation or manifested in gesture, glance, gaze and so on.

In this sense, as (Graham 1964, pp. 137 f.) asked rhetorically, is it not possible to have an 'irrationally-arrived-at solution to a rationally-posed problem?', to which he replied himself: 'A concrete "guess" is an unconscious continuation of a conscious process'. We agree with (Schmidt, 2012) that the more experiments and computations the scientist makes, the more likely his 'intuition' is to be correct. In other words, through the conscious planning of experiments the accuracy of 'intuition' will be sharpened (Graham 1964, pp. 137 f.). In other words, experiences will build the subconscious patterns where expertise-based intuition relies on and different stimulus as new data will allow the improvement of patterns and also the trigger of these same patterns.

There is a growing interest in the area of intuition. Some recent research has been concerned with tackling the challenges of this area by developing frameworks, models and heuristics that deal with intuition (Hoffrage and Marewski, 2015; Okoli et al., 2016). However, to the best of our knowledge there is no study in literature that proposes a collaborative strategy to accelerate expertise focusing in intuitive teams.

SHARING GUT FEELINGS TO SUPPORT COLLABORATIVE DECISION MAKING

The methodological approach considered for the development of this research is the Design Science (DS). The DS methodology aims to produce knowledge about how to design (Dresh et al., 2015). Hevner et al. (2004) argued that the DS seeks to extend the boundaries of human and organizational capabilities by creating new and innovative artifacts, including constructs, models, methods, and so on. Such new and innovative artifacts create new reality, rather than explaining existing reality or helping to make sense of it (Iivari and Venable, 2009). The application of this methodology is not intended to seek optimal results, but rather results that satisfy the problem addressed in the research. Research based on DS proposes solutions to practical problems and also contributes to the improvement of theories.

In our research we conducted three cycles using DS. Cycle I provides the development of the general idea of how to share the expertise between an expert and a team (Neiva and Borges, 2017) (Neiva et al., 2017). Our theory was defined through the cycle I and can be stated as that expertise-based intuition can be shared and as consequence the expertise is accelerated. To explore the theory, cycle II produced the following artifacts: a macro process based on models of intuition and knowledge sharing and an initial model to support the use of intuition in decision making considering collaborative teams (Neiva et al., 2018) and (Neiva and Borges, 2018). This paper presents the conduction of cycle III where it was expected to gather evidences through an evaluation process investigating the artifacts generated in cycle II regarding practices of work. Considering the evidences, we suggested the development of an expertise sharing system to support expertise-based intuition sharing from an expert to a collaborative team in order to accelerate expertise.

The approach presented in (Neiva and Borges, 2017) and (Neiva et al., 2017) consists of splitting the expert's knowledge and transferring it to a team parallelizing part of the process, thus potentially saving time. This approach was the result of our initial investigation considering the expertise sharing field. We realized that existing techniques to replace and/or train a new expert are not fast enough, especially for those organizations operating in critical areas.

Given that experts apply intuition to multiple actions, a central issue in the approach presented in (Neiva and Borges, 2017) and (Neiva et al., 2017) concerns the development of a similar intuition rationale by the team. In this way, the team should work collaboratively and intuitively to obtain results analogous to those of the individual expert when acting within the organization. In this way, representing the cycle II in the application of the DS methodology in our research, our paper (Neiva et al., 2018) and (Neiva and Borges, 2018) presented a macro process to support the development of intuition in collaborative teams (Figure 1) and a model to support collaborative intuitive decision making (Figure 2). The macro process was built from the combination of the

knowledge transfer/creation model proposed by (Nonaka and Takeuchi, 1995) and the conceptualization of intuition as a mental faculty (van Riel and Horváth, 2014). The model, called Collaborative Recognition-Primed Decision Making, was built as an adaptation of the model presented in (Ross et al., 2004) for work explicitly with teams making collaborative decisions. The artifacts generated in cycle II was evaluated through a proof of concept (Neiva et al., 2018).

In a briefly overview of the macro process (Figure 1), the tables with decision requirements are inputs into the first stage of the transfer process, which is Socialization. In Socialization a defined (sub-) process promotes the discovery of patterns. During Externalization, the patterns identified and discussed with the team are documented and stored forming the initial subsidies for the construction of a collective mental scheme. In the Combination stage, the team works in conjunction with the expert on the construction of decisions based on intuition. At this point, the expert individual is "part of the team". The team organizes the intuitive decision-making guided by the model represented in (Figure 2). The constant feedback from the expert supports the update of patterns used as triggers for intuition. In Internalization stage, the team internalizes the established patterns by being exposed to the accomplishment of environmental tasks. In this stage, the expert is no longer a "part of the team", he/she tries not to intervene during the decision making, conducting a discussion session only after the decision is made. After the completion of a first round of the process, a new one may begin by considering a new level as a starting point.

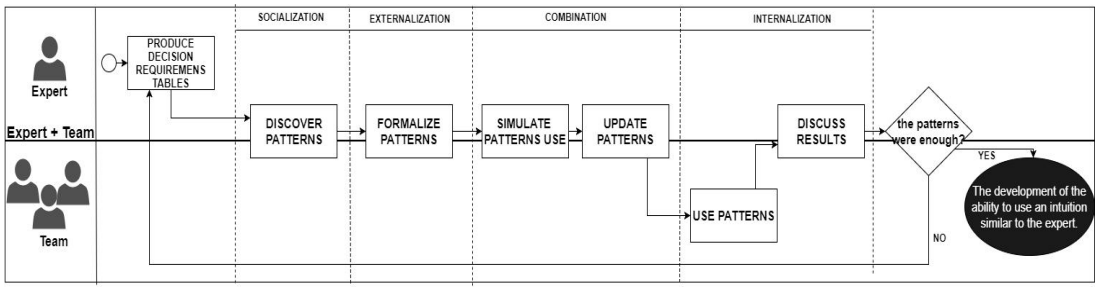

Figure 1. A macro process of expertise-based intuition sharing

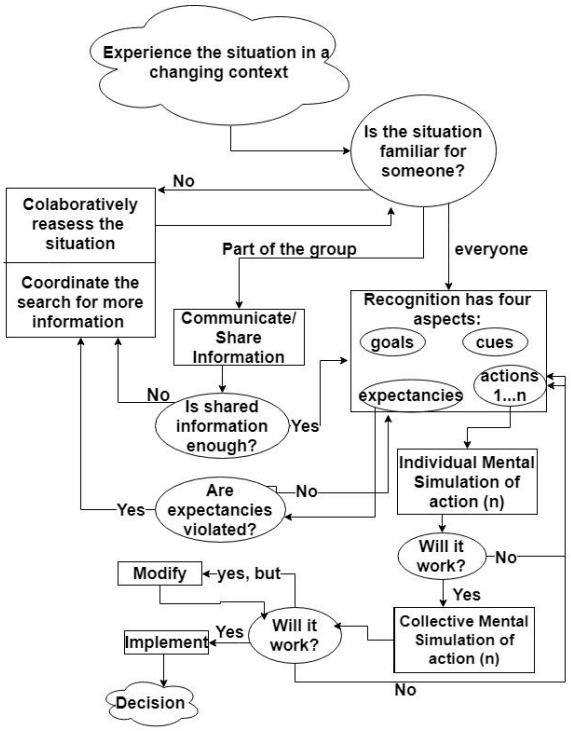

Figure 2. Collaborative Recognition-Primed Decision Making

The expected output of the process is the development within the team of an intuition capability similar to the expert's capability regarding the domain explored. For a more detailed explanation of the proposed artifacts, see (Neiva et al., 2018).

RESEARCH MODEL

The analysis of the artifacts was conducted considering a task where the expert-based intuition was shared using the artifacts. We imagine that the proposed artifacts have the potential to support an accelerated expertise by sharing the expertise-based intuition from an expert to a collaborative team. As a collateral effect the use of teams brings more resilience to organizations in the sense of knowledge sharing as discussed in the introduction section. Considering the proposed artifacts, the experiment aimed (i) to investigate their applicability in supporting the expertise-based intuition sharing and, (ii) to investigate if the artifacts contributed to the organization's work practice, also searching for strengths and weaknesses in them (iii) gather subsidies to generate insights about the evolution of the proposed artifacts.

In this way, the evaluation scope was defined based on GQM method (van Solingen et al., 2002) as following: **Analyze** the macro process of expertise-based intuition sharing and the collaborative recognition-primed decision making model **for the purpose of** evaluation **with respect to** behavioral, subjective, and performance dimensions **from the point of view of** experts and novices when performing decision-making tasks **in the context of** sharing expertise-based intuition.

The experiment was conducted in an organization that has dozens of courses in Higher Education. The organization is a public company with more than 500 thousand students. It is a dynamic company, constantly changing and improving its operations. Despite the organization does not belong to the emergency field, it is a complex organization, with a great capillarity, being present in 401 cities around the country. In this sense, by having this experiment being conducted in this organization, it was possible to gather evidence in order to mature the artifacts before exploring them in environments where the risks are higher, for example, those one involving the risk of losing human lives as presented in (Van de Walle and Dugdale, 2012). By being a public company, shareholders are an important factor to consider and the oscillations of the stock market also impact on decision making process that have to be agile and have impact in a great number of people, directly and indirectly. In a scenario of constant expansion and organizational changes, it is important to disseminate activities that support the decision making. A recurring and also vital task for the quality of the courses is the hiring of professors. In this sense, the experiment considered to support this task. For the hiring we had the participation of the coordinators of 4 different courses. The rules used for the hiring were the same defined by public notices in the organizational communication channels. It was possible that at the end of the hiring process it could be decided that no one would be hired. With the application of the task, the observer collected evidence indicating whether or not the decision was made using a rationale similar to the experts, in this case coordinators.

The experiment was divided into: Part 0 - The presentation of the Term of Free and Informed Consent. Only those who agreed and signed the term participated in the experiment. Part 1 - The definition of groups. Part 2 - Planning and design. Part 3 - Application of a follow-up interview.

Took part in this experiment 4 teams with 3 people. Each team consisted of 1 expert in the decision making process proposed by the task and 2 novices. The two novices were professors from the same work field who were interested in the coordinator position.

The team followed the proposed process and model to share the expertise-based intuition from the coordinators to the professors. One iteration in the process was made. To do this, before the experiment begins the organizer presented the objectives and operation of the experiment in a shortly briefing (about 15 minutes). The final outcome of the proposed experiment was the analysis of the similarity of novices and experts rationale regarding the related decision making.

Results

The results were divided into behavioral, subjective, and performance dimensions.

Regarding the **behavioral dimension,** through observations some insights were generated. It was observed that the patterns had different priorities, different weights regarding the decision that should be made. This became clear when we recorded in different groups, the novices questioned the experts about which indicators were more important in comparison with others. Also, during the use of patterns in the combination and internalization stages, it was observed that it would be important the use of a scale to express how much a pattern had been satisfied. We elicited this need by observing in our records that in different moments when the

groups were trying to make a decision, they realized that the satisfaction of the patterns was not a binary value, but rather, there were situations in which they were more or less satisfied.

The experiment made evident the prominence of patterns throughout the process of sharing intuition. It also showed that a pattern may have a qualitative feature but that it can be detailed to arrive at sub-patterns with more objective and measurable characteristics. We observed in our records that in different moments when an expert pointed out one of the patterns that he analyze in the decision making, if this pattern was not objective enough, the novices asked 'how to' analyzed it, and the answered always resulted in the decomposition of the original pattern.

Regarding the **subjective dimension,** all the participants were asked about what was their general opinion about the approach used to support decision making in this type of task, what are the strengths and weaknesses of the artifacts and what were their suggestions of improvement.

The coordinators informed that artifacts in their opinion were useful and supported the sharing of their rationale. They stated that the main advantage was to allow novices to make better decisions in real life situations without the need to have years of practice to take them. And for better or for worse, the team formed with the proposed artifacts would have the same characteristics as theirs. The novices stated that it was useful because they had access to the other novice's questions, in this way it was possible to expand the data for decision making. They also said that it is interesting because at the same time that they performed the task of decision making, they received instructions on how to improve their performance in this type of task by those who already have more practice. Regarding the use of teams, they stated that collaboration between different individuals is always beneficial because each one's abilities complement each other and doubts are solved more quickly. As a strong point they highlighted that the artifacts allowed them to expand their ability to analyze several points that only an expert would have. As weaknesses they pointed out that in some cases, a new way of resolving the task can be left out, once the novices deems it unnecessary as it is not considered by the expert. In this way, in some cases it can cause the non evolution of the decision making process because it will always follow the expert's rationale. They also indicated the difficulty in putting their own criteria aside. As suggestion of improvement they stated that there was a lack of representation formality of the patterns and also the lack of a support tool to consolidate all the gathered data. They also suggested that more than one expert could participate because in the process of making decisions, personal opinion may interfere. So they believe that having the vision of more experts, the patterns considered would be broader and more impartial.

Finally, regarding the **performance dimension,** at the end of the process, the 4 novices teams (professors) ended up made the same decision as the expert (coordinator).

Considering the results presented in behavioral, subjective and performance dimensions, our evidences pointed to that the expertise-based intuition from the expert was shared with the team regarding the decision-making task. The collected data generated evidence to accept our alternative hypothesis (H1). Revisiting the objectives of this experiment, the use of the proposed artifacts in a real scenario generated initial evidences about its viability addressing the objective (i). Even in a short period, there was evidence that the team was able to develop and use a rationale equivalent to the expert for the proposed task addressing the objective (ii) and also, the gathered subsidies generated insights about the evolution of the proposed artifacts that are explored in the following section, addressing the objective (iii).

GRAPH BASED SOLUTION

Based in the subsidies generated through the experiment, we have some insights to evolve the artifacts. Once the patterns proved to be the core of the role sharing expertise-based intuition process and it was observed that a better representation (not in natural language) in conjunction with a intelligent tool to manage the patterns is missing, this section explores a potential path to address these elicited requirements. In other words, we explore how to computationally support the sharing of expertise-based intuition rationale.

Pattern recognition enables the expertise-based intuition to emerge (Ross et al., 2004). In a simplified way, we can say that experts have a repertoire of patterns stored in mind and pattern recognition is a cognitive process that matches information received with a retrieved stored pattern. According to the Recognition Primed Decision (RPD) model (Ross et al., 2004) patterns are relationships between the most important cues that in conjugation generate an expectancy linked to a goal, which suggests a certain action.

It is possible to represent this situation as a graph. In this graph the nodes represent the important cues (C1, C2 ...) for a given expectancy be satisfied (E1). As observed during the conducted experiment, cues do not have the same weight to address an expectancy. In other words, some cues are more important than others. Figure 3 represents the pattern as an oriented graph with edge weights.

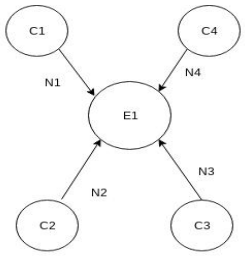

Figure 3. Stored Pattern Representation

The structure can become more and more complex, for example, we can have cues that are associated with more than one expectancy, with edge weights to each relation. Or also a pattern having other patterns in its composition being expressed by an expectancy linked to other expectations. Even more, we can have more cues merging in a bigger cue (Figure 4) transforming itself in an new expectancy or even a cue being broken down into sub-cues .

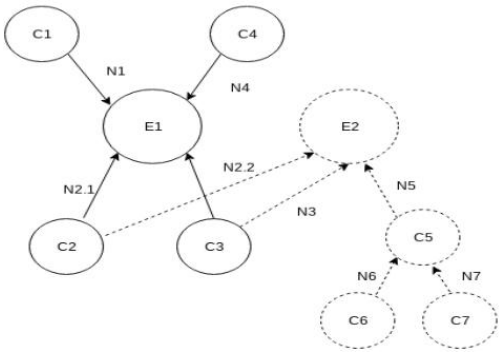

Figure 4. Patterns associations.

Evolving the structure and also using an analogy, the cues can be compared with filters that receive information from the environment and let only the chunks of information related to a certain cue passing. Information flows through the structure as resources flowing through pipes, each pipe with its own capacity, from a source to a sink (destination). In Figure 5, it is possible to notice new things, such as node A that represents the environment from which all the information is retrieved, We can also notice (N, M) pairs at the edges that connect the nodes, respectively representing the maximum flow rate and the incoming flow. In the context of this research, the incoming flow is how much a cue was perceived in relation to the weight (maximum flow) of this cue regarding an expectancy. We have also represented in Figure 5, the expectancy E linked to a goal G, which suggests a certain action depending on how much flow has reached the G node (sink).

This structure can also become more and more complex, for example, we can have more than one expectancy associated with a goal and also the same expectancy associated with more than one goal. Once the graph is built, the collaborative team can use it. Also, there is a possibility of each member of the team work focusing on be aware of one cue or part of the cues that are linked to a certain expectancy.

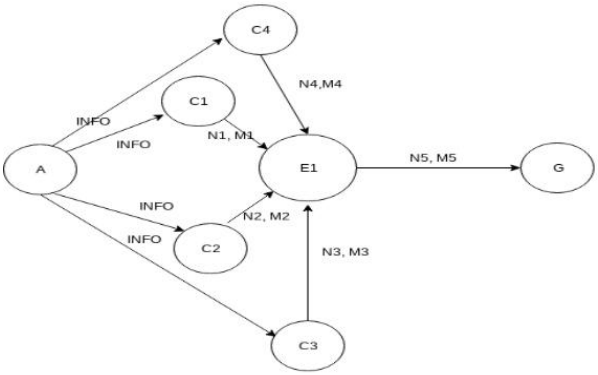

Figure 5. Decision-making support graph

This new artifact open new possibilities to the sharing expertise-based intuition research. Once we treat expert-based intuition as a form of knowledge, the graph based solution are a possible path to support the management of the complexity presented in sharing it, and also, enables the translation of unstructured data into a structured for of actionable knowledge for decision support. As claimed by the novices during the experiment, this new artifact allows the construction of the graphs using more than one expert. Furthermore, it is possible to explore the use of the wisdom of the crows (Chocron et al., 2016) in the construction of the graphs to promote the sharing of the expertise-based intuition. Besides that, it allows a more collaborative work by sharing a common structure among the participants.

CONCLUSIONS

In this paper we presented an experiment to analyze behaviors, subjective experience, and performance outcomes regarding the use of artifacts to enable sharing expertise-based intuition to support the decision-making process in complex environments. Our experiment generated evidence about the artifacts feasibility, as well their value to contribute the practices of work regarding expertise sharing activities.

This work was mainly motivated by the lack of studies in literature investigating how sharing expertise based-intuition can be explored to promote an accelerated expertise and also, a more resilient collaborative setup. Regarded this lack of studies, we conducted this work following the design science research methodology. The application of this methodology is not intended to seek optimal results, but rather results that satisfy the problem addressed, contribute to solutions to practical problems, the improvement of theories and understanding of a certain research field. Our theory is that expertise-based intuition can be shared and as consequence the expertise is accelerated. To work in this theory we designed artifacts to perform the sharing and experimented them in decision making practices. The insights generated in the experiment allowed the development of graph based solution to represent and manage the patterns used in the intuitive decision-making.

This experimental study presented some limitations. During the experiment, the participants knowledge on collaboration tasks proposed may influence the outcomes. In order to reduce this threat, a characterization questionnaire was used to select participants. The low number of participants does not allow generalizing results obtained. Nevertheless, this paper presents important contributions, new insights and increases the scarce body of knowledge of this research field.

As future works, the conduction of experiments with larger subjects sample and considering different complex environments can generate contributions to allow generalizing results obtained in this paper. Furthermore, we are planning the conduction of a new DSR cycle to explore and evolve the new artifact proposed, namely, the graph based solution.

ACKNOWLEDGMENTS

We thank CAPES and FAPERJ that supported this work and also thank the participants in the experiment for their patience and cooperation. The work of Marcos R. S. Borges has been supported by FAPERJ under grant # E-26/202.876/2018.

ABSTRACT

The paper describes the need for, and work in progress to provide the French population with a modern emergency communication infrastructure that uses open source components to deliver real time communications from smart phones as well as traditional routes.

The article puts forward the vision of the NexSIS 18-112 project aimed at designing and implementing the next generation AI enhanced emergency services response platform for France. The vision and ambition of the NexSIS 18-112 system is to rewrite the command and control system from scratch at a national level, providing it with state of the art functionalities.

Anticipating the future deployment of 5G networks, the work described in the article explains how to ensure the transition of the legacy emergency operation systems to an operational IP-based model, capable of offering voice, video, Instant Messaging, and Real Time Text (RTT) services to emergency services' operators.

Keywords
Emergency services, digital platform, personalization, individual centric, virtualization, cloud, emergency hub, AI, unified communication, IoT, SIP/RTP, NG112, ESInet.

INTRODUCTION

As Tom Wheeler, former chairman of the American Federal Communications Commission, pointed out in 2015, our emergency response systems face an emergency of their own in the form of outdated technology. Simply put, the communications technology behind the emergency response system is dangerously out of date. Currently, the French PSAP (Public Safety Answering Points) handle about 18 million calls a year, an increasing number of them from cellphones.

But these PSAP can't receive any data such as real time location, text, photo or video from a person in need — capabilities that are considered commonplace for any European citizen with a smartphone. Similarly, the generalization of connected objects is a new challenge for emergency services.

The future deployment of 5G networks will have considerable implications for the emergency communications sector. The increased performance of the 5G wireless and mobile networks, the enhanced security and the improved device-to-device communications will open a realm of new possibilities, which have the potential to greatly improve emergency responses and ultimately save more lives.

Faced with this situation, the French government has taken the decision to revolutionize the organization of emergency call processing to make the most of the capabilities of mobile phones and other connected device. Thanks to the NexSIS 18-112 project, the population and the emergency services will move into the era of data and online services.

The incredible new functionalities offered by the information technology (integrated communication, cloud, web, social networks, mobile, Internet of Things…) are not used by traditional existing software solutions. Innovative solutions such as 112 mobile applications or social networks are emerging, but their integration in existing information systems is difficult and costly. The issue is how to replace these obsolete analog emergency response infrastructures that are ill-suited to the demands of a highly digital public.

New approaches, like cloud-based architecture or software defined architectures, are "cost killers" and provide an answer to the overall and growing cost of a multitude of different and local systems.

Public Safety Answering Points (PSAP) need to be equipped with the latest unified communication tools allowing rich and personalized exchanges between emergency services and distressed population. A simple photo or a short video brings an incredible amount of information if they can be taken and easily transmitted by the citizen to the PSAP, or from the first responder on the field to the operation center. For this, current telecommunication technologies based on telephony must be replaced by technologies based on IP networks.

Virtualization, allowing different PSAP to act individually but also collectively, is also included in the original specification of the project. Virtualization and multi-tenancy feature allow also to support complex and rapidly evolving organizations and provides an answer to more and more global, distributed, dispersed threats and attacks. This is a crucial improvement compared to the existing local, not inter-connected ICT systems.

NexSIS 18-112 is both an operational system dedicated to shortly replace all existing local solutions, and also an "online platform" able to exchange with third party platforms and citizen provided solutions (the "emergency hub"). AI and big data are also taken into account in the core design of the platform and the first releases will include AI algorithms to propose the most adequate answer to complex emergency situations.

THE CONTEXT OF CIVIL SECURITY FORCES IN FRANCE

Civil rescue forces include 250 000 firemen, 80% being volunteers and 20% professionals. 18 million calls are processed each year leading to 4,5 million operations. 3,6 million victims are taken in charge by rescue operations.

The organization is based upon a departmental approach (about 100), each department having a 112 Public Safety Answering Point managing both entering calls and rescue operations.

Today, each department has its own decentralized information system (hardware and software) managing entering emergency calls, operation management and crisis management.

The NexSIS 18-112 project is aimed at providing all Public Safety Answering Point (PSAP) organizations, located in France or overseas, with a complete set of common application services (ICT, CAD, C2, mobile application, etc.) based on SaaS (Software as a Service) mode allowing to fulfill each PSAP requirements but giving also a possibility to have a global view upon all the territory and to pool forces in case of complex emergency situations.

The use of innovative and advanced architecture and technologies, which have a strong and positive impact on existing PSAP operational practices, has led to the decision to set-up several PoC (Proof of Concept) to implement and validate both the technology feasibility and the new functionalities and organizations allowed by the technology. Three PoCs are running today, and the first operational PSAP to use NexSIS is planned end 2020. Among features already operational are the unified communication platform developed in the private cloud of the French ministry of interior, the core AI based mobilization algorithm, the multi-tenant data structure and API's. Those were chosen being considered as the most innovative and less risky for the project.

UNIFIED COMMUNICATIONS FOR NEXSIS 18-112

The words "unified communications" refer to different definitions. In the NexSIS 18-112 project, unified communications make reference to several concepts:

Using IP networks and normalized IP protocols

The unified communication module relies on the use of the pair of SIP and RTP protocols:
- RTP (Realtime Transport Protocol) allowing streaming media such as voice, video, messages and applications such as WebRTC, video conferencing, push-to-talk features
- and SIP (Session Initiation Protocol) which allows the initialization of a session between 2 or several users and then the exchange of voice, images, videos and data between them.

This concept is extensively used in NexSIS 18-112 through a SIP-based communication solution serving as an integrated engine to deliver emergency calls. Deployed in the private cloud of the French ministry of the interior, this application layer includes advanced routing and contact center features. It delivers a very scalable and intelligent Public Safety Answering Point (PSAP) communication platform able to receive signalization (SIP header and message body) of an incoming call, to locate the caller by different means, and to determine to which PSAP the call must be routed under sophisticated algorithms: for instance, suppose a PSAP is not able to receive and to process an incoming call for any reason, the call may be routed to another emergency service designed as a backup. If many calls arrive from a known location where has been detected an "event" (an important fire, a car accident), all incoming calls can be directed to a dedicated temporary crisis center… RTP enables the PSAP to receive and process multimedia emergency calls, to use location-based services to pinpoint the exact location of a caller, or to establish real-time visual assessment using the smartphone camera.

The "intelligence" and the "multimedia" aspects allowed by NexSIS IP communication platform are not limited to the incoming calls from the population but are also available for all security forces and for any device (PC, tablet, phone). They provide enhanced situational awareness. They leverage video and data to allow first responders to share live footage with the Public Safety Answering Point (PSAP), or with other public safety services. Any fireman can take a photo of a victim to ask support in a real time or to share with the operation center a real time video of a fire. This provides a much more accurate picture of an emergency situation, speeding up incident response times by using a multitude of potential data sources for incident command.

With a single platform connecting 100 PSAP and all the first responders sharing this platform, data fusion can be done, and applications shared among the public safety community.

A simple user interface available on a web browser

With no pre-installation on the PC, the user interface allows functionalities such as WebRTC phone, visual voicemail, contacts and presence, chat and messaging. Integration of unified communications within dedicated applications (like a 112 mobile application for the population, or field crisis management application for advanced command centers) are also made very easy whatever operating systems of the device.

An exclusive Open Source software approach

As seen before, all data streams and advanced routing features are controlled by software: there is no telecommunication dedicated hardware other than basic IP network device. The different software "bricks" come from different open source software communities such as Asterisk PBX (Asterisk community, *https://www.asterisk.org*) and Kamailio SIP server (Kamailio community, *https://www.kamailio.org/w/*). Wazo community (Wazo community: *http://wazo.community*) provides the integration and a full set of APIs allowing central applications to drive all communication events and flows. All software modules are installed in the (OpenStack based) private Cloud of the Ministry of the Interior. It is to notice that the communication software can request dynamically additional virtual machines using native OpenStack APIs (OpenStack community, *https://www.openstack.org*) to answer to unusual growth of calls, with no other limit than the number of physical servers of the Cloud: this functionality is very important knowing that NexSIS 18-112 has to serve all existing PSAPs of the territory and that national crisis event (like a tempest on the whole territory) can increase heavily the number of instantaneous calls (typically, 20 000 additional calls per hour).

INFRASTRUCTURE FOR NEXSIS 18-112

A dedicated innovative architecture

The main different elements of the infrastructure are the following:

- An NG112 compliant network, i.e an ESInet (Emergency Services IP network), that includes all the functions (BCF, ESRP, ECRF, LNG, LIS) for data transport, delivery and end-to-end connectivity between the requester, NexSIS applications in the Cloud, and local PSAP workstations.
- The RIE ("Réseau Interministériel de l'État") network which is an existing private and secure IP network dedicated to data exchange between State organizations.
- Remark: the ESInet MPLS network is able to exchange data flows (http) in case of RIE failure, and conversely, the RIE network can transport SIP and RTP fluxes in case of ESInet failure.
- The dual site of the Ministry of the Interior consists of two different cloud sites, where unified communication and NexSIS applications are hosted, in an "active/active" mode. The two sides are linked by a black fiber for fast exchanges and the access infrastructures of each side are secure and redundant. They are based on OpenStack open source software.

- A local Public Safety Answering Point (PSAP) infrastructure where local LAN is linked by two links to the ESInet and two attachments to the RIE. The local PSAP

infrastructure also include a local WAN network to connect all operation centers of the department (there are 7 000 local operation centers in France)

Besides above infrastructure components, the following principles apply for application architecture : a full WOA (Web Oriented Architecture), RESTful based, where a Single Page Application (SPA) (Angular community: https://angular.io) is executed in the browser of the workstation (or more generally, on a device) and makes request to application servers hosted in the cloud datacenters.

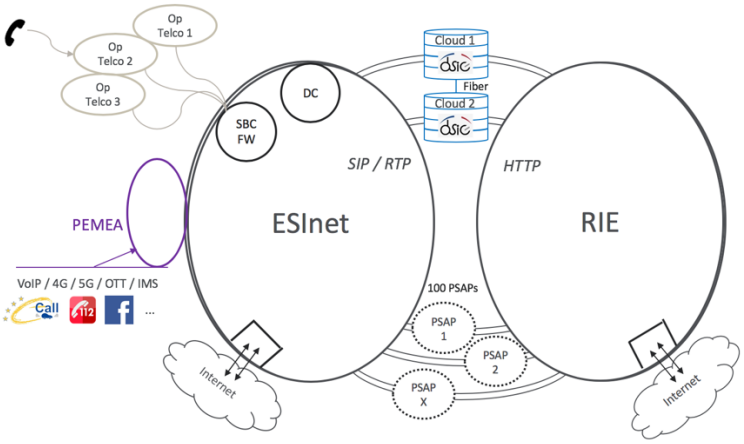

Figure 1. NexSIS 18-112 Infrastructure summary

In addition to the "rich" communication capacity with the population, the enormous advantage of this full IP and cloudified architecture is that it allows all Public Safety Answering Points (PSAP) to benefit from a set of webized services at the best of technology and responding to their needs. It also provides a common application environment for all operators greatly facilitating the mutual assistance or the resumption of activities between PSAP. Finally, it lays the necessary technical foundations for the development of software services focused on citizens in distress.

The support of individual-centric emergency needs

Technology brings new relationships between emergency services and the population. Building user centric information systems means taking full advantage of the potential offered by mobile internet and connected sensors.

The personalization of an emergency call is based at first on a precise localization of the requester: NexSIS 18-112 supports existing localization services provided by Telco's but supports also the emerging AML (Advanced Mobile Location) protocol being implemented in IOS and Android OS.

Getting the caller location before picking up the call allows a pre-processing of the request: for instance, if the location is a public building with dedicated and predefined security processes, or an already known "event" (big fire, flooding zone…), or the caller already identified by a previous call, the routing algorithm can apply rules and prepare the personalization of the exchange with the PSAP operator.

The use of a 112 mobile application is another means to implement individual-centric approach for emergency management.

Apps are key to a meaningful user-centric strategy, because they make it possible to fully exploit the data from the different sensors of mobile phones, thus providing valuable

information for a personalized support of distressed citizens. NexSIS 18-112 supports PEMEA architecture allowing citizens of other European countries to access French Public Safety Answering Point (PSAP) with their mobile and own specific Apps.

Along the same lines, public warning or private warning can be personalized in advance by the specific data entered by the requester, as it is the case in the framework of BE-ALERT platform (*http://be-alert.be*).

In addition to supporting the general public, these user-centered capabilities facilitate emergency communications by individuals with disabilities (e.g., persons who are deaf, deaf-blind, hard of hearing, or have a speech disability).

The growing role of IoT

The Internet of Things (IoT) envisions billions of objects connected to the Internet that continuously generate data about the physical environment. Thanks to the IoT, devices may initiate calls to 112 without human intervention. Data is presented to a call-taker with – or without – a human voice behind it. This is the impact that the Internet of Things will have on Emergency Services and the Public Safety arena. More and more emergency alerts are incoming by IoT devices. Taking into account this growing role of the Internet of Things in reporting emergency needs requires IP technologies and data exchange capabilities such as those offered by the NexSIS digital platform.

Thus, NexSIS 18-112 supports the e-Call service which is a European compulsory emergency system installed in all new vehicles. In case of accident, car sensors trigger an automatic emergency call and convey data to a dedicated call center in charge of handling and filtering those alarms. When confirmed, the alarm is transmitted to the proper 112 Public Safety Answering Point (PSAP) using dedicated APIs. Much information can be used to personalize the intervention, for instance the speed of the vehicle when the crash occurred and the type of the vehicle. This later information can be used to define which kind of tool kit has to be brought to process the extrication of the victims, reducing drastically rescue times and saving lives.

Fire-detectors alert transmission and support, automatic AI image processing of highways or city cameras to detect accidents, senior tele-assistance… are examples of new emergency devices able to increase personalization, especially when associated with pre-loaded data transmitted along with the alert itself.

NEXSIS 18-112, THE DIGITAL HUB OF EMERGENCY SERVICES

Citizens becoming part of the rescue process

Fueled by the explosion of social networks and propelled by an « open data » and API strategy, co-creation encourages the involvement of citizens in the execution of relief operations. More and more initiatives created by citizen communities allow a better identification of emergency needs. Dedicated applications allow to rapidly involve a first aid individual for the emergency support of the victim while waiting the emergency forces arrival. Several applications already exist such as “permis de sauver” (*http://permisdesauver.info*), “staying alive” (*http://www.stayingalive.org*), “qwidam” (*http://www.qwidam.com*).

The efficiency of those platforms will considerably grow when connected to NexSIS 18-112. For this reason, NexSIS 18-112 is built upon the concept of being the “Digital Emergency Hub” allowing connection between all the emergency requesters (citizen, other organizations, device…) and all the stakeholders involved in the response to the emergency needs.

NexSIS 18-112 front-end applications (call processing and routing the alert) and NexSIS back-end applications (mobilization, operation and crisis management) extensively uses the Digital Hub to communicate between themselves but also with other third parties and other forces platforms. The platform logic advocated by the architecture adopted in the framework of the NexSIS project makes it possible to give substance to the notion of open innovation. Indeed, the platform includes the exhibition of its data models as well as an API library allowing the private and citizen initiative to add services to those developed by the Ministry of the Interior.

The merger of social networks and IoT gives birth to the Social Internet of Things (SioT) concept. For instance, vehicles commuting from home to office can join a social network to share information (traffic congestion experience, accident warnings) with emergency services. This is why the NexSIS digital platform has developed the ability to receive information flows produced by the Waze social network and to edit information in the online maps produced by this application.

Finally, citizens can also be integrated in emergency management teams helping authorities in the VOST (Virtual Operations Support Team) context. It is the case of VISOV in France (*http://www.visov.org*) or CanVOST in Canada (*https://sites.google.com/site/vostcanada/*). The challenge is to integrate within the NexSIS crisis management modules the data from the VISOV action such as the collection of information published on the web and the edition of collaborative maps. The interconnection of NexSIS 18-112 and the VISOV platforms will drastically increase the efficiency of the cooperation between the official emergency agency and this social media based upon trusted agents.

The growing need to inter-operate with other forces

The decision has been taken in France to pool 112 call centers to provide a unique and professional identification and qualification of the request, and to transmit the alerts when properly qualified to the different concerned public safety forces (firefighters, police, urgent medical help). The digital emergency hub is designed to support all these exchanges between the different organization using mainly the EDXL (Emergency Data Exchange Language) messaging standard for this purpose.

NexSIS 18-112 Digital Hub is based upon a standardized set of APIs for real-time exchanges and also the use of the standard EDXL for inter-messaging needs. The Hub has its own directory to support intelligent routing of messages, and security features to assure a continuous service. This architecture model might provide a foundation for the development of cloud-based services for emergency services.

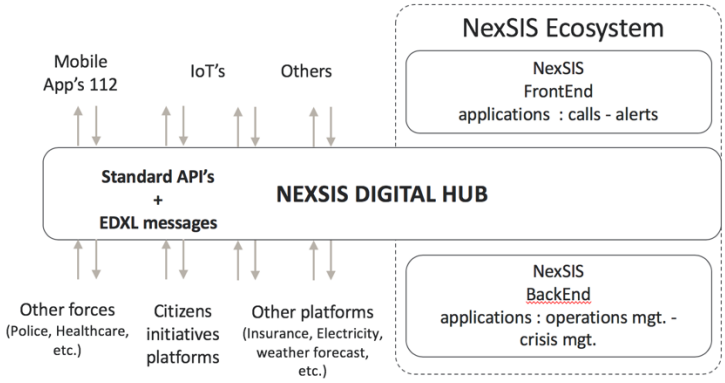

Figure 2. NexSIS 18-112 Digital Hub Principles

As an example, the digital Hub integrates the technical engine allowing to support the EDXL-DE (Distribution Element) which ensures message distribution. Another feature of the digital Hub is to offer several different formats of entities interchange such as JSON, SQL, mimeType, EDXL and even CVS and to allow format conversion.

HOW AI CAN IMPROVE IN ANSWERING CITIZEN NEEDS, PERSONALIZATION AND RESPONSE OPTIMIZATION

Finding the "best" answer to an emergency situation

Historically, the algorithms used to transform an emergency call to an operation, based upon available resources (vehicles, tools, and firemen), has been designed on simple principles like choosing generally the nearest operation center able to provide the resources needed. The algorithm for mobilizing and dispatching relief resources within NexSIS 18-112 is based on a more sophisticated approach that integrates some artificial intelligence tools such as expert systems (rules inference engine) (Business Rules Community: http://www.brcommunity.com) and optimization under constraints.

This architecture can take into account much more complex situation when dealing for instance with a major event where different constraints have to be taken into account in the decision process like the rapidity of intervention, but also the need to keep forces in back up, and the need to mobilize very specialized and scarce forces, the need to separate what is urgent and has to be done immediately and what can be done later on. Another advantage is the fact that "declarative programming" is much more powerful than procedural programming for this kind of application and can be externalized from the application itself, allowing to improve the algorithms without changing the application code.

This feature is actually under testing in a PoC to be available as soon as the first release.

NexSIS 18-112 will rapidly acquire an enormous amount of data, dealing with 18 million calls and 4,5 million operations each year. This offers a tremendous opportunity to apply deep learning to the existing AI based algorithms in a second phase.

Many dedicated AI applications in the NexSIS 18-112 roadmap

Besides this first application, several AI based opportunities have been identified during the specification phase:

- Call signals analysis

- Automatic translation capabilities to help processing foreign language calls
- Automatic detection of wrong or malicious calls
- In case of major crisis (terrorist attack, large flood), identification, extraction and diffusion to the authorities of the new and pertinent information often diluted in the massive information flow (flitering)
- Crisis analysis support and decision-making assistance
- Image analysis on the field
- Predictive analysis of emergency situation
- Linguistic analysis of social networks…

Another example of application is to detect in advance "non-nominal situations" like having several alerts over a large area with reports of a strong pain in the stomach. In that case, it could be an intoxication of people having the same meal several hours before.

Likewise, in the case of a global terrorist attack at different points of a city, AI could rapidly detect the "non-nominal" aspect of the situation and sends warning to the crisis center.

Those different opportunities will be evaluated during the year 2019 using POCs when needed and will be placed upon NexSIS18-112 roadmap of future releases.

QUALITY OF SERVICE AND SECURITY

NexSIS 18-112 being a common, unique, centralized system delivering its services to all Public Safety Answering Points (PSAP) in France, the questions of quality of service (QOS) and security become essential.

It is out of the scope of this paper to detail the different solutions to guarantee QOS and security, but it is possible to outline the major assumptions:

- QOS, and essentially the availability and the response time of the system for users, is guaranteed by the systematic use of modular growth (horizontal scalability) and fault tolerant capabilities which are natively offered in the Web Oriented Architecture (REST) coupled with cloud based hosting. Two different dedicated networks are used to link the cloud hosted application and the PSAP, each one is a backup of the other in case of failure. Administration and supervision tools are part of the original design to guarantee Service Level Measurement to be compliant with Service Level Agreement. NexSIS 18-122 is ITIL V3 2011 compliant.
- Cybersecurity measures designed to protect digital assets and network devices are essential to NexSIS 18-112. Two of the main infrastructure components upon which the project relies are already at a very high level of security:
    - the private cloud of the Ministry of interior is hosting the most sensitive applications of the French government,
    - the "RIE" network (ie an existing private and secure IP network dedicated to data exchange between State organizations), which is also highly protected from malicious attacks.
    - The ESInet design follows the recommendation described in the NENA_08-506_Emergency_Services_IP_Network_Design_12142011 document.

Each connection with an external link (Telco SIP Trunk, Mobile Apps APIs, PSAP…) is provided with defense modules adapted to each case and identified risks.

Besides, NexSIS 18-112 has to receive the Security Official Approval delivered by the independent National Digital Security Office before going live.

CONCLUSION

NexSIS 18-112 digital platform under construction has the ambition to take advantage of the latest technology innovation and research to build and deliver a whole set of new services both to the population and to the emergency agencies. The multi-tenant approach of NexSIS 18-112 allows new cooperation processes between emergency operation centers themselves, but also with other third parties involved in emergency situations such as citizens as well as other public safety forces and VOST organizations. NexSIS 18-112 makes possible real-time and immediate reporting and crisis management at higher levels such as the region or even the nation.

Virtualized and software based Unified Communication platform embedded in NexSIS 18-112 coupled with the creation of an ESInet constitutes the first operational implementation of the NG 112 standard in Europe. It will allow new communication paradigms such as the shift from the telephone to multimedia and data exchanges between the citizens, emergency centers and field operators. The increasing personalization and characterization of each emergency call should ultimately save many lives. The Digital Hub allows the improvement of communications between the different forces needed to answer to an emergency situation. The Digital Hub allows also to connect easily the growing number of mobile Apps 112 and to support VOST organization where citizens become active part of the emergency process.

AI, already present in the first version, opens a very large field of new applications and opportunities, which will be progressively incorporated in the NexSIS 18-112 platform.

The concepts and the technical architecture selected for this project seem to us to be able to provide a foundation for the development of cloud-based digital services for emergency forces.

Finally, we hope that the moto “NexSIS 18-112, the digital platform that saves lives” will become true when the project will enter in operational phase.

ABSTRACT

Emergency managers receive communication training about the importance of being 'first, right and credible', which is not easy. For instance, in October 2018, the Aude department in the South-West of France was hit by intense rain. Flash floods were hard to forecast and only the 'orange' level of vigilance could be raised initially, but the population dismissed this very usual warning in that season. The 'red' level was then raised too late, leading to high criticism. The main problem here is the loss of trust induced by too many 'false alarms'. In this paper we propose a serious game called **VigiFlood** for raising awareness in the population about the difficulty of crisis communication and their own responsibility for reacting to the alerts. The implemented game still has limited functionality but already shows interesting results in helping the user to visualise and understand the trust dynamics.

Keywords

Flash floods, early warning, crisis communication, trust, agent-based modelling and simulation, serious game

INTRODUCTION

Nowadays, our societies are exposed to multiple risks: natural disasters, epidemics, terrorist attacks, industrial accidents, etc. During such disasters, the population has access to multiple sources of information (including images, videos or field information shared by other citizens), leading to possible confusion and information overload. As a result, they do not always listen to or trust official messages, and might not react appropriately. Emergency managers are therefore trained in risk communication and learn how to communicate in a timely and credible manner, while taking into account the psychology of their audience, in order to refute misinformation, and maintain trust and good relationships (Reynolds and Seeger 2014).

The question of **when** to raise an early warning about a predictable natural disaster is crucial: too late, and there might be many victims; but too early, and the clues might not be very reliable, leading to possible false alarms and subsequent loss of trust (Pearson 2012; Geleta 2013). For instance in October 2018, serious flash floods hit the Aude department in the South-West of France[1]. The day before, the level of vigilance was set to 'orange' (level 3 out of 4) for heavy rain and risk of flood, but the population did not react to that very usual warning for that season. When the vigilance was risen to 'red' (level 4 out of 4) early the next morning, it was too late and many towns and villages were already flooded. As a result, several people died and the authorities received severe critics.

There are several ways of addressing this problem: training the alert services to use the orange and red vigilance cautiously in order to avoid false alarms (Geleta 2013); providing them with decision-support systems to help raising timely early warnings (Friedemann et al. 2011; Behrens et al. 2008); or making the population **aware** of the difficulty of risk prediction and communication, and of their responsibility for still responding even after several false alarms. Here we focus on the **population**, and aim at providing them with a **serious game, VigiFlood** where

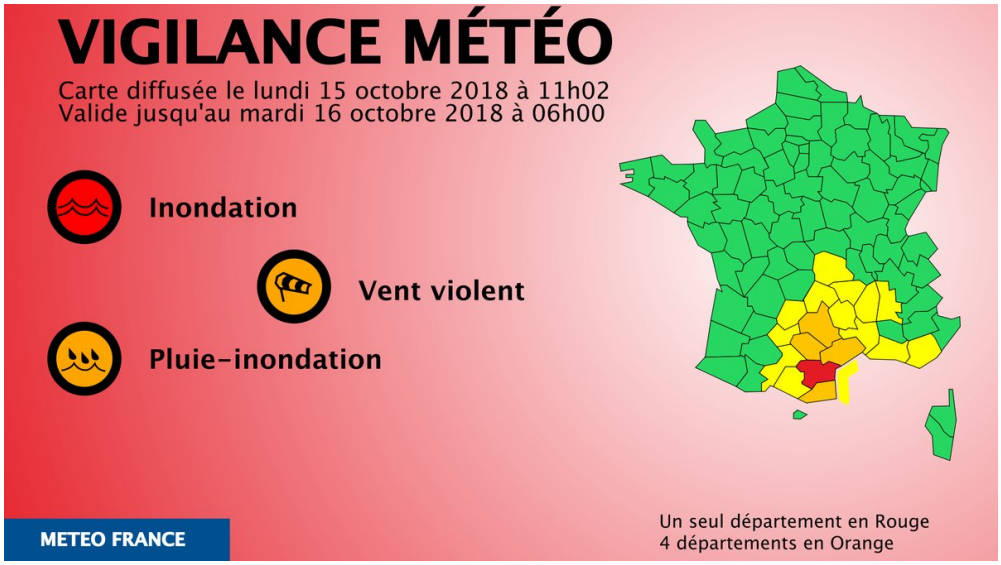

Figure 1. MeteoFrance vigilance map, 15 October, 11am (source: MeteoFrance)

they can play the role of an emergency communicator. They will have to set the vigilance level based on the (uncertain) weather forecast, and observe reactions in the simulated population. Our **hypothesis** is that this change of perspective will increase their awareness.

This paper is structured as follows: the first section provides some background about flash floods, crisis communication, trust dynamics, and existing simulators; the next section then describes our conceptual agent-based model; we follow up with exposing the implemented game and first experimental results, before concluding the paper.

BACKGROUND

Flash floods

Flash floods generally occur due to rapid rain on an already saturated soil (after a particularly wet period) or on a soil with a poor absorption capability (such as concrete, as is often the case in urbanised settings), or due to extensive rain because of a storm or hurricane. They can also occur from more occasional events such as a glacier melting after a volcanic eruption, an ice dam melting, or a man-made dam failing. In this paper we focus on rain-induced flash floods, whose prediction depends on the meteorological services.

The indicators used by forecast services include: forecast quantity of rain (radar or satellite or model based), soil absorption capacity, soil moisture or dryness level, topography, basin or catchment capacity, etc (CEPRI 2008). In France, the agency in charge of forecasting the expected amount of rain is Meteo France[2]. Weak rain is defined as 1 to 3 mm/h, moderate rain is between 4 and 7 mm/h, and heavy rain is over 8 mm/h. Another agency is in charge of monitoring the main waterways and broadcast their expected height and debit 3 to 6 hours ahead of time: Vigicrues[3]. However, only part of the waterways are monitored, and the European Flood Risk Prevision Center (CEPRI[4] notices that half of the 63 victims in the Languedoc-Roussillon region (south of France) alone between 1996 and 2006 died on catchment basins that were not monitored by flood vigilance services.

The meteorological services in charge of the area then analyses these clues (rain forecast, waterway height and debit, etc) to define and announce a level of vigilance on a 4-colour scale, from green (no problem), yellow, orange, to red (higher risk). This level of vigilance is publicly available online[5] (example map on Figure 1). Each region has its particularities and can be more or less used to receiving heavy rain in a short amount of time, so that the vigilance thresholds are not the same everywhere. The Aude department in France (see map on Figure 2) depends on the CNP center in Toulouse; its critical rain threshold for the orange vigilance is 50-100 mm in 24 hours, with a regional record of 551 mm in 24 hours. On Sunday 14 October 2018 the meteorological station of Carcassonne received 139.8 mm of rain. However the vigilance level was first only set to orange, until Monday 15 October morning at 6am when it was finally raised to red. As a result, MeteoFrance vigilance system was harshly criticised

in the media (Libération-AFP 2018). The representative of the Ministry of the Interior, Frédéric de Lanouvelle, interviewed on LCI-TV, evoked a *"weakness in the orange vigilance level which is used very often and when there is a real problem, people do not take it into account anymore"* (our translation). He adds that based on residents' statements, the red vigilance level was indeed raised too late, but explains it is due to the difficulty in forecasting such a powerful episode.

Flood simulations

Axelrod (1997) defines 7 purposes of simulations, including prediction (simulate a system very realistically to predict its future behaviour, *e.g.* meteorology), training (provide a believable interactive environment to rehearse actions, *e.g.* flight simulator), or education (let the user learn by trying in a virtual world). Predictive simulations require a high degree of realism to lay valid predictions, while training and education simulations can be simpler and less realistic (they "need not be rich enough to suggest a complete real or imaginary world"). Besides, Axelrod also claims that "the simpler the model, the easier it may be to discover and understand the subtle effects of its hypothesized mechanisms"; educational simulations are therefore often quite simple.

Simulations have often been used in crisis management for various purposes. For instance (Yang et al. 2018) provide a very realistic model based on field data, to **predict** the impact of early warnings on population behaviour in terms of reducing material losses from floods. Others focus on realistically modelling the physical flood phenomenon in order to **support decisions** regarding early warnings for tsunamis (Friedemann et al. 2011), based on data from multiple sensors (Behrens et al. 2008).

Other simulations are aimed at **education**, often in the form of a serious game. Anycare is a table-top role-playing game to involve stakeholders (Terti et al. 2019). LittoSIM (Becu et al. 2017) is very realistic and aimed at emergency managers; SPRITE (Taillandier and Adam 2018) teaches risk management to engineering students; however both games focus on longer-term management and protection against coastal submersion (*e.g.* building dykes) rather than communication.

Other simulations focus on communication, but not necessarily during floods. (Arru et al. 2019) study if the population should be alerted or not of an ongoing crisis (*e.g.* terrorist attack), depending on the anticipation of their potential reaction (*e.g.* crowd panic), which is based on a psychological model. Since events considered are ongoing, they do not deal with false alarms and their potential impact on long-term trust. (Adam and Dugdale 2018) study the propagation of awareness in the Australian population after a bushfires warning, depending on its channel and (familiar vs unfamiliar) source. Since they consider a single event, they do not deal with long-term dynamics of trust over multiple (right and wrong) alerts. (Adam, Bailly, et al. 2019) also proposed a serious game for trying various communication strategies to alert the population (focused vs wide targeting, information vs recommendations) before and during fires, but they do not deal with the timing of alerts nor the impact of false alerts. Indeed, they report no habituation phenomenon to fire alerts, which could be due to the easier predictability of fires compared to flash floods, or to normative and cultural differences.

Crisis communication

Reynolds (2010) identifies 6 principles of efficient crisis emergency and risk communication (CERC):

- **Be First**: in times of crisis, people need information fast, and will often stick with the first source they get information from.
- **Be Right**: information should be accurate and transparent, explaining what is known or not, and what is being done to get more information.
- **Be Credible**: communicators should be honest and trustful, and avoid to promise what they cannot deliver, at the risk of losing the public's trust.
- **Express Empathy**: communicators should acknowledge the population feelings and challenges to build trust and a good relationship.
- **Promote Action**: messages should not only be informative but also action-oriented, to empower the population, give them a feeling of control, and release their anxiety.
- **Show Respect**: communicators should account for the vulnerability of people during crises, their messages should be respectful and promote cooperation and rapport.

(Infanti et al. 2013) review the literature to explain the "complex and unpredictable ways that individuals perceive risk", and find that risk communication is influenced by socio-cultural, environmental and linguistic factors. Covello *et al.* (2001; 2003) identify 4 factors of risk communication:

- **Risk perception** is subjective, influenced by socio-cultural and cognitive factors (*e.g.* the individual feeling of agency or control).
- **Mental noise** created by stress and threat reduces the ability to process information: technical and scientific concepts must be "translated [...] into understandable messages", which should be visual and repeated.
- **Negative dominance**: upset people focus more on negative (losses) than positive (gains) information, so communication must counter-balance negative messages with many more positive, action-oriented messages, and focus on progress rather than failures.
- **Trust determination**: upset people tend to not trust authority, so trust must be created well ahead of any crisis, through proactive community communication.

Further, (Hurnen and McClure 1997) discuss the importance of the locus of control of individuals: if **external** (*i.e.* they believe they have no control) they will feel helpless, and be less likely to take preventative action or react to warnings than if **internal** (*i.e.* they believe they can do something). This is in line with the CERC principle to 'promote action' and give people something to do so that they feel (more) in control. Similarly, (Khan et al. 2012) discusses the lack of response of the population when the perceived risk is either too high (fatalism) or too low ("blasé effect"): in both cases, people feel powerless. He concludes by recommending to pay careful attention to the level of risk that is communicated to the population in the warnings to avoid undesirable reactions or inertia.

The American Center for Disease Control and Prevention issued a report about Crisis and Emergency Risk Communication (Reynolds and Seeger 2014) focusing on specific psychological factors of information processing during a crisis, and how messages should be adapted subsequently:

- People **simplify** messages, might not hear, not remember, or misinterpret them. Logical reasoning is impaired and decisions might rely more on habits, routines or imitation. Messages should therefore be simple.
- People **hold** on to their current beliefs, and prefer trusted and familiar sources of information even if inaccurate and non-expert, to reputable experts who might disagree with each other. Messages should therefore come from credible sources.
- People try to **confirm** information before acting, via complementary information and additional opinions. Messages should therefore be consistent between the different channels.
- People believe the **first** message, and compare any further message with it; lack of information creates anxiety, leading to speculation and rumors. Accurate messages should therefore be released as early as possible.

These findings are in line with research showing the importance of cognitive biases in disasters (Murata et al. 2015; Arnaud et al. 2017).

Trust and risk

According to Slovic (2016), risk management has become much more "contentious", with risk managers blaming the public for being irrational, and the public blaming the stakeholders for their poor management. In his view risk communication, aiming at aligning population and experts' perceptions with experts, has failed due to the lack of trust: "if trust is lacking, no form or process of communication will be satisfactory" (p. 410).

Slovic also explains that trust is "fragile", builds up slowly but can be destroyed instantly and is then hard or impossible to regain (p. 319). He provides several reasons for this asymmetry:

- Negative events are more visible than positive ones (one missed alarm stands out in many days of correct predictions);
- Negative events have more weight because they have lower probability and higher consequences (a flood is rarer than a "normal day" and can do serious damage);
- The media also tends to give more coverage to bad news than good news;
- Sources of bad news are seen as more credible, less likely to lie, than sources of good news;
- Distrust strengthens itself, by limiting further interactions and biasing future interpretations towards the reinforcement of existing (distrustful) beliefs.

Conclusion

Existing simulators are most often aimed at training or supporting decisions of emergency managers. We adopt a different approach where we propose a serious game aimed at changing the population's perspective by letting them play the role of an emergency manager confronted with difficult decisions.

This approach is in line with the risk communication principles advocating transparency and empowerment of the population (Reynolds 2010), and is currently lacking research. Our claim is that such a game will improve the population's awareness of the difficulty to predict and announce natural disasters, and their responsibility to react despite a certain rate of (unavoidable) false alarms.

Our serious game is based on a conceptual agent-based model of human behaviour in flash floods. The validity of the underlying behaviour model is ensured by its grounding in psychological and sociological theories of trust and risk communication described above. The physical model of flood on the other hand need not be extremely realistic to reach our educational goal, in line with (Axelrod 1997). This conceptual model is described in the next section.

CONCEPTUAL AGENT-BASED MODEL

The hazard: flash flood

Among the many available clues used by hydrologists and meteorologists to forecast floods, we selected only clues understandable by non-specialists players. As discussed above, this simplified model is more likely to be understood, and sufficient for educational purposes (Axelrod 1997). Figure 3 provides a representation of our environment model in the Unified Modelling Language (UML). Each area has various attributes: its name, geographical coordinates, population, rain forecast, vigilance level; rivers in this area (name, dangerousness, overflow height, water height and vigilance level); buildings (name, type, are they safe, are they official shelters, distance to water, altitude); history of hazards and their severity.

The weather forecast services (MeteoFrance) is represented as an agent having a precision attribute (0-100%); it predicts the expected amount of rain (in mm). The emergency manager (human-piloted agent) relies on this rain forecast to sets the vigilance colour that is communicated to the population.

Population

The population is composed of a number of heterogeneous civilian agents, whose attributes are listed in Table 1. Civilians receive vigilance alerts from the emergency manager, and observe real rain. The core of their behaviour is their subjective evaluation of risk (*i.e.* expected rain) based on their (dynamic) **trust** in the vigilance alerts, their **memory depth** (how many past events they can remember), and their **update strategy**. This strategy reflects their personality: optimistic (consider the minimum amount of rain observed during past events where the same vigilance colour was raised; if a false alarm was raised in the past this can lead to expect no or very little rain); pessimistic

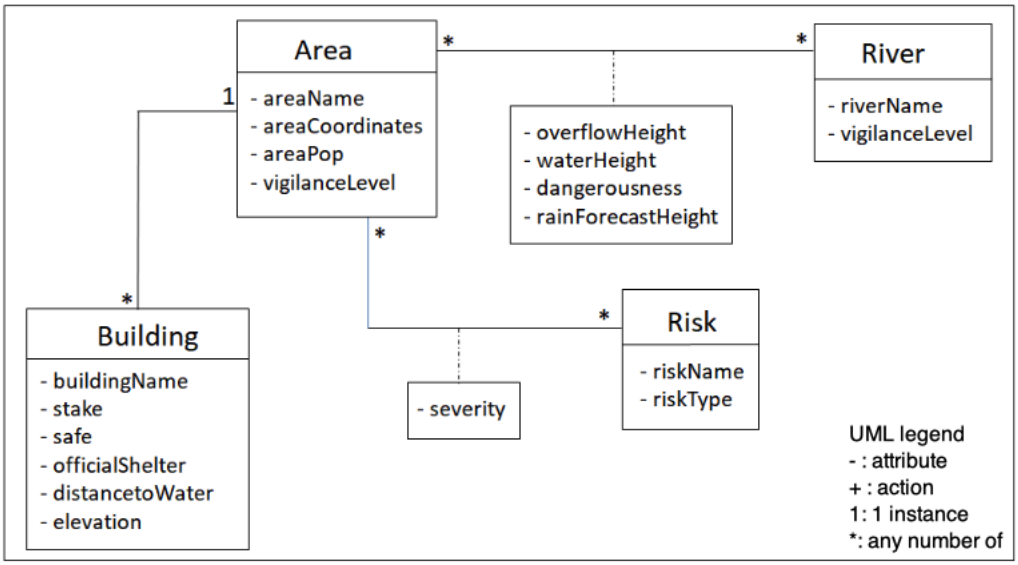

Figure 3. UML conceptual representation of the environment in which flash floods occur. Boxes are the classes, linked by relations with numbers indicating the number of instances. For instance the link between 'building' and 'area' states that a building can be in 1 area only; an area can contain any number of buildings.

(consider the maximum amount of rain; this is very forgiving to false alarms); rational (consider an average of observed rain on past occurrences); or short-memory (consider only the last occurrence). This process is in line with psychological theories saying that humans evaluate risk based on previous experience and emotions (Reynolds and Seeger 2014).

Trust then mediates the relative importance of the official vs personal forecast: if trust is 100%, the civilian will expect exactly the amount of rain corresponding to the vigilance colour; if it is 0% they will expect the subjective value resulting from their past experience, which can be quite low after many false alerts.

Finally the civilians' decision to evacuate is based on the comparison of this subjective value with a personal risk aversion threshold (initialised randomly), which can lead to delays in evacuation if expected rain is under-estimated. Civilians can also evacuate after directly observing high amounts of rain (exceeding their aversion threshold), but this often happens too late.

Attribute name	Range of values	Initialisation
Initial trust	0-100%	Parameter
Subjective risk	0-?? mm	0 (no risk)
Update strategy	min, max, avg, last	Parameter
Memory depth	5-10 events	Random uniform
Evacuated	True, False	False
Risk aversion threshold	50-100 mm	Random uniform

Table 1. Attributes of civilian agents

IMPLEMENTATION

Goal of the game

The VigiFlood serious game is **targeted at the population**, with the **goal** of raising their awareness about the difficulty of choosing the right level of alert under uncertainty and high stakes. This is done by changing the player's perspective, getting normal citizens to play the role of an emergency manager having to set the level of flood vigilance based on uncertain rain forecast before facing the population reaction. Our **hypothesis** is that this change of perspective will improve awareness of risk communication challenges.

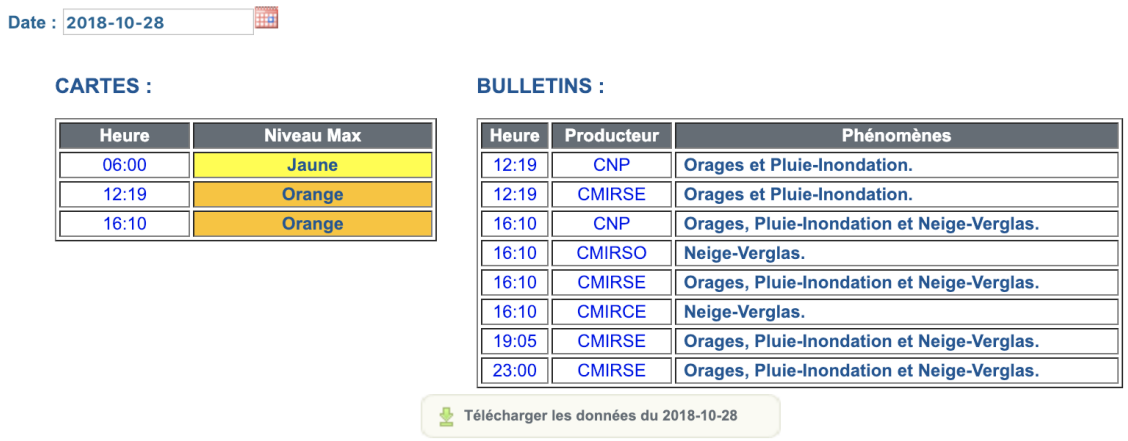

Figure 4. Example of Vigilance Public Meteo output for 28 October 2018

Real data

Getting the data

We implemented 2 Python scripts to extract two types of meteorological data useful to our serious game (rain and vigilance level) from websites where archives are publicly available.

- Rain data: Infoclimat[6] provides archives of daily, monthly and yearly meteorological data since 1973: temperatures, wind, rain, etc. The earlier years can be incomplete. We have implemented a Python parser `getraindata` (300 lines) to extract the following data: normal monthly rain (seasonal norms computed by Infoclimat between 1981-2010), number of days of rain (at least 1 mm) per month, and actual daily readings of rain amounts. We used this parser for Carcassonne-Salvaza (station number 07635) for the years 2010-2018.
- Vigilance data: Vigilance Public Meteo[7] provides a PHP interface (see Figure 4) letting users search for a specific date to get information about vigilance alerts in the entire country that day: time, level (green, yellow, orange, red), emitting agency (each covering a different region; Aude department depends on the CNP agency in Toulouse), and phenomenon concerned (floods, high winds, waves and coastal submersion, snow and black ice, etc). We implemented another parser, `getvigidata` (300 lines) that can query this website for a series of dates (we used it between 2010 and 2018), download the alert bulletins (XML files), select only relevant ones (emitted by CNP, concerning floods). We searched each bulletin for the vigilance colour associated with rain and floods only. When there was no bulletin for a date, we set the colour to green; when there were several, we kept the highest colour.

The output of both scripts is a dictionary dumped to a binary file (with the `pickle` module) that can be loaded from any other Python script to recover the entire dataset.

Difficulties and limitations

Our main difficulty was handling missing and inconsistently formatted data. First, some daily rain data was missing, in particular for the earlier years, which is why we only extracted data after 2010, but some days are still missing. Also the format of the vigilance bulletins was not always consistent, making it hard to extract the exact colour of the flood alert. Besides, on yellow vigilance days, no bulletin was issued. This means that for these days, in the absence of information, our parser will extract a green vigilance instead of yellow. In fact out of 3294 vigilance values, we have 3009 green days, 274 orange days, 11 red days, and no yellow days. To improve this, we need to find another source of vigilance information that also provides yellow alerts; however this is not too much of a problem in this paper since we are mainly interested in the habituation to orange alerts.

Finally, the vigilance level that we extract concerns the entire area covered by the CNP agency, while our daily rain values concerns the Carcassonne-Salvaza meteorological station. This means that the vigilance level is not always

[6] https://www.infoclimat.fr. For instance, archives for Carcassonne-Salvaza for the entire month of January 2010: https://www.infoclimat.fr/climatologie-mensuelle/07635/janvier/2010/carcassonne-salvaza.html and for a specific day 2 January 2010: https://www.infoclimat.fr/observations-meteo/archives/2/janvier/2010/carcassonne-salvaza/07635.html

[7] http://vigilance-public.meteo.fr/

consistent with the actual rain amount, when the floods are located in a different part of the South-West region. In our model, this might be interpreted by the residents as a false alarm because an orange vigilance is raised but the observed amount of rain does not match; in reality, humans would understand which area is concerned with the vigilance; to improve this we would need to mine the text of the bulletin for the locations concerned.

Genericity

Data could be recovered from the same sources for other regions with minimal adjustment of the scripts. Data from any source and in any format can also be fed to the game provided it is saved in the expected input dictionary format, making the game generic and easily adaptable to different areas. We are indeed currently discussing with Grenoble township to get local flood data and provide them with an adaptation of VigiFlood. What might change however is the human reaction to floods, that are much less frequent in Grenoble than in Carcassonne.

More realistic hydrological data

Our current model only relies on the forecast height of rain to set the level of vigilance. To improve scenarios realism without undue complexification of the model, we intend in future versions to add a few more relevant clues, namely soil saturation and river capacity. We will use real hydrological data from various national waterways monitoring agencies[8]. This will require implementing new data extraction scripts and working with hydrologists to design a realistic model of the flash flood process and its prediction.

Implemented game

Technical details

Our current program is a 1800-line Python script. It uses the `pickle` module to load the data created by our previous scripts (`getraindata` and `getvigidata`) from local dump files. This is done only once at the start of the program, and the object created can then be used for the duration of the game. The game has a textual (screenshot on Figure 5) or graphical (screenshot on Figure 6) interface, in either French or English. A batch simulation (no output) over 1 year of simulated time, with 10 repeats and a population of 100 agents, runs in about 120 seconds; with a population of 10000 agents one repeat runs for almost 20 minutes.

Game parameters

Before playing, the user can set a number of parameters:

- **Population size**: number of residents in the population.
- **Starting date**: between 1st of January 2010 and December 2018, which is the range covered by our data.
- **Duration of the game**: in days (at the latest the game stops on December 31st, 2018).
- **Trust initialisation**: either heterogeneous with random initial trust for each resident; or homogeneous with a set initial trust value for all residents (between 0 and 100%).
- **Risk update strategy**: residents can update their subjective risk (expected amount of rain) based on the minimum, maximum, average, or last amount of rain observed on the past occurrences (that they can remember) of the same vigilance level. This strategy is chosen as a parameter and is the same for the entire population.
- **Precision of rain forecast**: the weather forecaster agent computes forecasted rain based on monthly norm of rain, real observed rain for the next day, and precision parameter (0-100%). With higher precision, the forecast is closer to real rain, while lower precision predicts values closer to the norm, potentially missing exceptional events.
- **Interface parameters**: the user can choose between textual or graphical interface, can toggle text feedback on/off, and can choose between French and English language.

[8] In particular `http://www.hydro.eaufrance.fr/` and `https://www.vigicrues.gouv.fr/`

Game loop

The game loop proceeds as follows:

1. The date of the day is displayed, as well as the observed amount of rain that day (in mm).
2. The residents react to the observation of the rain: they compare it with the current vigilance level (set the day before) to update trust, and they might evacuate if needed.
3. The player is provided with feedback about the population: average trust and its explanation (in terms of how much rain they expected based on the vigilance colour); and percentage of evacuated residents.
4. The weather forecast service announces a forecast amount of rain for the next day.
5. The player is asked to set a vigilance colour based on this forecast.
6. The population reacts to this vigilance level: compute subjective expected rain based on previous similar alerts, and might evacuate if this is above their risk aversion threshold;
7. The player receives feedback about the percentage of the population aware of the risk (if any); their average expected rain (in mm); their average trust (in %); and the percentage that evacuated as a result of the alert.
8. Rain and vigilance for the day are stored in game history, and the time moves forward to the next day.

Getting feedback

At the end of the game, final feedback is displayed in the form of statistics about the population and communication:

- **Population statistics**: average percentage that stay unaware of risk; average expected amount of rain for each vigilance colour; average trust and its evolution before/after the game; and average evacuation percentage.
- **Communication statistics**: total days played; for each colour: number of alarms raised, number of false alarms (raised but observed rain lower than expected), number of alarms missed (not raised and observed rain higher than expected).

Game modes

We have implemented 4 possible game modes:

- **Visualisation**: this mode lets the user explore the available data. The user inputs any date since 2010 and obtains the amount of rain in Carcassonne on that day as well as the vigilance level.
- **Play**: the user chooses the desired parameters, and plays the role of the emergency communicator in charge of setting the vigilance level. The game proceeds along the loop described above for the selected number of days, and final feedback is provided to let the player debrief his actions.
- **Automatic**: in this mode the human player is replaced with an AI that automatically selects the vigilance level based on the rain forecast (above 10mm: yellow, above 20mm: orange, above 50mm: red). The same final feedback is displayed at the end. This allows to compare human players' strategies with a predefined static strategy.
- **Batch**: in this mode all displays are disabled and the game is repeated a number of times with the same initialisation to smooth out the randomness. The output is an average of the trust evolution over all games played with these same parameters. This allows to draw statistics and compare the impact of each parameter.

PRELIMINARY RESULTS

Scenario 1: forecast precision

We have run a first scenario in order to explore the positive and negative evolution of population trust in function of the precision of the weather forecast. We have run the simulation for 3 months, starting October 1st 2018, and therefore including the events of October 14-15, on a population of 100 agents. The population was defined with random heterogeneous initial trust (around an average of about 50%) and their algorithm for computing expected rain is based on the average of past rain. With these settings, we only varied the precision of rain forecast and observed the evolution of trust over these 90 days.

- Perfect forecast (100% precision of the rain forecast): trust increased slightly from an average of 52.81% to an average of 58.71%.
- Realistic forecast (80% precision): average trust remained stable around 50% (from 49.76% to 49.65% exactly).
- Same but with 50% forecast precision: the average trust dropped from 54.23% to only 22.57%.

First, we observe that trust decreases faster than it increases: lost trust is hard to restore, so it is best to maintain trust. Second, this shows the importance of reliable forecast to set an accurate vigilance level, yet flash floods are hard to predict because they depend on many other factors than just rain. It is therefore very important that the population is made aware of these difficulties and the fact that false alarms are unavoidable. This is part of being transparent in order to maintain trust, as recommended by (Reynolds 2010).

Scenario 2: population reasoning

The scenario above was based on an averaging of past events, and an "objective" update of trust where observed rain was compared with the objective meaning of the vigilance colour. This means that if the vigilance level was set to orange, the observed rain was compared to the official 20-30mm range supposed to be meant by that alert. But the population actually relies on a subjective expected rain based on their previous experience of past orange vigilance days; this is how they get habituated to this orange vigilance meaning "not much", when it is raised and it does not rain much. We have therefore run another set of games with a subjective update of trust based on comparing observed rain with the individual's subjective expectation, computed using our various algorithms. We have set the forecast precision to 100% and run 90 days during year 2010 to limit the number of false alarms in history. Results are very sensitive to the period played and which events occurred:

- The averaging of past rain on same-vigilance days: this strategy considers the more different past alerts, and leads to the worst loss of trust when there are many false alarms. However, correct alarms in the past history will improve the subjective prediction and hence the final trust of the population.
- The "last-event only" strategy means that after a false alarm, the next alarm will be inefficient, people will expect it to be just as false. But then only one correct alarm is enough to reset expectations.
- The "maximal last event" strategy makes residents pessimistic, they will expect as much rain as the worst event on record; the player might lose some amount of trust for announcing too much rain, but people will rather react too much than not enough.
- The "minimal last event" strategy on the other hand makes residents more optimistic: they will only expect as much rain as the lowest rain that occurred in the past when vigilance was set to that same level. This means that they are very likely to not react to an orange vigilance, for instance, as long as they have not forgotten that one day when it was raised and it did not rain.

In reality, we expect humans to use combinations of these strategies, possibly dynamic depending on the context and their personality. Changes are therefore needed in our game to improve the residents' reasoning, and also to make it heterogeneous. However, validating this reasoning strategy would require to find supporting data about how people actually reason about subjective risk, which might be difficult.

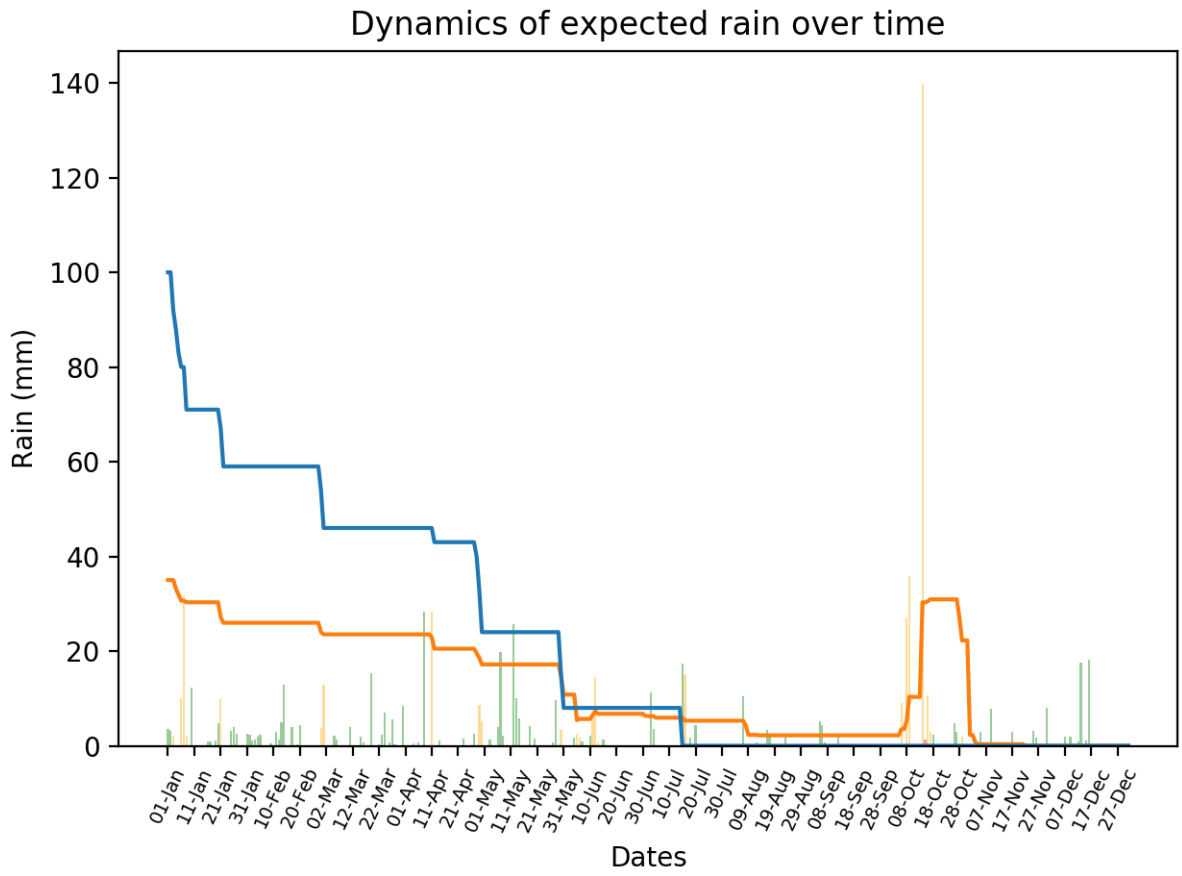

Figure 7. Dynamics of trust (blue line), expected rain associated with orange vigilance (orange line), observed rain (bars height), and vigilance (bars colour), over year 2018.

Visualising the dynamics of trust

Figure 7 illustrates the dynamics of trust in the population over the real events of year 2018. We initialised the population with full trust (100%), a 'realistic' update strategy (averaging past rain on orange vigilance days in memory) and a memory depth of 7. One can see that at the start of the year, trust is 100% (blue curve) and the expected amount of rain on orange vigilance days (orange curve) is around 35 (the middle of the official 20-50 mm range).

The bar chart shows the actual amount of rain observed each day, and the colour of each bar shows the associated vigilance colour as announced by the authorities. As the year progresses, various 'false alarms' are raised where orange vigilance is announced but it does not rain much: as a result, trust goes down, and the average expected rain on orange days also decreases, making the residents more likely to be surprised in case intense rain really occurs. This is the case in October, when the orange vigilance is set on the 14. A positive effect of this surprise is that the expected amount of rain on orange vigilance days goes up again (counting that exceptional event in the average), but a negative effect is that trust drops near 0.

We believe such visualisations can be very helpful for people (residents or emergency managers alike) to understand the dynamics of trust in crisis communication. This makes our model already useful as a visualisation, before it is even interactive and playable.

Discussion

The game exposed here is just a proof-of-concept with limited playability, preventing immediate evaluation. The main obstacle to playability is the repetitiveness of the game that makes it quickly boring. So far the player is asked everyday to set a vigilance colour, while most days almost no rain is forecasted and the vigilance will be green more often than not. This will be improved by creating pedagogical scenarios that do not rely on actual past data, but that trigger more frequent interesting events in order to engage the player. Other ideas for improvement include using an

interactive map built from OpenStreetMap data, similar to other serious games used in emergency management (for instance SPRITE (Taillandier and Adam 2018)); and displaying feedback about emotions of the population.

We would also like to explore other scenarios, in particular assessing the impact of the vigilance thresholds (10mm for yellow, 20mm for orange, 50mm for red) on the average trust of the population and their subjective expected rain, depending on the forecast precision. This will require implementing various (automated) strategies with dynamic vigilance thresholds, and making the choice a parameter of the automated player.

Prospective evaluation of the game

As discussed above, the underlying behaviour model is grounded on psychological theories and is realistic enough for an educational purpose. What requires evaluation however is the **impact of the game**. In order to verify our claim that playing this game can **improve awareness**, we have planned the following evaluation process.

Once the playability of the game has been improved, the first evaluation will be with other researchers and students in our university or at workshops and conferences, in order to refine gameplay and interface; this can happen at medium-term. The second evaluation will require to first implement a logging functionality to store the history of players' actions, and to analyse logs to draw interesting statistics. We will then be able to analyse players' strategies to face the different pedagogical scenarios that we define, and observe how they adapt over time to measure the evolution of their awareness.

Finally, a more complex evaluation will be in the form of a survey of people in the affected area (Aude) in order to assess their trust in orange vigilance and will to act on it, before and after playing the game. This survey will also gather their qualitative feedback about the game. This can only happen at longer-term, after finalising the game and carefully designing the experimental protocol and questionnaire.

CONCLUSION

In this paper we have presented the **VigiFlood** serious game, a disaster alert game based on a real case study, the flash floods in the Aude department in October 2018. Although preliminary, the game is based on real pluviometric and vigilance data from local weather forecast agencies, and already provides interesting insight and novelty compared to previous work. In particular we have shown that it allows the player to visualise the dynamics of trust over time, and the impact of events such as repeated false alarms.

This game is however still a preliminary proof-of-concept and many things remain to improve. The implementation of more roles (journalists, etc) is already ongoing and should be finished at short-term, allowing us to explore more complex pedagogical scenarios. In the longer term we then want to improve playability, evaluate the game and its impact on awareness, and adapt it to other contexts.

ABSTRACT

Understanding human behaviour and interactions in risk situations may help to improve crisis management strategies in order to avoid the worst scenarios. In this paper we present a geospatial agent-based model and simulation of human behaviour in bushfires. We have modelled the social interactions between different actors involved in bushfires such as firefighter, police, emergency centre managers and civilians. We use the Belief, Desire and Intention (BDI) architecture to model realistic human behaviour, and the FIPA-ACL standard to model the communications. We use geospatial data to represent the environment in a realistic way. We show how the model has been implemented and how we have unified the communications model and the BDI architecture. Finally, we compare the processing time of two implementations of our model representing a 2D simple and a 3D GIS environment.

Multi-agent systems, cognitive agents, GIS, communication, bushfires

INTRODUCTION

Between 1998 and 2017 climate-related and geophysical disasters killed 1.3 million people and left a further 4.4 billion injured, homeless, displaced or in need of emergency assistance (EM-DAT, 2017). Bushfires represent 3.5% of these disasters. Wildfires are uncontrolled fires which occur frequently in dry and hot climate zones. These fires devastate big forest areas, destroy properties and kill many people. In 7th February 2009, also called Black Saturday, bushfires killed 173 people in Australia in the state of Victoria. The Australian government created a commission in order to understand why so many people died despite its effort to prepare people for bushfire events. The conclusion of the commission (Rhodes, 2014) was that the responsibility was shared between all the actors involved: emergency managers, firefighters, police and civilians. In case of fire, the Australian Fire Authorities Council advise residents to choose between two courses of action: "Prepare, Stay and Defend" their house from fires, or "Prepare and Leave Early". The emergency managers expected that civilians would follow instructions, prepare their fireplan and then apply it during the crisis. Despite the authorities' expectations, many civilians did not have a fire plan or they applied it too late waiting for a personalised message from emergency centres.

Multi-agent modelling and simulation has proved to be a useful tool for exploring "what-if" scenarios, emergency management strategies (Almeida et al.,2013; Chu et al., 2009; Dugdale et al. 2010; Thorp et al., 2006) and communication strategies (Adam et al., 2019; Mancheva et al., 2015; Sakellariou et al., 2008) for a

better understanding of the human behaviour in crisis and emergency situations.

The focus of our work is to provide a realistic simulation of bushfires and people's behaviours and interactions. Our goal is to provide a tool for emergency managers and stakeholders to allow them to explore different strategies and scenarios. To achieve our goal we have used a combination of different research approaches including multi-agent simulation, cognitive modelling and geospatial information representation.

In this paper we present our conceptual agent-based model of human behaviour and interactions in bushfires and its implementation. In the first section, we describe the state of the art concerning the research areas involved in our model. Then, we describe the theoretical foundations of our model and how it was constructed. We then show how this model was implemented and compare a 2D simple model and 3D GIS model in terms of processing time. We conclude with a summary and discussion about the model and our contributions.

STATE OF THE ART

We use an agent based modelling (ABM) approach to model and simulate human behaviour, and geographic information system (GIS) data to provide a more realistic environment.

ABM had been widely used for modelling and simulating human behaviour in different natural hazard situations such as earthquakes (Bangate et al.,2017), floods (Dawson et al., 2011), tsunamis (Mas et al., 2012) and bushfires (Adam et al., 2016; Minelli & Tonini, 2016; Thorp et al., 2006). ABM can capture emergent phenomena in complex systems, provide a natural description of such a system, and is flexible enough to model the micro and macro levels in a system (Bonabeau, 2002). Agents are defined by the following characteristics: (1) autonomy: each agent can control its own actions and its internal state; (2) heterogeneity: each agent can have its own specific set of attributes and behaviours; (3) social ability: agents can interact with each other via some kind of agent communication language (ACL); (4) bounded rationality: agents' knowledge is not universal but depends on their context; (5) reactivity: agents can perceive their environment (physical or abstract) and respond to the changes in it; (6) proactiveness: agents do not only perceive and act in their environment but exhibit goal-directed behavior (Wooldridge & Jennings, 1995; Crooks et al., 2018). These agents' characteristics show that ABM is an appropriate tool to model a complex system such as bushfires where different actors with heterogeneous behaviours interact with each other. Another way to model complex systems is to use equation based models. The advantage of using ABM instead of mathematical equations is that ABM can model entities with heterogeneous behaviour often with nonlinear relationships and with multiple interactions. For a complete discussion about ABM vs equation-based modelling see (Parunak et al. 1999).

There are several ways to model human behaviour in ABM, the simplest one is to use reactive agents whose behaviour is based on a perception - action loop. A more realistic and sophisticated approach is to use the BDI (*Belief, Desire, Intention*) (Rao & Georgeff,1991) cognitive model. This model is based on Michael Bratman's philosophical theory of action (Bratman, 1987). Human behaviour is described in terms of mental attitudes: *Beliefs, Desires and Intentions*. The *Beliefs* represent the knowledge that the agent has about the world (not necessarily true); the *Desires* represent the actions that agent would like to do in the future; and the *Intentions* are the chosen actions that will allow the agent to accomplish its goals. It is possible that the agent has different plans to achieve the same *Intention.* In this case, if one of the plans fails, another one will be selected. For (Adam et al., 2016), BDI is a more appropriate approach for modelling human behaviour in crisis situations involving complex decision making, influenced by emotions and by the social context than reactive agents.

Another important issue that should be considered when modelling human behaviour in emergency situations, is communication. Modelling communications allows us to implement a realistic spread of the information between different actors. Communication is a social interaction and can be viewed as a complex system where entities, e.g. humans, interact using a common language. Different standards for Agents Communication Language (ACL) exist, we have chosen to use FIPA (Foundation for Intelligent Physical Agents) - ACL (Fipa, A.C.L., 2002) that is widely adopted in ABM. Based on its theoretical foundations FIPA-ACL can be easily integrated into a BDI agent architecture. For example, (Mancheva et al., 2015) used FIPA and BDI to model the communications in a medical team during cardiopulmonary resuscitation. In ABM of bushfires (Sakellariou et al., 2008) used FIPA-ACL and BDI to model firefighters cooperation for extinguishing forest fires. Also (Adam et al., 2019) used BDI agents and created their own framework for agent's communication in order to study the best ways for information spreading concerning bushfires.

(Wise, 2014) argues that combining GIS and ABM allows researchers to gain better insight into how a crisis may develop and to explore how boundedly rational individuals behave in a complex physical environment. There are several examples of models combining GIS and ABM, for a complete review see (Crooks et al., 2018). Here we are interested in how ABM and GIS have been used in bushfires. (Minelli & Tonini, 2016) designed an ABM that simulated alpine forest fires, urban traffic and firefighters using GIS data. (Thorp et al.,

2006) also used ABM and GIS to model wildfires, traffic simulation and evacuation in Santa Fe, USA. Although these models provide good frameworks to study fire spreading, traffic simulation and evacuation in a geospatial environment, they do not provide any fine grained behaviour model of different actors in such a situation. On the contrary (Adam et al., 2016; Adam et al, 2017) created a detailed cognitive model of civilian behaviour in bushfires and simulated it using ABM, but they did not use GIS data.

This paper describes a unified framework for simulating realistic crisis situation scenarios. To our knowledge, there is no research study that has simultaneously employed detailed cognitive modelling of different actors in bushfire situations, using an advanced language for communication based on speech act theory, and integrating spatio-temporal information.

CONCEPTUAL MODEL

The model is inspired by a body of work modelling the human behaviour in bushfires (Adam et al., 2016; Adam et al. 2017; Adam et al. 2019). The model has been designed based on the data from witness statements (Exell, 2009) of people who survived the 2009 Black Saturday fires in Victoria, Australia. These witness statements provide realistic data of how civilians responded to bushfires. We have manually analysed the 100 witnesses' interviews to help to construct the model, and also used statistics about the victims (Teague et al., 2009), for example:

- Causes of death: 14% died while escaping (4% by car and 10 % by foot); 69% died while passively sheltering in a building; 17% died trying to defend their house.
- Preparation: 58% of victims had made no preparation to their property or themselves; 20% intended to stay and defend their property and were well prepared.
- Awareness: of those who died, 30% were taken by surprise, 38% did not have any knowledge about what to do.

System Specification

The architecture of the model is shown in Figure 1. For the sake of readability, we have removed all attributes and methods of simple reactive agents and have kept only BDI agents definitions. We have defined 3 abstract types of agents: WeatherAgents, LandAgents and GameAgents.

Weather agents

Fire

Since the focus of our work is on modelling human behaviour in bushfires, we did not use a complex fire spreading model, as done in other studies (Duff et al., 2013). The fire starts at a random time (measured in simulation cycles), and location at the beginning of the simulation; simultaneous fires are also possible. Fire has different attributes such as damage radius, heat radius and intensity. The intensity is the fire strength of damaging buildings within a damage radius. The heat radius represents the radiant heat around the fire that injures civilians. At each simulation step, based on a probability, the fire can grow by increasing its intensity, propagate in a radius, emit embers, injure civilians and damage buildings. It can also stop burning when extinguished by firefighters, by modifying its intensity to null.

Forecast

The Forecast agent has the role of observing fires and displaying different fire danger ratings as a function of the number of fires and their intensity. The ratings include: low, high and severe state. Different agents (e.g. civilian, emergency managers) can check the Forecast agent's danger ratings at any time.

LandAgents

LandAgents include all landscape agents: roads, buildings, water areas and forests. The LandAgents are created from real geospatial data. The processing of the GIS data is explained in the Implementation section. The number, location and shape of roads, water areas, forests and buildings depend on this data.

Roads

The roads are represented by a graph. This road network is used by agents (e.g. civilian, police and firefighters) driving a car or a truck. A road could be blocked by a fire or by the police. In future versions, we would like to

calculate a speed coefficient (as a function of the road capacity and width) that will decrease the speed of driving agents, simulating traffic jams.

Water Area

Water areas are used for recharging fire truck water containers. Since the available quantity of water in these areas is huge, we simplify and consider it to be unlimited for now. In the future versions, water areas can be used as shelters for civilians, as noted in witness statements.

Forest

The forest has attributes describing its density, dryness and height.

Obstacles

The obstacles are an abstract class of agents that gathers all non-human agents that could block the movement of human agents (e.g. civilian, firefighter and police). We have implemented a mechanism so that agents avoid buildings and fires.

Building

Three types of buildings are modelled: house, shelter and base (for police or firefighter agents). All buildings have a fire resistance level. For shelters and bases this resistance is set to maximum, they cannot be destroyed. Agents inside shelters and bases cannot be injured by the fire. A house can have zero or one occupant. This choice was done for model simplicity, since including family interactions can significantly increase the model complexity. Houses have some initial resistance that can be increased if the owner decides to prepare it (e.g. remove fuels and garden furniture, put sprinklers on). When the resistance drops to 0, the house collapses (shown in black in the simulation view). If the owner is in or close to the house, the collapse will remove his plans to shelter in the house or to defend it.

GameAgents

GameAgents have common characteristics like speed, perception radius (auditory and visual), list of fires, and ability to communicate. The agent's speed depends on the agent's mean of transport (e.g. by car/fire truck or by foot). The perception radius represents the area around the agent where it can "see" and "hear" other agents (e.g. civilians, fire, buildings, etc.). The list of fires contains the perceived fires by the agent in its perception radius. Note that, even if some of the fires are extinguished, the agent will continue to believe that a fire exists at a certain location until it perceives that there is no longer a fire at that location. All GameAgents are implemented with a BDI architecture.

Helicopters

Helicopters search for fires and report their coordinates to emergency managers. For simplicity's sake, the helicopter agents are basic and do not extinguish fires. At the beginning of the simulation helicopters are located at their base and once they receive an order from an authority agent, they start to search for fires. If they perceive a new fire in their perception radius, they will report its location to the authority agent. Helicopters continue to search for fires until the end of the simulation, when all fires stop.

Police

According to the witness statements, the Australian police has the role of informing people and blocking roads to prevent citizens from moving towards a fire. At the beginning of the simulation, police agents are located in their base. They can go to a specific road location when requested to do so by the authority agent, moving only by car on the road network. The police agents can inform the authority agent about newly perceived fires, or inform civilians about further fires on the road.

Authority

To simplify, we have decided to model the emergency manager's behaviour and the authority's behaviour into one single abstract agent that we call Authority. The Authority agent has two main goals: extinguish fires and save residents. At the beginning of the simulation, the Authority agent observes the forecast provided by the Forecast agent. If the fire danger level is high, it can decide to achieve its goals with plans among the following:

- Get global information about the fire location: by requesting helicopters to fly over specific areas
- Get local information about fire location: by requesting the police to go to strategic road network hubs
- Deploy firefighters trucks to fire locations: by managing busy or available firefighters and active fires locations
- Broadcast emergency evacuation alert to civilians

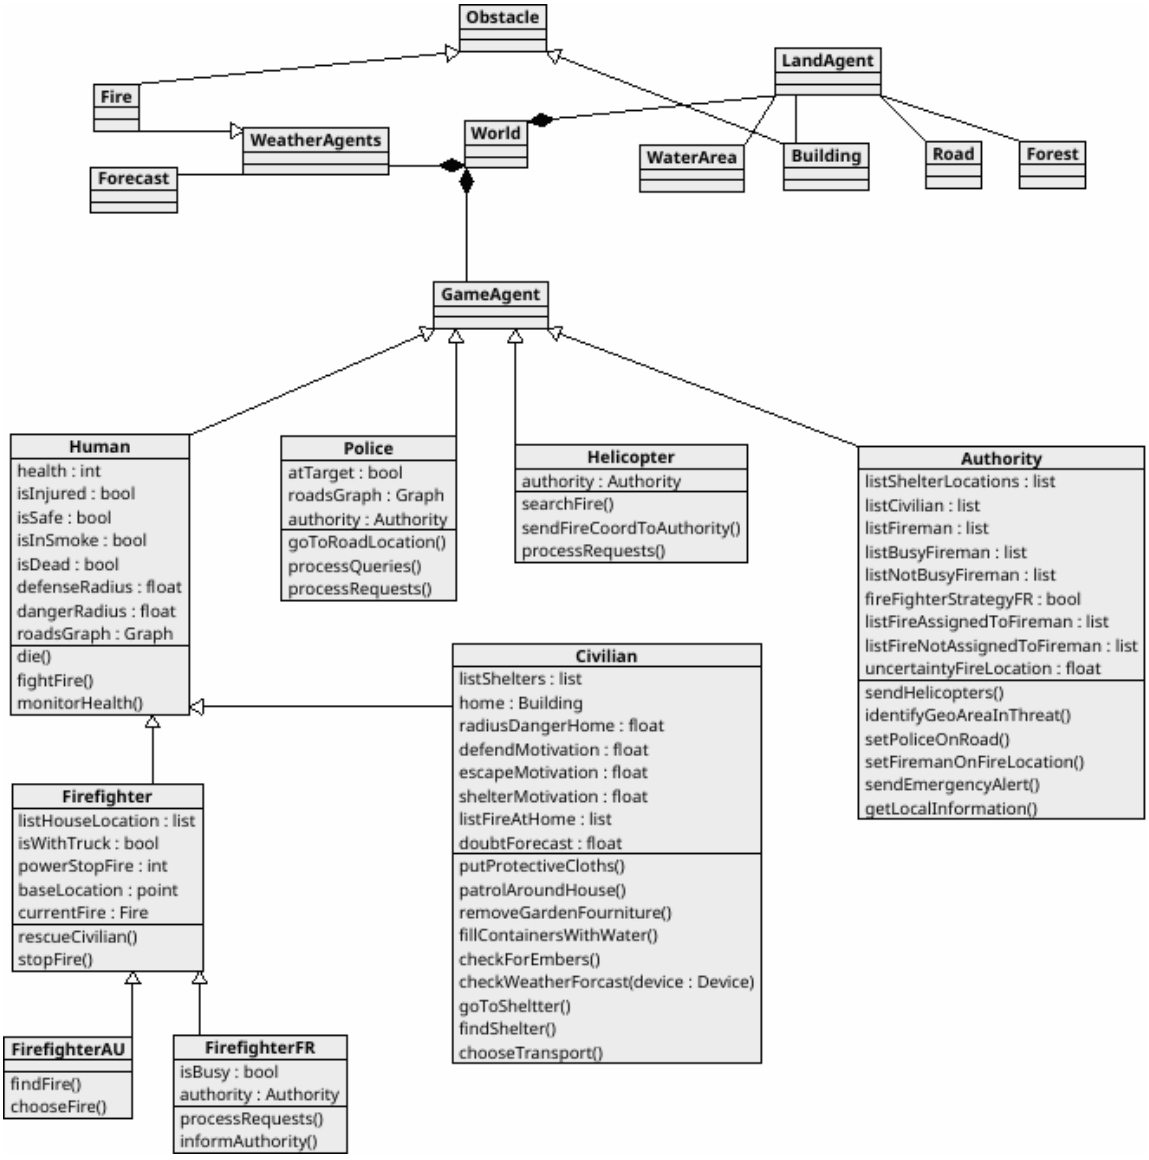

Figure 1. Simplified UML class diagram of the model

Firefighter

In our model the firefighters have 2 main goals: extinguish fires and save civilians. The firefighter's priority is always to save people's lives even if there is a nearby intense fire[1]. In the introduction we stated our goal of providing a tool for testing emergency management strategies. Firefighters in different countries have different protocols and strategies when they extinguish fires. We have decided to model and implement both the Australian and French firefighter's strategies. From interviews, we know that Australian firefighters work in a decentralized manner, going from one fire to another. Conversely, French firefighter management is more centralized. French firefighters are given orders to go and extinguish a fire at a specific location and when the fire is under control, they go back to their base and wait for new orders. Depending on a boolean parameter, the firefighters in our simulation apply either the Australian or French strategy. In both cases at the start of the simulation, the firefighters are located at their base. French firefighters receive orders from the Authority agent to go to a specific location and extinguish a fire. Once the fire is stopped they go back to their base and inform the authority that they are available and that the fire on that location is stopped. Australian firefighters listen to the forecast and when they believe that there is fire danger, they start to search for fires. When they stop a fire, they search for another one. Firefighters move on the road network driving fire trucks at a random speed. The fire truck has limited water capacity and when the water is used, firefighters refill with water at the closest water area. At any time during the simulation, if firefighters perceive an injured civilian, they will put on hold all other

[1] Source: private communication with French firefighter, requesting anonymity.

plans and will attend to the injured civilian. Once the civilian has been attended to, it is removed from the simulation; this represents the idea that the civilian has been driven to hospital or a safe area.

Civilian

Our model uses data of civilians that survived the Australian bushfires. Residents have to choose between two fire plans: "Prepare, Stay and Defend" or "Prepare and Leave Early"[2]. In our model, civilians can either defend their house, leave it or passively shelter in the house depending on a motivation parameter. At the beginning of the simulation, civilians are located in their houses or they move (by car or by foot) around their environment. There are 2 ways for a civilian to believe that there is fire danger: either they perceive a fire in their perception radius or they receive an evacuation alert from the Authority agent. If a civilian knows that there is fire danger, he will activate his fire plan to stay, to go or to passively shelter in his house. Civilians can escape by foot or by car depending on a probability parameter, set from the statistics shown in the beginning of this section. Civilians can go to a shelter selected among their known shelters list. If the civilian decides to defend his property, he can choose first to prepare his property and/or himself. To defend his property, the civilian goes around his house within a protection radius and searches for fires and embers. Beyond a danger threshold based on the number of fires around his house, the civilian may decide to shelter inside until the end of the simulation or go to a shelter.

Communication model

We model agent's communications with FIPA-ACL (Fipa, 2002). FIPA-ACL is based on speech act theory (Searle, 1969) that considers an utterance as having a performative function in language and communication. Based on that theory, exchanging information (receiving/sending a message) is an action in our model. A FIPA message has several parameters; we have simplified the message structure as follows: type, sender, receiver and content. FIPA specification defines 22 communicative acts. From witness statements and based on our agent BDI model's constraints, we have chosen to use the following 3 acts:

- **inform-ref**: the sender informs the receiver for an object description.
- **query-ref:** ask another agent for a referred object value (e.g. fire location).
- **request:** the sender requests the receiver to perform some action (e.g. go to fire location).

Here are some examples of messages exchanged between two agents in our model:

request (authority, police, [GO_TO: {125; 456; 852}]): the authority agent requests a police agent to go to road location with coordinates {125; 456; 852}

inform-ref (helicopter, authority, [FIRE_LOCATION: {863; 15; 335}]): the helicopter agent informs the authority about a fire perceived at coordinates {863; 15; 335}

query-ref (authority**,** police, [FIRE_LOCATION]): the authority agent queries the police if the police knows of a new fire location

We will demonstrate in the next section how we have implemented these specifications into the agent's BDI model.

Dynamic model

We have used the Tactics Development Framework (TDF) to design the dynamic specifications (Evertsz et al., 2014) of all cognitive agents in our simulation. This methodology has already been used for crisis situations and has proven its utility in other studies modelling human behaviour in bushfires (Adam et al., 2016). The TDF methodology is composed of 3 phases: (1) *System specification:* definition of goals, scenarios, percepts, actions, data, actors and roles; (2) *Architectural design*: specification of agent's interactions (via protocols) and messages; (3) *Detailed design:* detailed agent plan diagrams including subgoals, internal messages and actions. Here we will describe the architectural design and the detailed design of our model.

Architectural design

In the architectural design we have specified all agent interactions that can occur during the simulation. Figure 2 shows a detailed view of all possible messages between different agents as well as their contents. We have used the formalism defined in the previous section. Each colored square in Figure 2 represents the communications for a specific agent and the directed arrows - the receiver agent. For example we can see that the Civilian agent can send messages to the Authority agent, the police, the firefighters and to the other civilians.

[2] Hereafter referred as 'stay' or 'go' plan

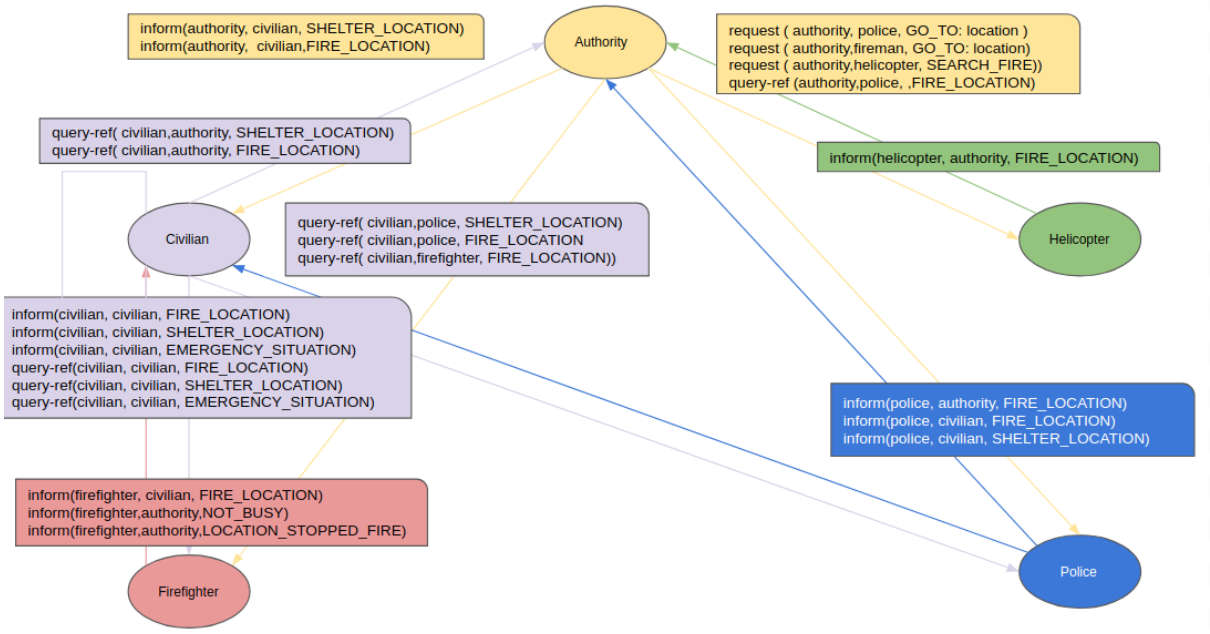

Figure 2. Architectural design: specification of agents' interactions

Detailed design

The detailed diagrams are very useful for the modeller since they allow making a direct link between the agent's goals and its BDI specifications and implementation. Due to space limitations we will only show a detailed diagram of authority agent goals.

Authority

Figure 3 details the authority subgoals and plans of the Stop Fire goal. The Stop Fire goal is activated when the authority agent believes that there is fire danger provided by Forecast agent. To stop the fire the authority agent has to know where the fire is and then deploy firefighters to that location. The authority agent can also deploy police agents at strategic road locations in order to inform residents. We split the Stop Fire goal into 2 sub-goals Get fire information and Set emergency service on road. Get fire information goal is achieved by applying 2 plans Get global information and Get local information. Get local information is executed under certain conditions: police have to be already deployed on the road network, and the authority's uncertainty level about the fire location should exceed a fixed threshold. This threshold increases with each simulation step and decreases when the authority agent receives fire location information. Using the threshold condition means that we can model in a realistic way several calls of Get local information plan. This plan consists of one action, the authority queries the police if it knows about new fire locations. As we explained in the previous section, we consider a communication as an action. As in real life, when an emergency manager is uncertain about the fire location, he will call the services located on-site. Set emergency service on road is split into 2 plans: Deploy firefighter on road and Deploy police on road. The Deploy firefighter on road plan will be called only if the authority is managing French firefighters and if the list of active fires is not empty. In this case, the authority agent has to optimise the deployment of firefighters resources to specific fire locations.

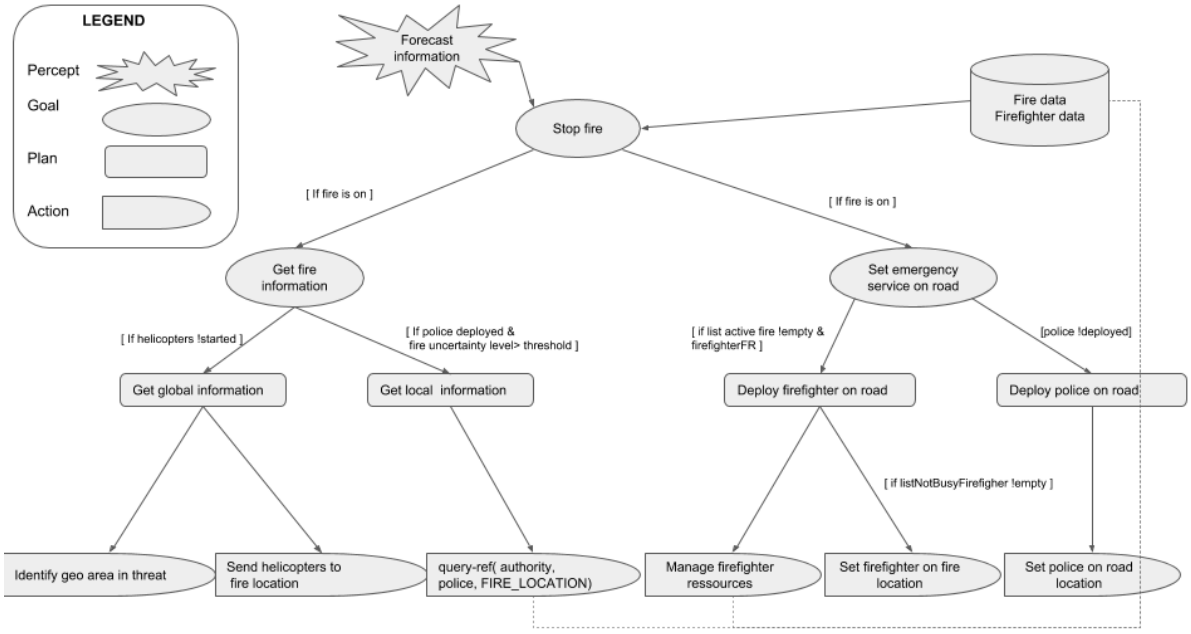

Figure 3 . Detailed design: Diagram of authority agent Stop fire goal.

IMPLEMENTATION OF THE MODEL

Many agent based simulation platforms exist; for a review and comparison see (Kravari & Bassiliades, 2015). We have used the GAMA platform (Grignard et al., 2013) for implementing our model. GAMA is an open source modelling and simulation development environment for building spatial agent-based simulations. GAMA uses a meta agent oriented programming language called GAML. GAMA combines GIS data and 2D/3D visualisation and supports the implementation of large scale models. It also includes a BDI plugin that allows modellers to easily implement BDI agents, and it is FIPA-compliant. All these characteristics fit very well with the requirements of our model.

Agent's world

The agent's world can be built in 1 of 2 different alternative ways: (1) 2D model; (2) 3D GIS model. All agents in our model are world-agnostic, meaning that they have a generic implementation independent of the world's specifications. This allows us to use different environment visualisations, setups and different maps. At the beginning of the simulation, in the GUI view, we can select between the 2 different models.

2D model

The 2D model has simpler view and smaller dimensions than the real 3D geospatial model, allowing us to see small agents without zooming (e.g. civilian are 2m high). Figure 4 is a 2D model screenshot. All agents are generated at random locations. The map represents roads graph network, painted in pink. We can see small fires close to some houses and civilians 'defending' them. On the bottom right side, firefighters are leaving their base (green square) and driving towards fires.

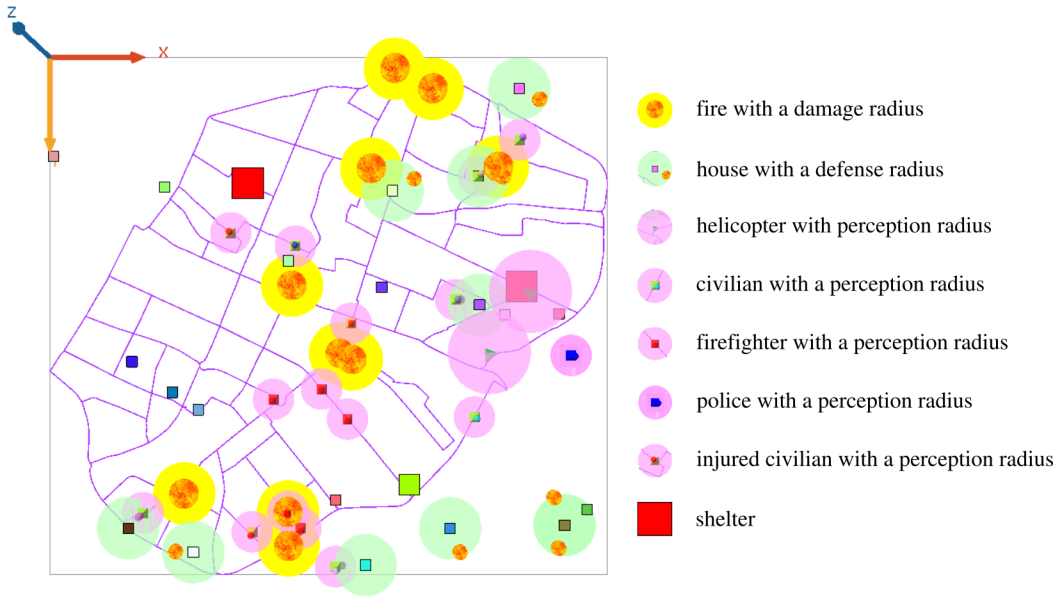

Figure 4. 2D model screenshot at cycle 17 since the beginning of the simulation

3D geospatial model

GIS data can be easily integrated into the agent model by providing shapefiles[3] that specify different geographical objects. Non-human agents, such as forests, buildings, roads and water areas, are created from these shapefiles. We have used OpenStreetMap[4] for obtaining GIS data and then GAMA to process and save them into shapefiles. We used also QGIS[5] to change the shapefiles spatial reference system to the corresponding Australian one, GDA94[6]. We model the Kinglake city area, in Victoria, because its was one of the most affected cities during Black Saturday. Figure 5 shows a screenshot of the simulation using the GIS data of Kinglake city; we can see the same agents and colours but with a different layout. Although buildings, fires and road network are visible, we cannot see civilians, firefighters and police since their size is too small at this scale. The green area represents the forest.

BDI implementation

GAMA provides a BDI plugin (Taillandier et al, 2016) to create BDI agents with the GAML language. A BDI agent has a plan library and 3 different databases for beliefs, desires and intentions. An engine updates these based on the agent's perceptions of its environment and its internal rules. In GAML, a specific type called predicate is used to describe the domain ontology. Here is a code snippet giving an example of predicate definition.

```
predicate get_local_info_fire <- new_predicate ("get local info fire");
predicate set_emergency_service_police <- new_predicate ("set emergency service police");
```

Below is an example of an authority agent rule that generates the desire to get local information about fires only when it believes that the police are deployed on the road and when its uncertainty level exceeds a threshold. This example shows part of the implementation of the conceptual model described in Figure 3.

[3] A shapefile is a widely used geospatial vector data format for GIS.
[4] OpenStreetMap is a free editable map of the world, created by volunteers, https://www.openstreetmap.org
[5] QGIS is an open-source platform for GIS data processing.
[6] GDA94 is Geocentric Datum of Australia 1994

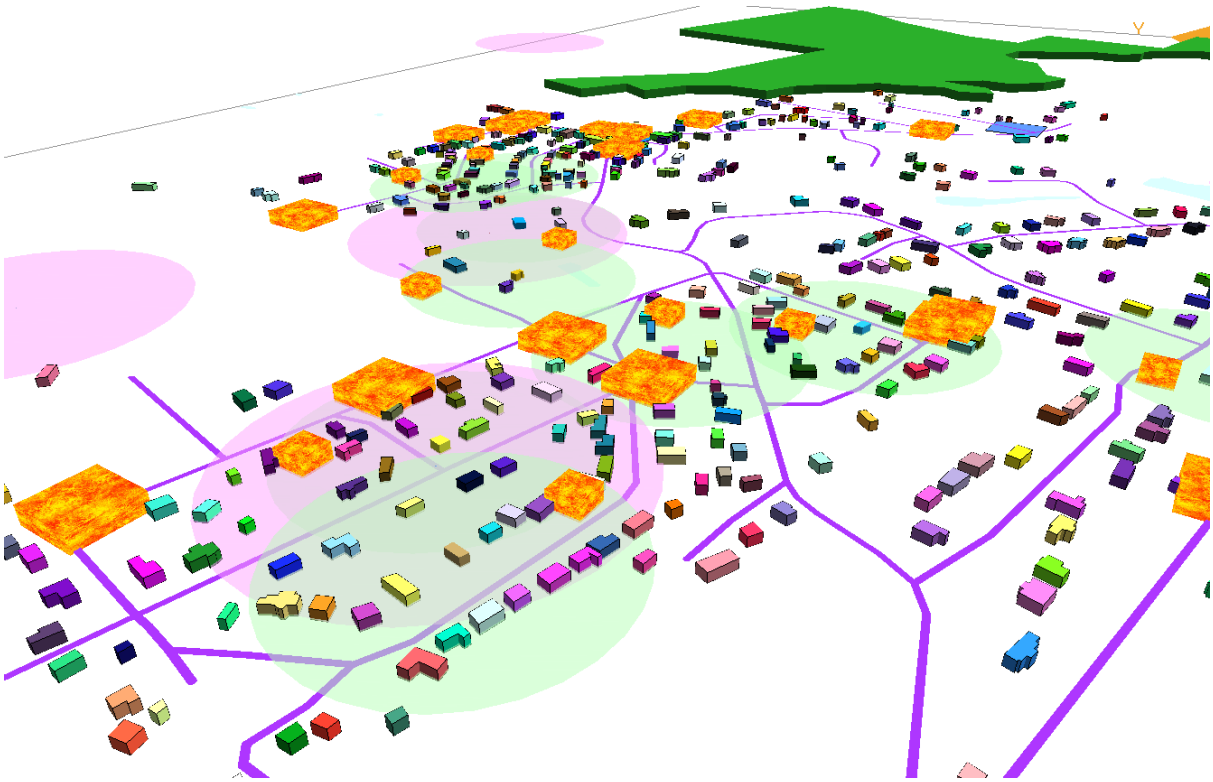

Figure 5. 3D model screenshot of Kinglake city in Victoria state, Australia, representing 4000m x 3000m map

```
rule when: has_belief(set_emergency_service_police) and uncertainLocationFire > 0.7 new_desire:
get_local_info_fire ;
```

BDI agents also have a library of plans for achieving their intentions. For instance, the following plan accomplishes the get_local_info_fire intention by calling the action queryPolice.

```
plan getLocalInfoFire intention: get_local_info_fire {
    do queryPolice;
}
```

In that action, the authority agent queries each Police agent, one by one about the fire location. Since, it knows that it will receive the fire location information, the uncertainty threshold decreases to 0, so the next simulation step the rule presented earlier won't be executed. Adding the belief of getting the local information will remove the get_local_info_fire intention from the intention stack.

```
action queryPolice {
        loop p over:list (Police) {
do start_conversation to: [p] protocol: 'no-protocol' performative: 'query' contents: [ (
FIRE_LOCATION )] ;
    }
        uncertainLocationFire <- 0.0;
        do add_belief(get_local_info_fire); }
```

FIPA implementation

In GAMA, if an agent is specified with a FIPA capability, it is provided with embedded actions and lists that hold different FIPA communicative acts and communications. Below are GAMA examples of the speech acts that we model:

```
do start_conversation to: [a] protocol: 'no-protocol' performative: 'inform' contents: [ ( msg )] ;
do start_conversation to: [a] protocol: 'no-protocol' performative: 'query' contents: [ ( msg )] ;
do start_conversation to: [a] protocol: 'no-protocol' performative: 'request' contents: [ ( msg )] ;
```

In the action queryPolice, the authority agent individually queries police agents about the fire location. GAMA also provides default lists for receiving different messages: informs, queries and requests lists. However, the modeller has to specify the message processing in different lists. Here is a code snippet of agent reflex[7] reading its list of informs messages:

```
reflex readInforms when:!empty(informs) {
        loop i over: informs {
                string msgContent <- string(i.contents);
..... }
}
```

PRELIMINARY RESULTS

Below are some preliminary results. We have compared the processing time (in minutes) between the 2 models with different scenarios (Table 1). We ran 5 simulations per scenario, varying just one parameter at a time; the remaining parameters did not vary between simulations. We have chosen to stop the simulation at 500 cycles in order to avoid waiting until all fires have been extinguished. We examined how the number of BDI agents and reactive agents affect the model performance for both the 2D and 3D model. We have chosen Civilian agents to represent BDI agents and Fire agents to represent the reactive agents in the model comparison.

Table 1. Simulation Experiments

	2D model	3D model
Scenario 1	20 Civilians & 5 Fires	20 Civilians & 5 Fires
Scenario 2	100 Civilians & 5 Fires	100 Civilians & 5 Fires
Scenario 3	20 Civilians & 100 Fires	20 Civilians & 100 Fires

Figure 6 shows the probability density function of the simulation duration for the different scenarios in Table 1. We verified the effect of increasing the number of reactive agents (from 5 Fires to 100 Fires) by comparing the processing times in 2D model Scenario 1 (the green bell on Figure 6) and Scenario 3 (ocher bell) (t-test p-value = 0.26 > 0.05) as well as in the 3D model Scenario 1 (pink bell) and Scenario 3 (blue bell) (t-test p-value = 0.21 > 0.05). We can see from t-test results, that that is no significant difference in processing times for 2D and 3D models when we increase the number of reactive agents (Fires). We have then verified the effect of increasing the number of BDI agents (from 20 civilian to 100 civilian) by comparing the Scenario 1 (green bell for 2D; pink for 3D) and Scenario 2 (orange bell for 2D; cyan for 3D) and we found that there is significant difference in the processing times (2D model t-test p-value = 0.00003 < 0.05; 3D model t-test p-value = 0.0002< 0.05). We have compared Scenario 1, 2, 3 for 2D and 3D model, and we have found a significant difference in processing times between both models, indicating that GIS data display and processing is time consuming.

[7] A method that is called each simulation step

CONCLUSION

The goal of our work was to present a unified framework for modelling a complex crisis situation such as the human behaviours and interactions in bushfires. We proposed agent-based model including BDI cognitive modelling combined with the FIPA standard for communications, and a GIS for modelling a realistic environment which to our knowledge has not yet been done before. We described how we built our conceptual model using UML and TDF and how the model was implemented using the GAMA agent-based platform. We also demonstrated the flexibility of our model showing that the same agents' implementation can be represented in a 2D simple model or a 3D GIS model. The preliminary results showed that a 3D GIS model takes significantly more processing time than the 2D simplified model and that increasing the number of BDI agents also significantly affects the processing time. This constrains the modeller to make a fair trade off between the model complexity and realism in the agent's design. In this paper, we have presented the first preliminary results and in the future work we need to do internal and external validation of the model.

In future work, we will explore the model's parameters space and perform a sensitivity analysis. The model will then be validated by comparing the model's results to the statistical observations reported by (Teague et al., 2009). Once the model is validated, we would like to examine different scenarios. For example, to assess the Australian and French firefighter strategies in different fire configurations (e.g. concentration of the fire at one location/more locations and in function of the distance between fires) in order to determine which strategy is more appropriated to which scenario. We can also test different emergency manager strategies for the management of the available firefighters (e.g. is it better to extinguish first fires with big fire spread or with big intensity?) or for the police locations (at which road location, the police will inform more civilian about the fire situation). This realistic model will allow emergency managers and stakeholders to get valid results transferable to real life situations. We then wish to modify the model into a serious game for emergency situation training.

ACKNOWLEDGMENTS

This research was funded by the University Grenoble-Alpes through AGIR project SWIFT (2016-2019). We would like to thank Patrick Taillandier for providing us a GAMA script for GIS data processing and Jérémie Glossy for participating in the GIS data processing.

ABSTRACT

Crowd simulation is suitable to evaluate evacuation strategies but its validity strongly depends on the quality of input data. The acquisition of adequate input data is particularly challenging when simulating the evacuation of public buildings such as universities. As they are publicly accessible, the exact number of persons on site is unknown. Yet, to investigate specific emergency situations by means of simulation, e.g. amok or fire, information is required about distribution and amount of people within the building at a specific point of time. Due to data privacy, public buildings do not implement access control. However, data artifacts are available in various information systems, e.g., wifi data, room administration. Our hypothesis is, that the acquisition and fusion of such data artifacts is sufficient to enable data-based ad-hoc simulation of evacuation scenarios as decision support for the operations management. To this end, we introduce a procedure for the situation-dependent collection fusion of simulation input data. Furthermore, a case study is provided to demonstrate the feasibility of the approach.

Keywords

Evacuation of Public Buildings, Data Fusion, Data Aggregation, Crowd Simulation, Social Simulation

INTRODUCTION

In case of emergency situations, the evacuation of a large crowd of people is a sophisticated task for fire and rescue services as different strategies must be applied depending on the specific situation. To support the operation of rescue forces, crowd simulation is an established tool for the ex-ante evaluation of strategies. It allows for the objective measurement and comparison of different scenarios. Thus, crowd simulation gains importance for the planning of major events such as festivals or sport events but also for the construction of stadiums, arenas, or travel centers.

Compared to this, the evacuation of public buildings such as town halls, hospitals, and universities is more challenging. These buildings are publicly accessible, they usually do not require physical access control, and the quantity as well as the distribution of visitors, patients, and employees within the building is dynamic as well as unknown. In practice, additional time is required by police, fire, and rescue services to get an overview of these locations. Information regarding the current room utilization must be provided by the management of the institution. Yet, as the quantity and distribution of persons in public buildings is not documented, people in charge at the institution cannot provide the required details such that information for rescue forces is insufficient. The resulting delay of rescue operations can have serious negative effects on the safety and well-being of people staying in the building.

*corresponding author
†http://cirt.uni-trier.de and http://wi1.uni-trier.de

From the perspective of institution's management, the problem is missing information within the decision-making. A lot of data that can be used for gaining a first impression of the current situation is electronically available in different organizational units (e.g., room planning, human resources, or IT department). Yet, it remains unused as it cannot be directly accessed and utilized in this situation. Information is distributed over and stored in different information systems. This heterogeneity of data is as much a challenge as the variability of the interfaces of the systems. With respect to technical gaps or legal contexts, e.g. data privacy, these information systems cannot be accessed centrally.

To overcome this lack of information and to facilitate the planning and execution of rescue operations, this paper aims at identifying, acquiring, and aggregating data sources. Our hypothesis is, that the use of such data enables ad-hoc simulation for decision-support within emergency situation. Therefore, we introduce an innovative approach to estimate the amount of people within public buildings by acquiring and aggregating data from available information systems. We demonstrate the feasibility in context of a case study at Trier University.

The paper is structured as follows: first we present the foundations of crowd simulation and data fusion. Then data acquisition challenges of simulating evacuation scenarios in public buildings are outlined. Finally, a case study illustrates how these challenges can be addressed using the example of Trier University.

BACKGROUND

For the planning of buildings and events as well as for the evaluation of evacuation strategies, crowd simulation is increasingly used, e.g., for evacuation planning of football stadiums (Bateman and Majumdar 2018). Advantages over conventional methods such as investigating flows of individuals using real persons or expert assessments are, among other things, that no people are endangered and that simulations can be repeated as often as required under controlled conditions. This enables the testing of a large number of different scenarios while decreasing costs. Various elements such as global and local route planning, local collision avoidance, behavioral modeling such as integration of personalities, stress or emotions, and movement generation are implemented in crowd simulations (Narain et al. 2009). In many models, the relevance and characteristics of these components differ significantly. Two basic types of models can be distinguished: *Macroscopic* and *Microscopic Models*. Macroscopic approaches consider the crowd as a whole, which offers great computational advantages especially for large crowds. The crowd's behavior is not attributed to specific individuals with their possible and own unique behavior. However, this results in a lack of realism, as individual behavior exists in crowds. Microscopic models, e.g. agent-based social simulation models, aim at precisely reproducing each individual's behavior (Lorig and Timm 2014). Due to increasing computing capacities, these microscopic models are more and more applied and research activities in this field predominate. There is, for example, research on social cohesion (Adam et al. 2019), emotional contagion (Xu et al. 2018), or social capacity of the actor (Valette et al. 2018) in crowd simulations. These factors can influence evacuation behavior, e.g. social cohesion helps to evacuate individuals who would otherwise not be able to evacuate on their own. Another advantage of the increase in computing capacities is that simulation is increasingly used not only to validate security concepts but also as real-time simulation, e.g. Löhner et al. 2018. In this way, simulation can be used as decision support system. Especially in dynamic environments, such as public buildings, this can be useful as not all potential scenarios can be simulated due to their amount. Nevertheless, limitations due to computing capacity may still occur. To this end, so-called *Hybrid Models* are used that combine aspects of both model types such as a parallelization approach to calculate particularly large crowds (Yu et al. 2015). Further details on different models of crowd simulation can be found in the surveys of Pelechano et al. 2008, Zhan et al. 2008, Thalmann and Musse 2013, Ijaz et al. 2015, among others.

Due to the distinctive research in the field of crowd simulation, there is a high quality in behavior generation of actors. However, the models' validity as well as the results' transferability to reality strongly depend on the quality of input data, e.g., the number and the exact position of the persons on site. As a result of insufficient data validity, the operational validity is also low, i.e., the accuracy of the transfer of the results into the problem domain (Sargent 1991). For this reason, there are studies that deal with the use of data from the Global Positioning System (GPS) in real-time simulations (Wirz et al. 2012) and also consider the significance of errors (Zhang et al. 2019). One approach that has been neglected in research in the context of data collection for pedestrian flow simulations so far is the use of several data sources to compensate for missing data and errors. In sensor networks and distributed information systems, data fusion is a common instrument to compensate discrepancies between different sensors and to fill gaps in individual sensors by integrating and aggregating different data sources. The basic principle for this is that intersections exist in the informative value among the individual sensors, which are exploited by many methods and algorithms. For instance, similar approaches use methods such as Bayesian Inference, Dempster-Shafer Inference or Fuzzy Logic (Nakamura et al. 2007). Further methods are presented by Dong and Naumann 2009 as well as in the surveys of Smith and Singh 2006, El Faouzi et al. 2011 and Castanedo 2013. They can also be

transferred from their application context to the given scenario. A similar and widespread approach is the visual evaluation of crowd video material by neural networks to derive behavioral rules of individuals for behavioral prediction in real time (Wei et al. 2018; Bera et al. 2015). These are also data fusion methods, which are not used to increase the validity of the data but to increase model validity.

Summarizing, there is increasing research on crowd simulations but the acquisition of input data is not considered thoroughly even though the simulations' validity depends on input data. Therefore, this paper addresses this research gap by proposing a process for the identification of appropriate heterogeneous data sources as well as fusion of data to simulate crowds in public buildings.

PROCESS OF SIMULATING EVACUATION SCENARIOS IN PUBLIC BUILDINGS

This section proposes a process for simulating evacuation scenarios in public buildings regarding heterogeneous data sources. The process consists of three sub-processes, which shown in Figure 1. It is related to the *JDL Data Fusion Model*, which consists of five levels: *Level 0 - Sub-Object Data Assessment, Level 1 - Object Assessment, Level 2 - Situation Assessment, Level 3 - Impact Assessment, Level 4 - Process Refinement* (Steinberg et al. 2008). In this section, challenges and methods related to identification of data sources, data fusion, and agent-based simulation are outlined in detail.

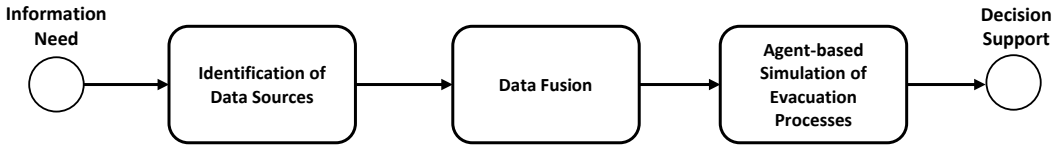

Figure 1. Identified Subprocesses for Using Heterogeneous Data Sources for the Simulation of Evacuation Scenarios

Identification of Data Sources

In a first step, which corresponds to Level 0 of the *JDL Data Fusion Model*, relevant data sources for the subsequent data fusion are identified. This subprocess is necessary because publicly accessible service institutions usually have numerous information systems which either do not provide any information gain or to which direct access is not permitted for legal reasons, e.g., accounting systems. Therefore, the targeted identification and selection of information sources ensure that a sufficient amount of information is recorded.

The process addresses two aspects: First, the emergency services' requirements on information and data quality are identified. Secondly, we outline how the consideration of the structure of the system landscape can positively influence the selection of data sources.

It must be ensured that data sources generate not only data but a **gain in information** which arises when a decision maker, e.g., the police, benefits from the knowledge of this data. However, this presupposes that the user has contextual information and that data is correct as well as not manipulated. In the context of special threat situations, the information requirement of the emergency forces contains two aspects: the evaluation of the threat situation on the one hand, as well as an estimation of when, where, and how many people with which characteristics are present in the area to be evacuated on the other hand (Vreugdenhil et al. 2015). If the number and location of people in the building is known, rescue and evacuation measures can be initiated more quickly and in a more targeted manner.

The second aspect tackles the influence of the **structure of the system landscape** on the selection of data sources. Most of the system landscapes in a building of public services can be characterized by a high degree of network connectivity and interdependencies. The result is that similar or even redundant data is recorded in different systems. For example, if a documentation system depends on the availability of an Internet connection, it could be sufficient and possibly more convenient to monitor Internet access alone, since both systems offer conclusions about the same information gain, i.e., the number of people on site.

However, aggregating more or less redundant data sources can also be advantageous as described in the following subsection. The decision to integrate a system with intersections of information into an already integrated system depends on the information gain generated by the integration of the new system. It is possible to end up with one system that contains a sufficient amount of relevant information but this probably depends on the homogeneity of people and the way they use information systems. In a public building, people are more likely to show heterogeneous usage patterns, suggesting that one data source is not sufficient. It is therefore necessary to aggregate data.

Data Fusion

After identifying relevant and useful data sources, data is usually not yet usable in the application context. Even if data is prepared for technical reasons, e.g., interface preparation, inconsistencies between different data sources can occur and gaps in the database are frequent. Therefore, data fusion aims at the homogenization of data by using several data sources, which probably increases the overall quality of data. This process corresponds to levels 1 to 3 of the *JDL Data Fusion Model*. Data fusion merges the data to avoid inconsistencies and gaps and make the data more accurate and useful. The fact that data from different systems originates from the system landscape of a service of general interest means that it may be available in different formats and that different strategies are pursued to collect measurement data, e.g., cyclic and acyclic measurement. Therefore, we need this process to ensure a basic applicability of the data.

Depending on the information and its source, different forms of information fusion can be classified, which also apply to data fusion: *Complementary, redundant, and cooperative fusion* (Durrant-Whyte 1988). Complementary fusion is characterized by the fact that a composite data image is generated from different information sources. Redundant fusion brings together data sources that basically describe the same information. However, since inconsistencies or gaps may exist in both data sources, the redundant fusion achieves a higher data quality. Cooperative fusion describes the process by which new information is generated by deduction during the merging of information of different data sources. The problem in practice is that the quality of data sources or information is often unknown. Particularly in redundant fusion, it is uncertain which data sources has a higher quality as well as information content and should therefore dominate during calculating the data. In the application context of threat situations in public buildings, it can be assumed that the information systems chosen as information sources diverge to a certain extent from actual reality. The uncertainty is therefore even greater than in a classical Wireless Sensor Network (WSN). For this reason, an empirical study is essential to value the quality of data and it is necessary to differentiate between types of data, the measurement method of the data, and the temporal as well as spatial dimension. This results in three classes of problems which have to be considered in the given application context:

1. the discrepancy between the measurement and planning data of the information systems and the real situation,
2. the discrepancy between the measurement time of the information system and the specific simulation time, as well as
3. the estimation of an exact geo-localization of individuals in the building.

The first problem is, that a certain discrepancy can be assumed between the measurement and planning data of the information systems and the real situation (1). For instance, during the work process in an administrative office for citizens, the system which measures the number of employees logged on to an information system may differ from the real number of people on site, as not all employees necessarily have to use this system for their work or several employees have different logins to this system. Furthermore, visitors can be counted in this public office by measuring the visit dates in the calendars of the employees. However, the number of visitors on site can deviate from this as on the one hand visitors may skip an appointment and on the other hand they may appear without an appointment. Simultaneously, there is an uncertainty whether the information of different data sources is complementary or redundant. Possible double counts can create a discrepancy between measurements and reality.

The second challenge is that there may be a discrepancy between the measurement time of the information system and the specific simulation time (2). This challenge can be divided into three aspects: First of all, with period-related data, a conclusion must be drawn about the time of simulation. For example, visitors to the administrative office for citizens can be late for an appointment. Secondly, in rare cases, measurements are collected continuously. Mainly, these are discrete measurements that are carried out in a certain time interval. In the above example of the registrations of the employees of the public office at an information system, if the data are collected in a cycle of 15 minutes, an interpolation must be carried out to determine the data of a simulation time, which lays between the collection of times. Finally, a measured time or information at a time (planning data) can have an effect on pre- or post-states. If a visitor of the public office has an appointment with an employee, he or she may be in the building long before the appointment, e.g., to be on time, or still be in the building after the appointment, e.g., to complete documents.

The third class of problems is that with many systems, especially in combination with the second category, an exact geo-localization cannot be carried out (3). If an employee of the administrative office logs in at a wifi access point, this person can be in the entire transmission area of the access point. During appointments, employees and visitors can be located anywhere in the specified room. This may be irrelevant for small rooms with a few people present but in large rooms with a large number of people present this can seriously effect an evacuation event. However,

observations and other knowledge can be used, e.g., queues or explicit waiting and sitting areas where people are more likely to stay.

We believe that all three problem classes can be addressed by methods of data fusion. Established methods like heuristics and Machine Learning mentioned in Section 2 will be used to remove gaps and inconsistencies. However, both aspects require a reliable evidence about real data, which is why an empirical data collection is essential to determine the error probabilities and to adapt the measured data to the real data. The overall aim of the data fusion's synergistic multiple use of different information sources is to produce more accurate and consistent data than could be produced by any single data source alone. This has to base on the measurement and planning data.

Agent-based Simulation of Evacuation Processes

Once data has been aggregated and adapted to the state of reality, an agent-based simulation of an evacuation process can be carried out, which corresponds to level 4 of the *JDL Data Fusion Model*. This sub-process is recommended because it allows us to react objectively to the numerous possible scenarios that can occur in buildings with high dynamics. It assumes that a model of the public building to be investigated exists in crowd simulation software. Usually respective simulators allow for the execution of a number of simulation experiments with systematic parameter combinations. By varying a large number of parameters, the best evacuation strategy can be determined without performing experiments within the real system.

Summarizing, the process of simulating evacuation scenarios in public building regarding heterogeneous data sources consist of three sub-processes: During identification of data sources, it must be ensured that there is a gain in information by integrating systems, whereby the structure of the system landscape can be regarded. In the sub-process of data fusion there are three main problem classes which have to be handled to generate consistent and accurate data. By using this data, the the validity of the crowd simulation can be increased. The applicability of the proposed methodology is demonstrated in the following case study.

CASE STUDY

On 24th November 2017, a student of Trier University threatened to use armed violence on the campus. Although police was able to identify and arrest the student at an early stage, they carried out an extensive intervention at the university and cordoned off the campus. At that time it was not certain whether possible accomplices existed or whether hazardous material or weapons were already on the campus. The campus of Trier University is characterized by its wide accessibility, since there are entrances in all directions. This implies that situation assessments take a great amount of time and that decision makers in special situations can only plan and carry out a necessary evacuation after a delay. Ultimately, the specific threat was not confirmed at Trier University but the incident has revealed exactly such delays. Therefore, there is still a lot of potential in the aggregation of information, especially since the information was actually available in various systems. The following case study is carried out using the example of Trier University respecting the specific described challenges. Its purpose is to show the applicability of our process using heterogeneous data sources for the simulation of evacuation scenarios in public buildings. Our study is initially limited to one building, which, however, has a particularly high dynamic in the number of persons on site. It contains the largest lecture hall of the university, the Auditorium Maximum, with over 500 seats, and the main canteen on campus (see Figure 2). The building has entrances and exits in all directions and the canteen consists of three open floors.

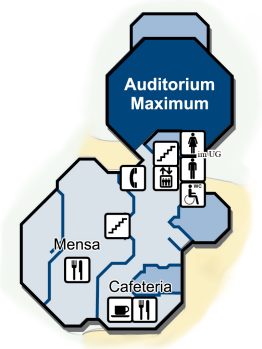

Figure 2. Site plan Auditorium Maximum and canteen (Floor 1)

Data Sources

In a first step, relevant data sources are identified to satisfy the need for information regarding the location of persons at specific points in time. We identify three useful data sources: the integrated campus management system of Trier University (**PORTA**), the **wifi access points**, and the **canteen cash system**.

PORTA provides information on events at the university's facilities. Each room has a capacity of seats and a list of events, e.g. lectures, taking place in the room. Participant lists exist for the events, since online registration is mandatory for participants to take part in a lecture or event. By using the PORTA system, conclusions can be drawn about the future planned occupancy of the Auditorium Maximum. Deviations from this plan can occur, for example, due to the short-term cancellation of an event or the absence of registered attendees.

Another source of information is the number of registered devices that are connected to a **wifi access point**. This is logged by the university's IT department. Each student and employee receives an ID which they can use to access the university-wide wifi. The SSID of all access points is identical, which guarantees a login at the best transmitting access point (probably the closest one). There are currently four access points in the selected building: two in the Auditorium Maximum (AP03 + AP04), one in the foyer area of the building (AP02), and one in the canteen (AP01). A further access point in the Mensa will be installed soon. Figure 3 shows an example of a day with wifi use in the corresponding building. The increasing number of registered devices at the access point at lunchtime (middle of the diagram) is obvious. It is characteristic of the two access points in the Audimax that the number of registered devices is relatively stable over the period of the lectures. The rapid rises and falls in the number of registered devices correspond to the times when the lectures begin and end. Between these events there are peaks of the access point in the foyer area, where most students enter and leave the building for visiting lectures.

Since the canteen also sells food to people who do not belong to the university, there may also be people on site who have not yet been registered by the two sources of information mentioned above. For this reason, the **canteen cash system**, which logs every meal sold, is also a relevant source of information to be used in the case study. A customer group, e.g. students or guests, is logged for each purchased meal, which is helpful for the subsequent data fusion process.

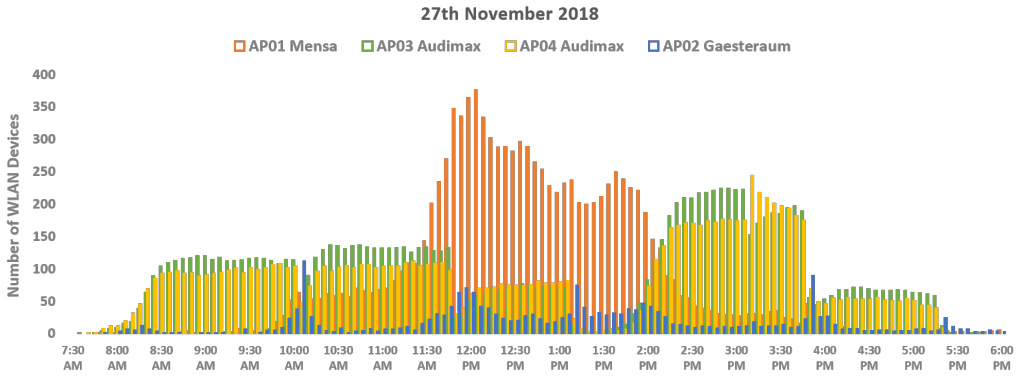

Figure 3. Number of devices logged at wifi access points

Data Fusion

Classical applications of the data fusion process can often determine the actual form of the information. Redundant fusion generates a sufficiently accurate measure that is often sufficient in practice. The given application case differs from these classical redundant fusion systems in that highly heterogeneous data sources are available and the problem classes described above occur simultaneously (cf. Sec. 3.2):

The first problem is that there may be a certain discrepancy between the measured as well as the planning data and reality (1). For example, if a system measures the number of registered devices at a wifi access point, this does not necessarily correspond to the actual number of people in the area of the access point. On the one hand, there may be people who are not logged in with a wifi-enabled device. On the other hand, persons may own more than one mobile device with which they are logged in. Furthermore, in the case of a system that documents student registrations for courses the number of students on site may differ significantly from the number of registered students. The question arises what is the real situation, since the examples show that both systematic overfitting and systematic underfitting are possible. Simultaneously, it is difficult to determine whether data is more redundant or complementary. For instance, double counts by logon to wifi and purchase of a meal are possible. Due to the

heterogeneity of the data and the lack of knowledge of the probability of errors in the data, it is not possible to approximate the most probable real state. For this reason, empirical surveys were carried out at various times during the semester in which the number of persons on site and the number of wifi devices used per person were counted. This data serves as fixed points (training data) to implement a valid approximation, e.g. by using neural networks to predict the real situation. Currently, we cannot assess the success of overcoming this problem. Nevertheless, both redundancy and complementarity allow us to limit the possible variable space by a lower bound (full redundancy) and an upper bound (full complementarity), which should be very helpful in the subsequent simulation experiments.

The second challenge is that there may be a discrepancy between the measurement time and the specific simulation time (2). As explained in Section 3, this challenge has three aspects, which are explained below: First, the PORTA data source is a period-related data source. Conclusion about a specific point in time can be subject to certain patterns. For example, it is possible that students regularly arrive too late for an event. These patterns can be detected using wifi data. Furthermore, the wifi data source represents an information source at a time measured in a cycle of 5 minutes. If the time to be simulated is not exactly such a measurement time, an approximation must be made, which can be done by interpolating the two adjacent measurement times. Finally, the information source of the food sold in the canteen has a time reference which, however, has a high impact on subsequent states. Thus, it can be assumed that a person who buys a meal in the canteen is highly likely to remain in the canteen for a specific period of time. The wifi data again helps to draw a conclusion from the time a meal was bought to the length of stay in the canteen.

The third problem is how to deduce the exact geolocation from the data collected (3). When logging on to the wifi, the person with the mobile device can be in the entire coverage area of the network. In room reservation plans, the registered number of persons can also be in the entire room. This problem is particularly serious because small deviations from reality can have fatal consequences in the evacuation process. We meet this challenge by dividing the area inside the building into zones. Using the wifi data, the PORTA data and an empirical survey of agglomerations, we suggest that specific zones are likely to be occupied.

At the end of the data fusion process, the fused and approximated data is provided in an SQL database to be accessible to decision makers from multiple systems, such as a dashboard. The completely fused data as well as the adjusted data of different data sources can be retrieved in separate tables. This ensures flexibility in the use of the data. Figure 4 summarizes the data fusion process of the three chosen data sources considering their specific interdependencies.

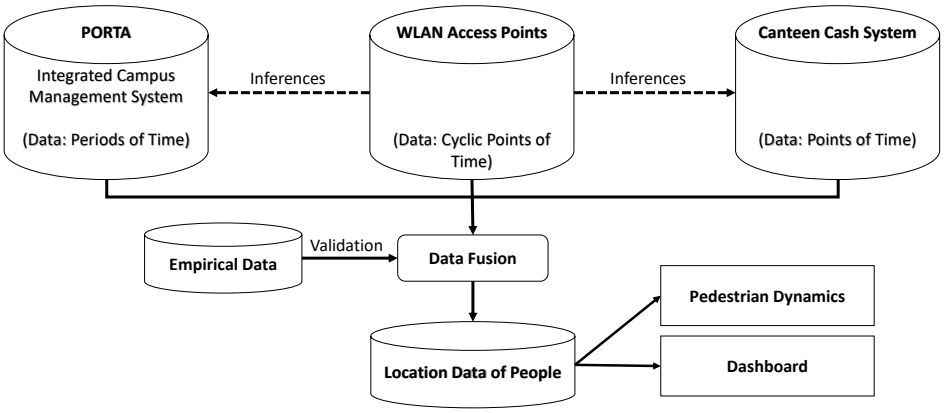

Figure 4. Used data sources for generating inferences

Evacuation Processes at Trier University

Even if a dashboard should be very useful for decision makers in threat situations to get aware of the current situation, the main goal of data fusion of heterogeneous data sources at Trier University is conducting evacuation simulation studies with focus on the flow of involved persons. The model of the relevant parts of the campus was implemented using the *Pedestrian Dynamics* simulator by *INCONTROL*. Figure 5 shows parts of the models. The challenge so far has been where valid data comes from as simulation input. We are addressing this challenge by processing the data in the data fusion process. In this way, we can achieve situation-dependent decision support concerning evacuation strategies.

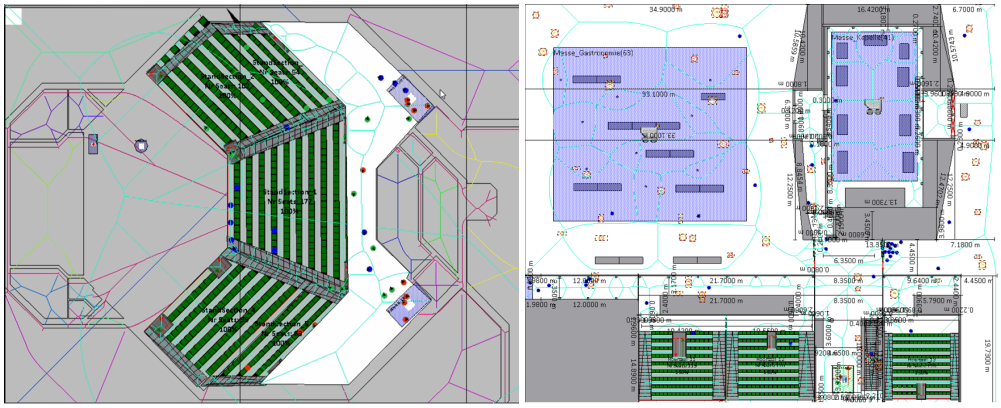

Figure 5. Pedestrian Dynamics models of Auditorium Maximum (left) and lecture halls (right) at Trier University

CONCLUSION AND FUTURE WORK

A lot of data required for gaining a first impression of the current situation in special threat situations is electronically available in different information system but remains unconsidered as it cannot be directly accessed and utilized. This paper proposes a process of the identification of appropriate heterogeneous data sources as well as the aggregation of data by means of data fusion. This process aims at supporting decision-making in emergency situations by using ad-hoc simulation of evacuation strategies. As a key aspect, we focus on increasing the quality of parametrization as well as the level of validity.

To evaluate this process a case study at Trier University is carried out. We identified and selected relevant data sources. Additionally, we built a simulation model of the campus in the software *Pedestrian Dynamics* for investigating evacuation scenarios. Currently, the necessary interfaces are being implemented to integrate the distributed available data into our workflow. In future work, we will elaborate on specific algorithmic approaches for the estimation of amount and distribution of individuals within public buildings. We will draw samples by manual people counting in our case study. Additionally, the agent representation should be extended by emotional and cognitive behavior such that realistic crowd behavior emerges.

ACKNOWLEDGMENTS

The authors would like to thank the research assistants Kira Huneke and Fabian Mirz for their substantial contribution to this research. Furthermore, the authors are thankful to the Studierendenwerk Trier (canteen) and the University's IT department (ZIMK) for providing data and information as well as to the administration of Trier University for financial support to this study.

ABSTRACT

This paper discusses the development of the CEM-DIT (Communication in Emergency Management through Data Integration and Trust) system, which allows decision makers in crises to send out automated data requests to multiple heterogeneous and potentially unknown sources and interactively determine how reliable, relevant and trustworthy the responses are. We describe the underlying technology, which is based partially on data integration and matching, and partly on utilisation of provenance data. We describe our cooperation with the Urban Observatory (UO), which allows us to develop the system in collaboration with developers of the kind of crisis-relevant data which the system is designed for. The system is currently in development, and we describe which parts are fully implemented and which are currently being developed.

Keywords

Provenance, Data matching, Data integration, Semantic web systems, Decision support

INTRODUCTION

It is well understood that responses to crises are often hampered by the inability to share data quickly and efficiently. Living in a world of data means not only that huge data sources are available but also that huge numbers of different data sources exist, many of which may contain data that is relevant to any given situation. But these data sources are generally heterogeneous, may be hard to understand and derive from a wide variety of sources, some of which may be unknown and/or untrusted. The traditional approach to data exchange during crisis management - largely through direct human interaction - is simply unable to access and process these data sources in depth, which can mean that important and relevant pieces of information are unavailable to decision makers at the crucial time. In order to make full use of all this data, automated and interactive intelligent systems are required to discover, filter, interpret and annotate potentially relevant data for efficient and effective consumption by decision makers. The fact that such

*corresponding author

systems are not in place is a reflection of the difficulty of designing them. There are several technical difficulties around this problem; two pressing ones that require intelligent solutions are *(i)* How to deal with data heterogeneity? When data in different resources will use different terminology, different structure, different formats and so on, how can this data be made mutually comprehensible and how can decision makers understand how data from some source is relevant to what they want to know when it might appear very different? Secondly *(ii)* when data is derived from multiple sources, some of which are unknown, how can decision makers trust that data? How can they find out what they need to know about where the data comes from in order to be confident in making decisions based on it? It is crucial for decision makers that the data they receive is believable, can be trusted and is of an acceptable quality (Prat and Madnick 2008). Provenance provides transparency into the sources and processing history of the data (Alper et al. 2016).

In this paper, we describe the CEM-DIT system, which will allow decision makers to send out automated queries to multiple data sources, and interactively explore potential responses to their queries in order to determine whether or not the responses meet their requirements. The system is based on extensive work by the authors in data integration and in provenance, and focuses on integrating these two orthogonal issues into a unified system that priorities the autonomy of the decision makers to explore options and explanations and thereby to make decisions with confidence.

The theoretical underpinning of the system is well developed and the system already exists in part. However, full integration and design decisions remain to be done, and we present this work in progress to the ISCRAM community in the hope of getting feedback and interaction that will be helpful in guiding this process.

In the paper, we first outline the related work to show how our approach extends the state of the art. Next we describe the CEM-DIT system, and then describe the underlying technology in a little more detail. We describe our data-driven development and evaluation, and finally outline our next steps and conclude the paper.

RELATED WORK

In this section, we describe how the overall approach compares to other attempts to address the problem, and then explain how the underlying technology is particularly suitable for this task, and to describe the concept on which the system is based.

Data-driven decision making support

During crises, communication must be created and maintained between different organisations, as well as between organisations and the public. A considerable amount of humanitarian data is widely available, including open data, which can be of value to decision makers. However the data formats vary massively and single problem context requires identifying and extracting the relevant and meaningful parts from many systems for representation (Paulus et al. 2018)

Much current research focusses on communication between crisis management organisations and the public, on creating channels for communicating necessary information to the public and using information from crowdsourcing and social media to contribute to the success of emergency management (Freitas et al. 2016), (Ruiz-Zafra et al. 2014). Trust and provenance are significant issues in using such data. Interoperabilty is also recognised as a problem in communication between organisations (Fischer et al. 2016). There is a lack of suitably structured information (Rietjens et al. 2009), and when structured information exists the terminology, formats and structures vary between organisations. While there is work at an organisational level on creating co-operation between agencies, our work focuses on data interoperability between agencies at a semantic level, and on dynamic use of disparate data so that data sources not previously identified and integrated before runtime can be utilised.

Query Rewriting and Provenance

The CEM-DIT system is based on dynamic structural semantic query rewriting, as well as user-focussed provenance encapsulation and exploration. To the best of our knowledge there are no other approaches using failure-driven reasoning techniques combined with matching techniques to dynamically rewrite queries. Work by (Quesada Real et al. 2017) and (Shamoug et al. 2018) addresses the differences in the ways language is used in different organisations which make information sharing more complex. Ontologies offer an approach to linking the different terminologies within organisations and to represent explicitly both differences and similarities in the way that terms are used and understood (Galton and Worboys 2011; Burel et al. 2017). Ontologies have been used to support decision makers in crisis management in different organisations. (Burel et al. 2017) derives an ontological model to represent crises and demonstrates its use to support document sharing for crisis management. RESCUER (Simas et al. 2017) provides semantic interoperability in crisis management by applying ontology-based schema matching to integrate

crowdsourced data with more detailed data from pre-existing systems in command and control. Our approach is similar to that of RESCUER, but differs in that we use structured semantic matching in addition to ontology matching, which allows us to match not only the terminology but the structure of a query, and we apply them to query response rather than data integration.

Data provenance is a structured form of metadata designed to records the activities and datasets involved in data production, as well as their dependency relationships. The PROV data model (Moreau et al. 2013), released by the W3C in 2013, defines a schema and constraints that together provide a structural and semantic foundation for provenance. This enables the interoperable exchange of provenance between data producers and consumers. In addition to containing references to data generation or transformation processes, a *provenance trace* typically includes input or intermediate data products as well as references to *agents*, that is the humans or software systems who were responsible for enacting those processes. In multi-party collaboration settings that involve data sharing, as well as in third party auditing of data and processes, there is a broad expectation that shipping the available provenance to collaborators, or more generally publishing it along with the data, may help data consumers, including auditors, form judgments regarding the reliability of the data itself.

There is however a tension between the potential for using provenance to establish data reliability, and its complexity. Provenance-aware information systems are equipped with provenance-capture capabilities, which in many cases allow fine-grained, detailed provenance traces to be collected automatically by the underlying system, cf. (Gehani and Tariq 2011). Provenance that is collected about high-level processes such as workflows is less detailed, but still not suitable to be understood by humans, especially decision makers on the receiving end of query results, who are not familiar with the systems that generated the data in the first place. For the same reason, it is not reasonable to assume that the same decision makers will be able to query the provenance in order to extract its expected value. it is therefore necessary to simplify the provenance content in order to make it understandable by these users. At Newcastle we have addressed this problem in the context of selective disclosure of provenance, i.e., when provenance that is exchanged between parties with limited mutual trust needs to be partially *obfuscated* (Missier et al. 2014). In this work we adopt a similar approach and reuse some of the same ideas, namely to create views over the raw provenance trace, this time with the aim to support interactive exploration of complex provenance graphs by decision makers.

The CEM-DIT system not only utilising this matching and provenance technology, but in addition the integration of these technologies is unique. This allows us to create a system where a decision maker can not only access heterogeneous data from multiple disparate data sources, but can be provided with the tools to appropriate evaluate the data, and hence make well-justified decisions, addressing two crucial and orthogonal issues in data sharing.

AN INTEGRATED SYSTEM FOR DECISION MAKERS

In this section, we outline what the CEM-DIT system will ultimately look like, highlighting what is already in place and what remains to be done.

We illustrate CEM-DIT through a scenario in which there has been a major unexpected flood in the city centre. Emergency services want to enter the central area by the fastest route, while people and traffic are leaving by many routes. The emergency services need to know who is still in the area and to plan routes which are open and not obstructed by the flood or by people leaving. Traffic levels in some parts of the central area are routinely monitored by local traffic police using CCTV and electromechanical sensors. In addition, a new service is available which monitors traffic in some locations using satellite imagery. However this service is under development and is not fully integrated. These different sources of traffic data are offered in different locations by services using different formats and interfaces. The CCTV and satellite image data are automatically interpreted using image analysis software and complex machine learning algorithms. Data from different sources is not always available and new algorithms may not produce fully reliable data. The CEM-DIT system gathers, processes and returns potentially relevant data to the decision maker, together with the metadata necessary for the decision maker to make an informed decision. Figure 1 illustrates the workflow this involves.

STEP 1: Data is requested

The decision makers send out an automated query[1], written in a formal querying language. The query can either be sent out to a list of known data providers, or can be broadcast to anyone interested in responding.

In our running example, we consider a query in which the decision maker needs to know the traffic levels which have been recorded by each of the sensors in an area at a given time, with their identifiers and locations.

[1]This can be pre-written prior to interaction for predictable queries. For non-predictable queries, we are investigating systems that automatically generate formal queries from natural language text. In the meantime, non-predictable queries will require the presence of someone (the decision maker or someone else) who is able to create queries.

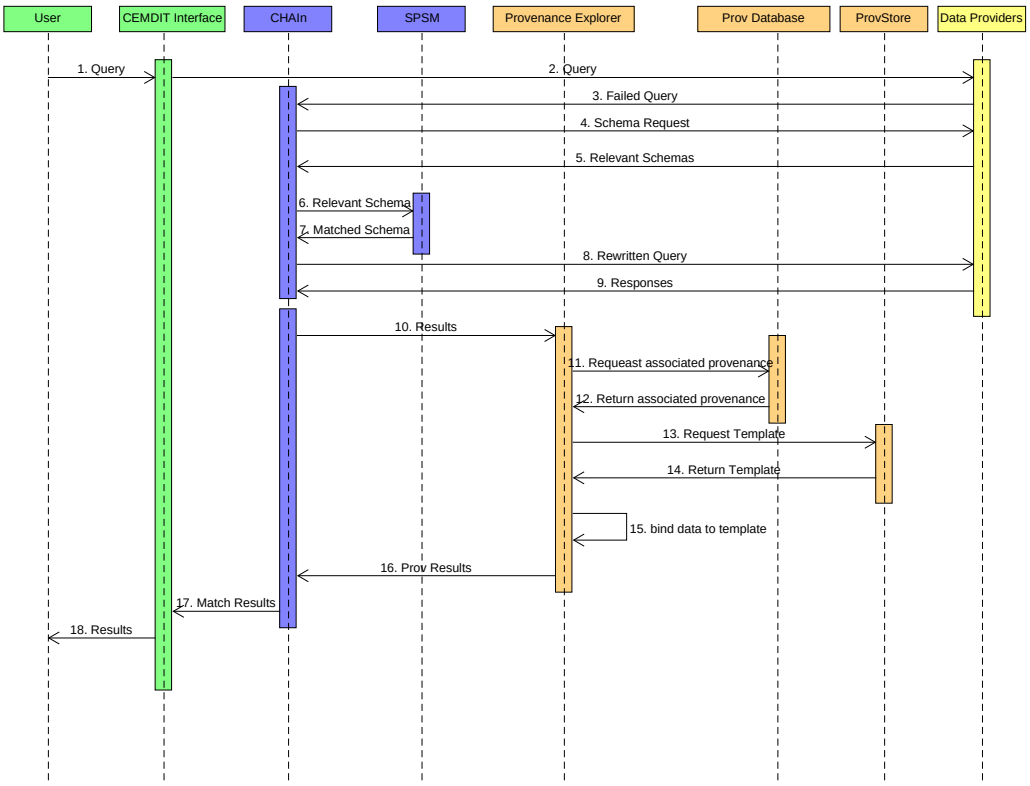

Figure 1. Sequence diagram showing the flow of data in the CEM-DIT system

STEP 2: CEM-DIT retrieves and sorts relevant data

- Multiple data sources receive the query. The query will be written according to a certain schema and will use certain terminology . Unless extensive pre-alignment has taken place, it is unlikely that the receiving data source will use precisely the same schema and/or terminology, and therefore the query will fail, even if there is data in the data source that is relevant. This is illustrated by the example query which initially involves six arguments in a given order, and talks about *latitude*, whereas relevant data sources may use the term *sensor centroid latitude* for a similar or identical concept, and may have additional or missing attributes. At this point, the CHAIn (Combining Heterogeneous Agencies' Information) matching system (McNeill et al. 2014) is initiated. It filters the data source for anything potentially relevant, and then perform detailed structural-semantic matching on potential candidates. This matching provides a map of how to rewrite the query in such a way that it is similar to the original query but capable of returning data from the data source. The process determines: 1) how similar, indicated by a score $S \in [0..1]$, the rewritten query is to the original query; b) what assumptions, rewritings and removals have been used to create the rewritten query. Any rewriting with a score S that passes a given threshold S_t is sent to the data source and the results returned to the CEM-DIT system.

- When the data is returned in response to the rewritten queries, it is annotated with any provenance data associated with it. This may be simple metadata such as the data source it came from and when it was generated, but may be much more complex - for example, complete pipelines which include applications and parameters that were used to produce the data. ProvExplorer is the part of the CEM-DIT system that extracts and visualises provenance.

  ProvExplorer requests access to the database that associates a query with locations where provenance is stored. The database also contains the ID of a provenance template which is stored in ProvStore[2].

STEP 3: Data is presented to the decision maker and evaluated

[2]ProvStore is a web service for storage of provenance documents (`https://openProvenance.org/store`)

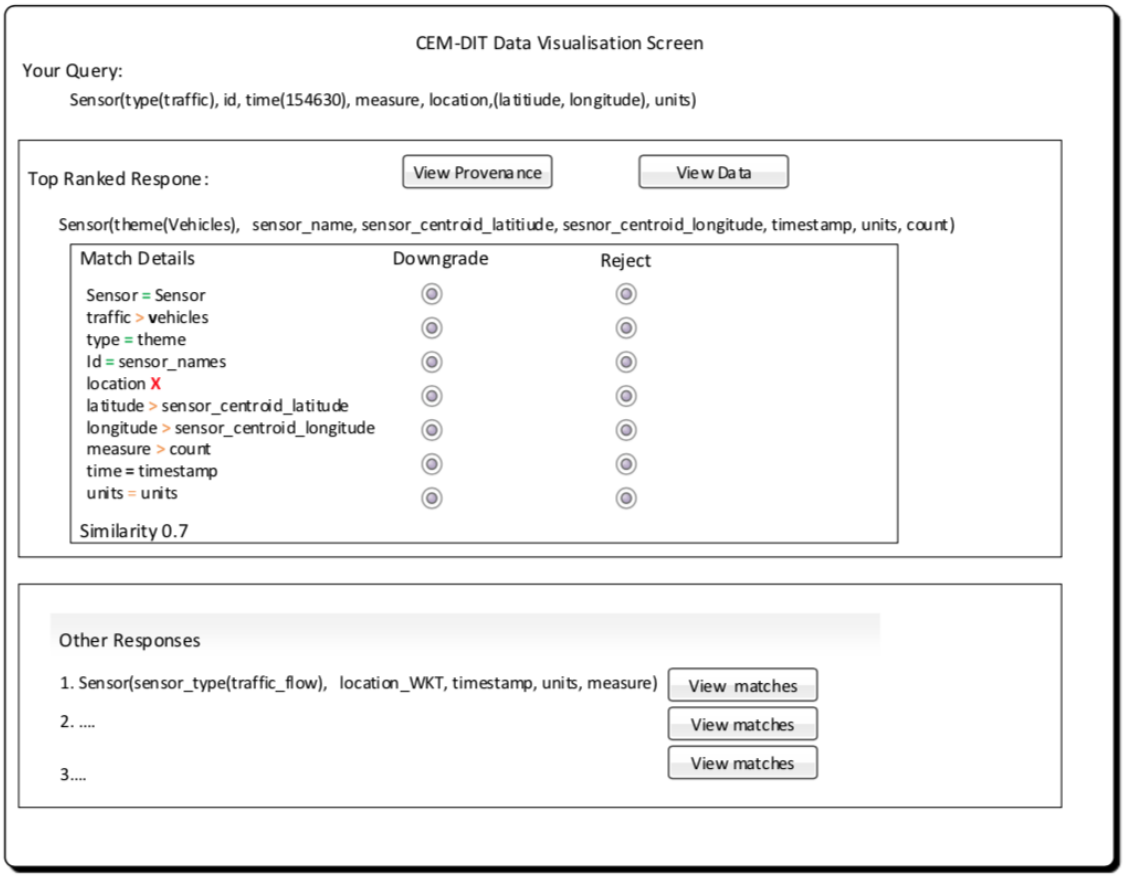

Figure 2. Mock up of a response screen for a query

The annotated responses are presented to the decision makers through the CEM-DIT system in a way that allows a decision maker to visually explore the potential responses. This step is currently under development. Here, we outline what the system is going to look like.

The CEM-DIT system presents the different options for query rewriting (if more than one passed the threshold) to the decision maker, clearly indicating where substitutions, approximations and non-matches have been made. Figure 2 shows a mock-up of the screen the decision maker would see after sending out the example query asking for data from sensors that are monitoring traffic at a given time stamp 154630. Although the query will have been sent to the data source in SQL or a similar querying language, it is presented to the decision maker as a first-order term, stripping out the querying language syntax, as this is easier for the decision maker to understand. The example query described in Step 1 will be rendered as follows:

sensor(type(traffic), id, time(154630), measure, location(latitude,longitude), units).

The schema of the top ranked response is shown, and a list of the matching of every aspect of the original query is given. The structural and semantic similarity between the top-scoring query and data source is reflected in the relatively high match similarity at 0.7. The score is lowered by differences in terminology and structure. For example, *traffic* and *measure* are more general terms than *vehicles* and *count*; a nested structure for *location* in the query is missing from the data source although its components (*latitude* and *longitude*) are both identified. Any components that are present in the data source but are not used in the query do not affect the match score. The decision maker can choose to downgrade or reject any of these matches, and if this is done it will cause all matches to be reranked, with all containing the unacceptable match either downgraded or removed from the list (depending on the type of downgrading chosen). Downgrading a match means penalising a particular aspect of it more heavily. For example, in the match details in Figure 2, we can see that a match *ID = sensor_names* is considered to be equivalent by the matching system, which means the match from the one to the other does not cost anything (i.e., reduce the overall similarity score), but the decision maker may consider that in this context they are related but not identical - hence choosing the 'downgrading' option - or that they are not related - hence choosing the 'reject' option. The former choice will add a cost to removing the match, and the latter will rule it out as a possibility, leading to a different (reduced) matching score. If this match also occurs in other schema matches, then similar alterations to the

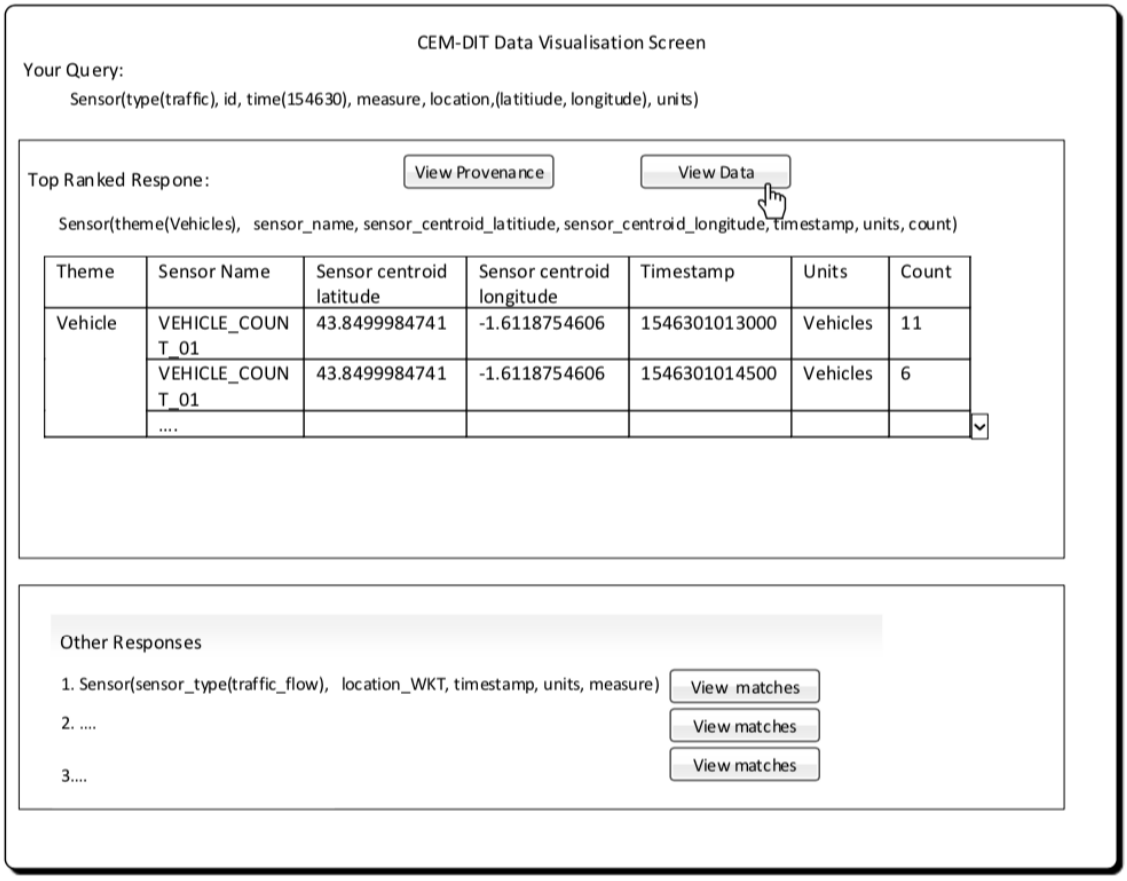

Figure 3. Mock up of data associated with the top-ranked response

cost will also occur in those matches, potentially leading to a reranking of the returned results. The decision maker can see the data associated with the top-ranked response by clicking on the *view data* button, as illustrated in Figure 3. The decision maker can also choose to view more detail about other matches lower down the ranking.

The decision maker can choose to view and explore the provenance associated with each aspect of the top schema. Initially a simplified provenance graph is presented, as illustrated in Figure 4. We can see some of the provenance of *count*, which is based on a model and an image. In order to feel confident of the data, the decision maker may then choose nodes in the provenance graph to explore further, to get more insight into how *count* is generated. Figure 5 illustrates the graph the decision maker would see if she expanded both *model* and *count* (this is shown outwith the CEM-DIT screen to improve readability). Any node highlighted in red can be expanded to expose more provenance data; for nodes that are not highlighted there is no more additional provenance data available. This additional provenance may be lacking either because data owners have not have recorded or stored full provenance for the data, or because they are unwilling to share all aspects of provenance for commercial or privacy reasons. If provenance data that the decision maker wants to see is not available, she can downgrade the match on that basis. As with the matching downgrades, in the finished system this information will be propagated to other matches, and any that do not contain essential provenance information will be removed.

Once the decision maker is confident that a particular result is acceptable from both a matching and a provenance point of view, she is able to accept it and the data attached to that result can be used, either automatically, interactively or by hand, in any decisions to be made.

This step is partially implemented. The key steps that are still to be implemented are outlined in the Next Steps section.

UNDERLYING TECHNOLOGIES

The core functionality of the CEM-DIT system depends on our work on provenance and on query repair. Here, we briefly explain these technologies.

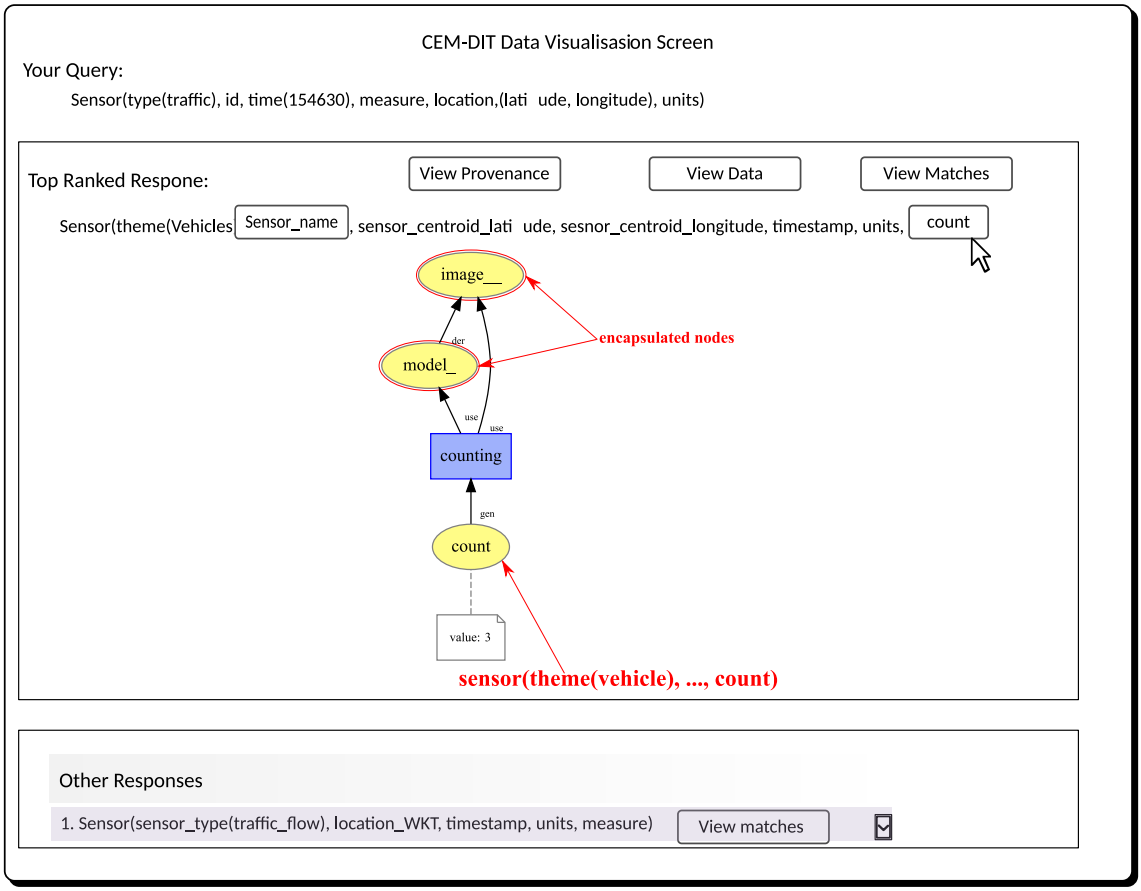

Figure 4. A simplified provenance model which is shown to the decision maker in the first instance. The original query is shown in red with an arrow pointing to the result for count.

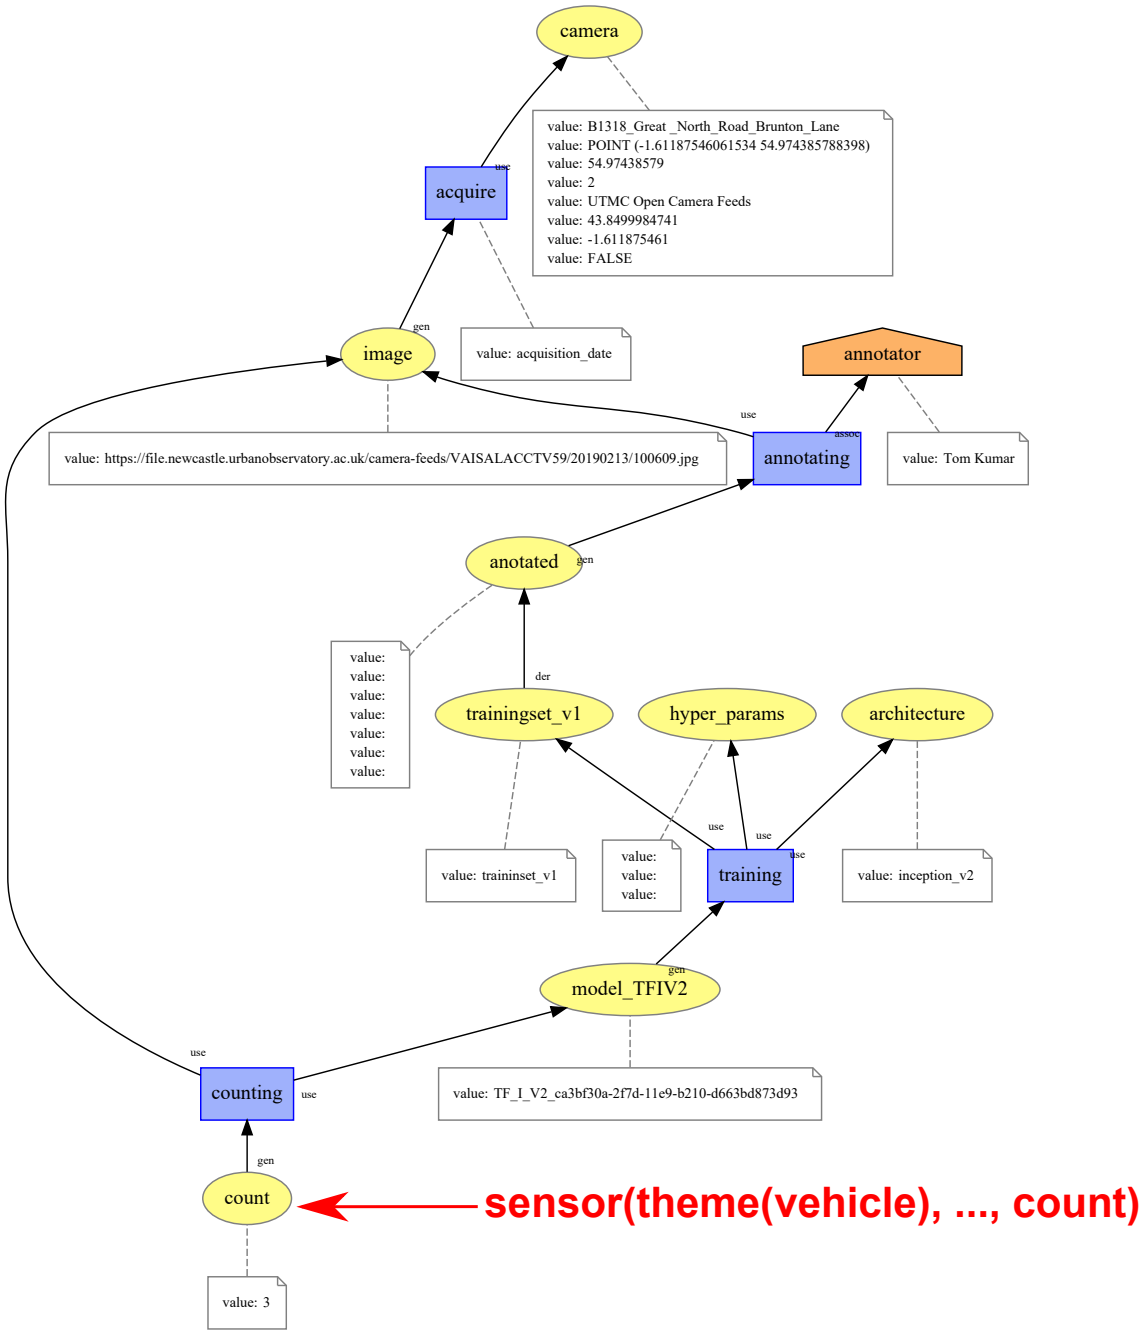

Figure 5. The provenance graph of all provenance retrieved for the results. Where 'value:' is shown, in the attributes, with no value, the provenance was not available.

ProvExplorer

Provenance can be provided as meta-data when queries are made. When provenance is not available directly with the data it may also be obtained from a separate provenance store which is maintained by the data provider or a third party such as ProvStore. By mapping the retrieved provenance to entities, activities and agents, according to the W3C provenance standards (https://www.w3.org/standards/techs/provenance#w3c_all), we are able to visualise it as a provenance graph. Such graphs can then be manipulated to encapsulate the provenance. To simplify and automate the process of adding and retrieving provenance for data obtained from queries we have developed an application, ProvExplorer, to serve as a workbench for the retrieval and exploration of provenance. The application is written in Java and makes use of the ProvToolbox API (Moreau 2019). ProvExplorer offers a GUI with a PROV-N (a human readable provenance notation) editor. The PROV-N can be viewed as a provenance graph. To encapsulate provenance data, operators can then be applied as policies.

The current system facilitates provenance users encapsulating (and thereby simplifying) their own provenance data. The potential to obfuscate (hide) provenance data will still be an important part of the process on the data owner's side, but the central focus of the system - that of providing relevant data to decision makers - requires the automation of graph simplification and the facility to expand simplified nodes as desired.

Query Repair

When a query fails, CHAIn uses structural semantic matching to repair the query with respect to the target data source and the queries are rewritten accordingly (McNeill et al. 2014; Giunchiglia et al. 2008). The matching part of the process is done by the SPSM algorithm (Giunchiglia et al. 2008), which performs pairwise matching of structured terms. SPSM combines structural matching with ontology-based matching, where existing ontologies and lexicons, such as SUMO (Niles and Pease 2001) and WordNet (Fellbaum 1998), as well as domain-specific ontologies where available, are used to determine how similar different words and terms are. Matching can usually be done in multiple ways and matches will rarely be perfect, so the similarity score is calculated to indicate the closeness of each match. For each match SPSM returns the similarity and a set of mappings between the different components of the two terms. The mappings are used to write a repaired version of the query which can be run on the datasource, and the repaired query, similarity score and mappings are returned.

SPSM is an expensive process, and it is not feasible to do it between a single query and every possible datasource. CHAin therefore performs a filtering step first, narrowing down the datasource schemas to a subset of likely candidates. Related terms are computed based on the SUMO and WordNet ontologies. In Figure 2 the schemas for the query and for the top ranked responses are all represented by the same predicate "sensor", and therefore these data schemas pass the narrow-down step and proceed to SPSM matching.

The schema-matching part of the process matches first-order terms: that is, terms of the form
$predicate(Arg, Arg, ..., Arg)$,
where each Arg may itself be a function. This process is therefore applicable to data formats that can be translated into this format. This is a very general format which includes a vast number of common representations. Currently, the CHAIn system can be used for SPARQL queries to RDF datasources and for SQL queries to RDB datasources, and may be extended to hierarchical and tabular structures such as JSON and spreadsheet tables.

DATA-DRIVEN DEVELOPMENT AND EVALUATION

It is important to develop the system with reference to plausible - ideally real - data that gives scope for both the matching and provenance side of the system. This allows us to base the development on plausible case studies and to carry out realistic evaluations on the resulting system. Currently, there is a paucity of data sources which contain deep, interesting provenance data. In part this is because tools to exploit that provenance are only now being developed. Fortunately, we have been able to work with the Newcastle Urban Observatory[3] (UO). The UO is an ongoing UKRIC project involving, among others, Newcastle University that provides the largest set of publicly available real time urban data in the UK. The Newcastle project covers city centre and the suburbs. More than 50 data types organised in 12 themes such as air quality, traffic, weather, are gathered from sensors across the city. A RESTful API is made available for developers allowing data to be downloaded in JSON or CSV format.

Although the UO does not address the issue of capturing provenance specifically, it does capture some data that can be used to verify the quality of data. As per our running example, we are working primarily with sensor data for sensors that are involved in counting cars and people. The process used for producing the counts make for an interesting pipeline for which the quality of data might be questioned by decision makers. For instance, a query can

[3] http://www.urbanobservatory.ac.uk/

be made for the number of cars that were detected by a sensor in a specific location at a specific time. Questions such as the following might come to mind when the results are retrieved:

1. How are these counts generated?
2. How are the counts affected by adverse weather and light conditions?
3. What happens if one car partially obscures another?

As well data as with good provenance data attached, we need data that comes from multiple similar data sources so that we can develop and evaluate the matching aspects of the system. The UO supports three different opportunities for data matching. First, there is some variability within the UO data sources. The UO gathers data from different sources. Sensors are of different types and similar data is returned from sensors provided by different services with varying data structures and semantics. In our use case information about traffic flow may be obtained from cameras, satellite images or electromechanical sensors, in different but possibly overlapping locations. Second, the generality of the CEM-DIT system can be tested by posing queries which are based on other city data sources such as NYC Open Data Repository[4], and attempting to repair these queries with CEM-DIT so that they run on UO data. Third, evaluation can be performed via synthetic queries which mimic the variability of real-life queries. We have developed a system, CRPTR for CHAIn, which takes queries which will run on an existing knowledge source and generates wide variety of plausibly corrupted queries. For evaluation we will create multiple corrupted queries and attempt to repair them with CEM-DIT so that they run on UO data.

Evaluation Aims

Evaluation for a system such as CEM-DIT is a tricky business. Ultimately, we want to ask the question *when decision makers are able to access a wide variety of data through the CEM-DIT system, and use the system to facilitate their understanding of and trust in this data, do they make better decisions than if they do not have access to such automated support tools?* Quite apart from determining how we evaluate 'better' decisions, direct access to decision makers in a simulated context that is meaningfully similar to a real crisis situation is expensive and difficult. It is essential that we carry out an evaluation that demonstrates the usability and value of the system before it is used in simulations with real responders.

Our concern at the moment is to evaluate two aspects of the system: (*i*) does the underlying technology provide results that are appropriate; (*ii*) does the system allow decision makers to interact with these results in a useful way.

- (*i*) Determining whether the results returned are appropriate means:
  - *are the matches returned relevant to the queries asked, and is the ranking a good reflection of the differing quality of the match?* Determining this is not straightforward as, in most cases, there is no gold standard against which we can judge our results, and there is some amount of subjectivity in assessing whether one rephrasing of a query is 'better' than another. There are various attempts in the matching community to create gold standards for evaluation, for example the Ontology Alignment Evaluation Initiative[5]. Whilst this initiative does not address the same matching problem as we are, we can use the test sets generated by this initiative to support evaluation. In addition, CRPTR for CHAIn corrupts data sets in a variety of ways to create plausible mismatched sets with a pre-existing gold standard, and hence facilitates evaluation.
  - *is the decision maker able to immediately access a simple version of the provenance data and then, if desired, use the system to access all the provenance information available?* Evaluating this is a much simpler prospect, requiring a definition of what an acceptable initial compression of the provenance data would be, and a demonstration that access to complete available provenance data was always possible.
- (*ii*) Since developing a sophisticated GUI that would be usable in the field is outside the scope of our current work, investigating the second point will involve getting decision makers who understand the data, and in particular the provenance, to give us feedback on the usability of the system.

We are currently working with the UO to develop a suitable evaluation scenario with multiple mismatched data sources and relevant accompanying provenance data generated.

[5] http://oaei.ontologymatching.org

NEXT STEPS

The majority of the underlying technology for the system described above is already implemented, but some steps remain of both theoretical development and implementation before the system described above is fully realised.

- **Extending the GUI to support the full functionality of the system.** The current project will include extending our existing GUI, which focusses on interaction with provenance data, to allow full visualisation of the matching data as illustrated in Figures 2 and 3. Creating a GUI suitable for use in the field is outside the scope of our current project but working closely with decision makers to understand the kind of interface they would need to use such a system is an essential part of bringing such technology to the field and something we intend to focus on in future.
- **Extension of the matching system to facilitate the dynamic reorganisation of matches based on user feedback.** The scoring algorithm of the matching system needs to be updated so that when matches are downgraded by the decision maker the downgrade is propagated to other relevant matches, and so that potential matches are removed automatically from the returned results list if they include aspects that decision makers have indicated are unacceptable.
- **Inverting the encapsulating functionality in the provenance system.** ProvExplorer has been designed as a tool for those who own provenance data to be able to control it, allowing them to encapsulate any parts they do not wish to view in detail. CEM-DIT requires this functionality to be inverted, as it requires a simple version of the provenance data to be presented to the user, with the ability to expand that as far as the user requires, or is possible.

CONCLUSIONS

In this paper, we introduced the CEM-DIT system, which is designed to support decision makers during crises by allowing them to easily access, understand and trust data from multiple heterogeneous data sources, which may be unknown and/or partially trusted. The theoretical underpinnings of the system and significant components of the implementation are in place, and we are currently working on the full implementation of the system.

ABSTRACT

This paper describes the design of an Internet of Things (IoT) system for building evacuation. There are two main design decisions for such systems: *i)* specifying the platform on which the IoT intelligent components should be located; and *ii)* establishing the level of collaboration among the components. For safety-critical systems, such as evacuation, real-time performance and evacuation time are critical. The approach aims to minimize computational and evacuation delays and uses Queuing Network (QN) models. The approach was tested, by computer simulation, on a real exhibition venue in Alan Turing Building, Italy, that has 34 sets of IoT sensors and actuators. Experiments were performed that tested the effect of segmenting the physical space into different sized virtual cubes. Experiments were also conducted concerning the distribution of the software architecture. The results show that using centralized architectural pattern with a segmentation of the space into large cubes is the only feasible solution.

Keywords

Emergency Evacuation, IoT, Software Architecture, Network Optimization, Queuing Network.

INTRODUCTION

Building evacuation plans are generally designed as static maps in which routes are pre-specified for people to follow when an emergency happens. However, such maps may increase risks due to their lack of real-time data consideration, e.g. emerging dangerous areas, congestion and obstacles. To obtain such a real-time situational awareness the building may be equipped with IoT components. IoT is defined as the internal/external communication of intelligent components via internet in order to improve the environment through providing smarter services (Muccini and Moghaddam 2018). An IoT infrastructure is generally composed of sensing, computation and actuation components that are distributed over the area. The way these components are related and combined together is specified by *software architectures*. IoT architectures can support rules for quicker and safer evacuation by tracking people in a building, detecting possible congestion, and updating the best safety paths. Consequently, the evacuation time under changing emergency conditions can be minimized.

Important questions are: *what kind of reasoning algorithm should an IoT-based emergency evacuation system use? How should it be embedded inside an IoT software architecture?* Some previous research have tried to address these questions. Regarding the logic, previous research (Arbib, Muccini, et al. 2018) (Arbib, Moghaddam, et al.

*corresponding author.
†All authors contributed equally to this work.

2019) found that the IoT system may be designed in such a way as to provide security staff with information to continuously monitor the shortest time required to evacuate people in a building. In addition, the occupants were shown the best paths to evacuate the building. Other research (Muccini, Arbib, et al. 2019) developed a network flow algorithm that can be used in a computer simulation for designing buildings, and also in real-time building evacuation. The authors (Muccini, Spalazzese, et al. 2018) (Muccini and Moghaddam 2018) further argued that the flow algorithm can be embedded into the core of IoT reference architectures. The algorithm decomposes both the space (building plan) and the time dimension into finite elements: *unit cells* and *time slots*. The space element is monitored by IoT sensors, whose data are constantly feed into the algorithm. The algorithm can be run on one centralized components or on distributed collaborating controllers. However, this may impact not only the quality of the solution provided by the system in terms of performance, but also the system's functionality.

This paper extends previous domain knowledge by addressing the following aspects: *i)* the operational delay (evacuation time) and computational delay (CPU time) are calculated by the algorithm, but they have never been practically used in an IoT system; *ii)* the feasibility of running the algorithm in distributed processing and storage (P&S) components and any possible delays needs to be assessed; *iii)* the impact of changing the granularity of the space cells on IoT system functionality needs to be analyzed.

This paper makes the following contributions:

- Queuing network models for an IoT software architecture: we introduce a novel set of queuing network models that can be exploited for estimating performance of IoT systems adhering to IoT architectural patterns, in order to support architectural decisions.
- Algorithm distribution feasibility: we present the algorithm and assess its reaction to time- and space-decomposition.
- Cell size optimization: we present an optimization model for deciding on a good cell size.
- Evaluation: we evaluate our work by using the real case study of an exhibition venue, in the Alan Turing building, in Italy, with real data. Using various techniques and simulations we design the best internal building layout to handle emergency evacuations.

To the best of our knowledge, this is the first attempt to fill the gap between IoT software architectures, optimization algorithms for minimizing delays and performance modelling and analysis practices, in the context of emergency evacuation.

OVERVIEW

There is a large body of previous work in the three topics that shape our research, namely IoT software architecture, queuing networks, and optimization algorithms. However, their application to the emergency management has been rarely explored.

Related Work

Prior work has addressed problems related to software architecture modeled by queuing network. El Kafhali et al (El Kafhali and Salah 2018) proposed an analytic model for a fog/cloud-based Medical IoT system to show how to reduce the cost of computing resources while guaranteeing performance constraints. They used the QN concept to predict the system response time and estimate the minimum required number of P&S resources to meet the service level agreement. However, they do not provide any kind of high or low level architectural modeling. Huang et al (Huang et al. 2018) propose a theoretical approach of performance evaluation for IoT services, which provides a mathematical prediction on performance metrics at the design phase before system implementation. The authors formulate an atomic service by a queuing system in order to model IoT systems by a queuing network and obtain performance metrics. Whilst using QN, this paper does not address any modeling based on software architecture to be assessed by performance indices. Whilst few related works have been found on IoT systems modeling with QNs, we did not find any previous work on modeling emergency evacuation systems by QNs.

IoT software architectures

IoT architectures are generally composed of three main layers (Muccini and Moghaddam 2018) namely *Perception*, *Processing and Storage (P&S)*, and *Application*:

- The Perception layer represents the IoT physical sensors that collect information. For emergency management, the Perception Layer hosts a large number of different types of sensors, e.g. temperature, smoke and movement detectors.
- The Application layer determines the class of services provided by the IoT system. For emergency management, the Application Layer hosts a large number of different types of actuators, e.g. dashboards, evacuation signs and alarms.
- The P&S layer is the central entity of an IoT system that stores and analyses data gathered by the perception components to be accessed by other entities for their applications. Based on the P&S design philosophy, this layer can be divided into various sub-layers to set up the *IoT patterns* as follows:

Centralized. In a centralized pattern, data coming from the perception layer are processed by a central component that makes decisions on actuation. This central component can either be a local controller or, for massive P&S requirements, the cloud. Based on this pattern, if a device wishes to use an IoT service, it must connect to the central P&S component. A centralized architecture simplifies things through a central implementation of analysis and planning algorithms.

Collaborative. In this pattern, data are processed and stored separately (locally and/or remotely) but with the potential collaboration of other local/remote P&S components of the IoT system. In this pattern, a network of local intelligent components can communicate in order to form and empower IoT services. The advantage is that, should a local P&S component fail, a service would still be provided.

Given the above, we designed a set of QNs for IoT architectures that are described in following sections.

Queuing networks

In order to estimate performance indicators and avoid the performance degradation issues associated with IoT architectural patterns, we rely on Queuing Network (QN) models. QNs have emerged as powerful instruments to model and estimate the performance of hardware and software systems. They ground on theoretical foundations based on an algebraic approach to computer system modelling proposed by Lazowska in 1984 (Lazowska et al. 1984), where the computer system is represented as a network of delay and/or queuing *stations* (i.e. topology of the QN). Different *classes of jobs* may flow through the QN, each representing different types of user requests (i.e. dynamics within the QN). While flowing through the QN, each task requires a certain amount of service, namely *service demand* (mentioned as *CPU time* in this paper) to each visited station, depending on the job class the task belongs to. It is worth mentioning that, service demands represent input parameters that must be specified during QN design. Beside service demands, *workload intensities* must be specified, that is the rate at which tasks of each job class enter the QN. For example, a request (of a certain job class) every 2.5 seconds.

Once a QN has been designed, it can be solved analytically or by simulation, carrying out performance indices of interest such as system/stations response time and throughput for both the overall system and single classes of jobs.

Algorithm

The building to be evacuated is represented as a graph $G = (V, A)$ with nodes corresponding to the unit cells i obtained by embedding the building into isometric square grids. Cell 0 conventionally represents the outside of the building, or in general a safe place. The arcs of G correspond to passages between adjacent cells: the passage has full capacity if cells share a boundary uninterrupted by walls, and a reduced capacity otherwise. With no loss of generality, arcs are supposed directed. Let us denote:

T = $\{0, 1, \ldots, \tau\}$, set of unit time slots;

y_i^t = state of cell $i \in V$ at time $t \in T$, that is, the number of persons that occupy i at t: this number is a known model parameter for $t = 0$ (in particular, $y_0^0 = 0$) and a decision variable for $t > 0$;

n_i = capacity of cell i: this is the maximum nominal number of people that i can host at any time (in particular, $n_0 \geq \sum_i y_i^0$); this amount depends on cell shape and size; if cells are assumed to be uniform one can set $n_i = n$ for all $i \in V, i \neq 0$.

x_{ij}^t = how many persons move from cell i to an adjacent cell j in $(t, t + 1]$: this gives the average speed at which the flow proceeds from i to j;

$c_{ij} = c_{ji}$ = capacity of the passage between cell i and cell j: this is the maximum number of people that, independently of how many persons are in cell j, can traverse the passage in the time unit (independence of cell occupancy means that congestion is not taken into account: this will be considered later).

The flow model uses an acyclic digraph D with node set $V \times T$ and arc set

$$E = \{(i,t) \to (j,t+1) : ij \in A, t \in T\}$$

In other words, D models all the feasible transitions (moves between adjacent cells) that can occur in the building in the time horizon T. Transitions are associated with the x-variables defined above, whereas y-variables define the occupancy of each room (and of the building) over time. In real-time, these values can be periodically obtained by the previously described IoT infrastructure. The x- and y-variables are integers and subject to the following constraints:

$$y_j^t - y_j^{t-1} - \sum_{i:ij\in A} x_{ij}^{t-1} + \sum_{i:ji\in A} x_{ji}^{t-1} = 0 \qquad j \in V, t \in T, t > 0 \tag{1}$$

$$0 \le x_{ij}^t + x_{ji}^t \le c_{ij} \qquad t \in T, ij \in A \tag{2}$$

$$0 \le y_i^t \le n_i \qquad t \in T, i \in V \tag{3}$$

Equation (1) is just a flow conservation law: it expresses the occupancy of cell j at time t as the number y_j^{t-1} of persons present at time $t-1$, augmented by those during interval $(t-1,t]$ that move to j from another cell $i \neq j$, minus those that in the same interval leave cell j for another cell $i \neq j$. Box constraints (2), (3) reflect the limited hosting capability of the elements of G.

Maximizing outflow at a given time. To model the relation between time and people outflow, one can try to maximize the number of persons evacuated from the building within τ:

$$\max \quad y_0^\tau \tag{4}$$

To find the minimum total evacuation time, one can solve an Max Flow Problem for different τ, looking for the least value that yields a zero-valued optimal solution. To reduce computation time, this optimal τ can be computed by logarithmic search. The method can thus provide the decision maker with the Pareto-frontier of the conflicting objectives $\min\{\tau\}, \max\{y_0^\tau\}$. Linearizing arc capacities that is quite standard in applications can be find in our previous work (Muccini, Arbib, et al. 2019).

DESIGNING PERFORMANT ARCHITECTURES FOR EMERGENCY HANDLING

Software Architecture for Emergency

Figure 1 shows an example of an IoT-based environment for emergency response: CCTV cameras detect peoples position and movement that is used to feed the algorithm running in a P&S component. The algorithm decides on the actuation set based on the situation. In normal situations, the system shows, on a tablet, a 2D-representation of the monitored space and shows where crowds are located and how they move at any time. In this mode, the optimal flow algorithm is periodically run to estimate the minimum evacuation time required under current conditions. This value can be used to regulate visitor access to a venue in order to comply with safety conditions. If an emergency happens, in addition to the tablet map, alarm actuators are activated and evacuation signs in each area show the best evacuation routes based on the network model described above.

Figure 2 shows the corresponding software architecture. As depicted, additional sets of sensors can be embedded for emergency detection to further enable controllers to decide about normal or critical mode and activate a special set of actuators. As shown in the upper part of Figure 1, in addition to the computational delay of the P&S component, the sensors take some time to detect peoples position, transmit these data, and display the best evacuation routes. Reducing these delays to a minimum improves the system's functionality: since people can follow the given instructions more quickly and more individuals will be in a better evacuation position at the next monitoring time-spot. It is worth mentioning that reducing the aforementioned delays is a function of software architectural patterns, to be improved by properly relating the IoT components to one another. The following section presents a Queuing Network (QN) method that is designed on top of the software architecture, so as to facilitate assessing the performance of our IoT-based emergency handling system.

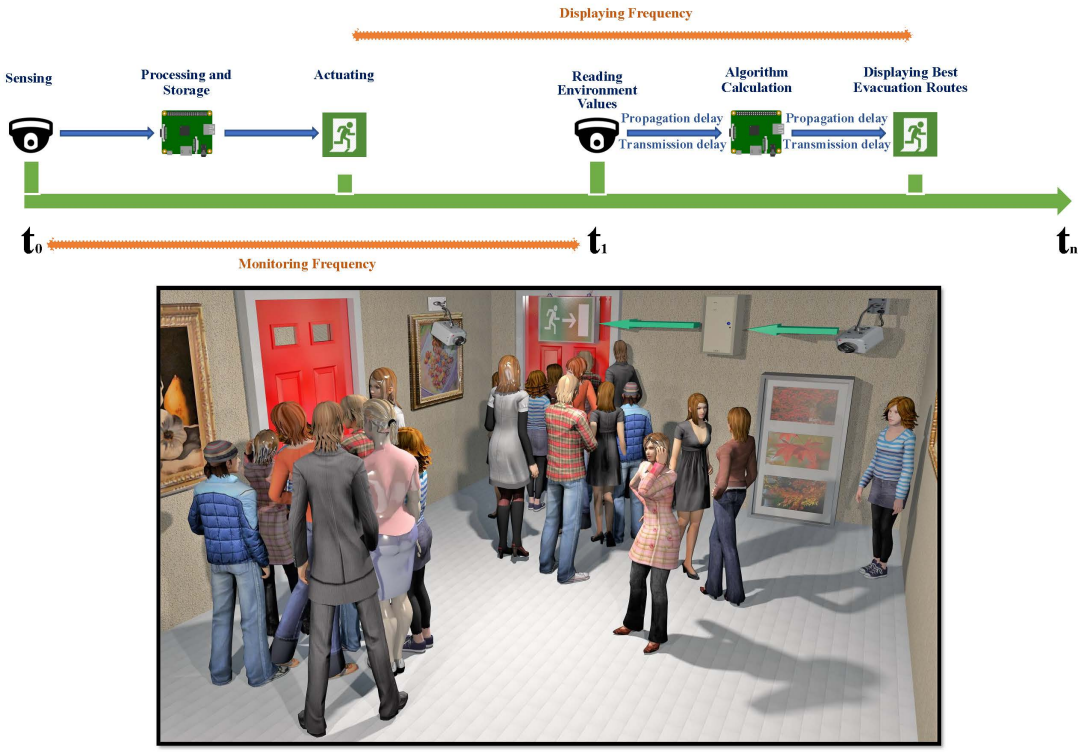

Figure 1. IoT Infrastructure for Emergency Handling.

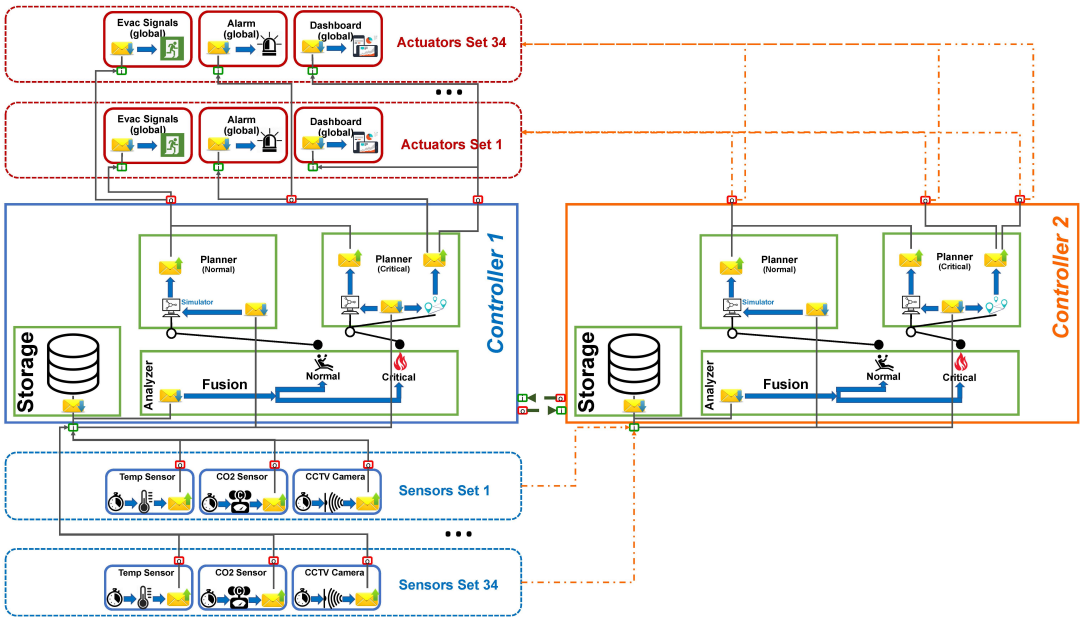

Figure 2. Architectural Patterns. Only Controller 1 Active: Centralized - Both Controllers Active: Collaborative.

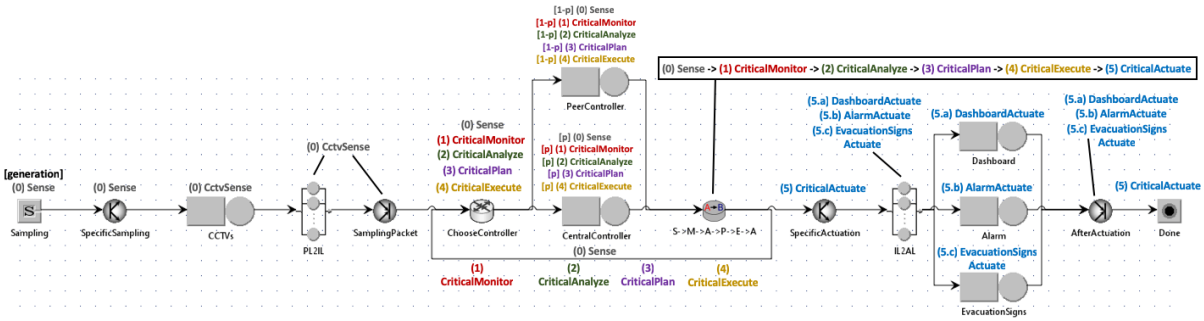

Figure 3. SMAPEA Queuing Network for the Alan Turing building case study.

Queuing Networks for Emergency

Fig. 3 shows a QN representing the performance model that we will exploit later in the paper for our case study. The QN conforms to the architectural patterns of Fig. 2, in fact, from a topological perspective:

- *CCTVs* corresponds to a specific kind of sensors, i.e. cameras.
- *Dashboard*, *Alarm* and *EvacuationSigns*, correspond to the three kinds of actuators.
- *CentralController* and *PeerController* correspond to the two P&S components.
- *PL2IL* and *IL2AL* represent networks between sensors and controllers and between controllers and actuators, respectively.
- The two QN constructs on the left and right of the figure, namely *Sampling* and *Done* represent the entry and exit points of the QN, respectively. In particular, *Sampling* indicates the point where data sampled by sensors is generated and *Done* represents the point where actuation ends.

Concerning dynamics, we devise the following control flow within IoT architectures: *i)* Data are sampled by sensors and forwarded through a network to controller(s); *ii)* A control layer aims at achieving the goal of evacuating people during emergency, through an actuation plan that is forwarded to actuators; *iii)* The actuation plan is implemented by actuators, thus possibly achieving the common goal.

The above control flow can be translated into QN language, by identifying a minimal set of 6 different kinds of tasks within a QN for IoT system performance (namely *SMAPEA* loop), sequentially executed as follows: *1.)* *Sense*: Raw data retrieval. *2.)*Monitor: Raw data aggregation and refinement for analysis at controller level. *3.)*Analyze: Interpretation of monitored data. *4.)*Plan: Building an actuation strategy. *5.)*Execute: Pre-processing the actuation strategy towards actuation. *6.)*Actuate: Practically undertaking the actuation by implementing the planned execution.

In order to implement the SMAPEA loop, a *class-switch* that transforms each SMAPEA task to a subsequent task is introduced (see the $S \rightarrow M \rightarrow A \rightarrow P \rightarrow E \rightarrow A$ element of Fig. 3). Moreover, routing probabilities for the switch must be properly defined. In particular, right after the switch, any SMAPEA task type is routed back to controllers through the *ChooseController* router (except *Actuate* tasks that are routed to *IL2AL* for actuation). By exploiting a probability-based routing strategy for *ChooseController* both Centralized and Collaborative patterns can be implemented, in fact the former may route any task to *CentralController*, whilst the latter may route tasks to *CentralController* or *PeerController* with 50% probability.

Notice that, in the QN of Fig. 3, fork/join nodes have been introduced, namely *SpecificSampling* (fork), *SamplingPacket* (join), *SpecificActuation* (fork), *AfterActuation* (join), aimed at modelling the fact that *Sense* and *Actuate* tasks involve the specific sensor and actuator sets, respectively. For example, each *CriticalActuate* task is split into three new tasks, namely *DashboardActuate*, *AlarmActuate* and *EvacuationSignsActuate*, because in case of emergency *i)* the best evacuation paths must be displayed on dashboard, *ii)* an acoustic alarm must be triggered and *iii)* evacuation signs must be properly turned on.

Algorithm Settings for Emergency

Cell Size Setting and its Impact on Architecture.

The cell size has an obvious effect on the resulting spatial patterns, and consequently on both the computational efficiency and model accuracy: the larger the cell, the fewer vertices in G and the lower the refresh frequency

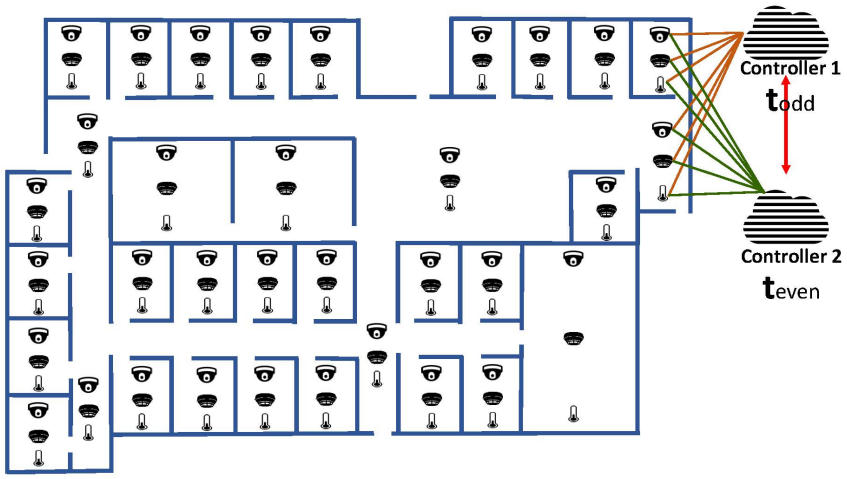

Figure 4. Alan Turing Building IoT Infrastructure.

at which people's positions are updated. Given the speed at which people move and the data that are acquired, relatively low refresh frequencies are not an issue. Instead, partitioning each room into identical cells may result in a huge network with consequently high CPU time. This issue has a direct impact on software architectural patterns since an operation which requires a huge amount of processing time on a low capacity machine is not suitable for real-time applications. Therefore it should be processed on a more powerful (potentially remote) P&S component.

In general, one can approximate the diverse room shapes by $a \times b$ rectangles as large as possible, while still minimizing any consequent error. Various ways can be adopted to measure approximation error: the most natural is the difference between real and approximated room area, in which case, for room k of size $p_k \times q_k$, the error is given by

$$e_k(a,b) = q_k[p_k \mathrm{mod}(a)] + p_k[q_k \mathrm{mod}(b)] - [p_k \mathrm{mod}(a)][(q_k \mathrm{mod}(b)]$$

As we need isometric cells and look for a uniform approximation, we set $a = b$ and find a minimizing $\max_k\{e_k(a,a)\}$, meanwhile limiting the total number of approximating cells to some predefined m: hence we choose among the values of a that fulfill $\sum_k \lfloor p_k/a \rfloor \lfloor q_k/a \rfloor \leq m$. A brief description of the method implementation is presented in the Application section.

Time and Space Decomposition Setting and its Impact on Architecture. In order to run the algorithm in distributed P&S components (collaborative pattern), we assessed the space- and time- decomposition feasibility. In the former case, we can give, for instance, two controllers the responsibility of two distinct areas, and let them share border information. Since the global objective cannot generally be satisfied by summing up two local objectives (that is running the algorithm in two local controllers instead of a central one), this method mostly leads to a non-optimal solution obtained by "gluing" together the two distinct areas. In the latter case, we conjectured that the optimal flow obtained at time t can be extended to $t + 1$ and stay optimal. This means that, for instance, one P&S element is in charge of solving the algorithm for t_{even}, and for t_{odd} (Figure 6) whilst sharing a level of data. Assessing this decomposition and taking into account our main requirement of optimally is described in the Application section. Here we can observe the ability of the algorithm to be run in a distributed way or centralized.

APPLICATION

Our proposed model has been applied to the evacuation of the Alan Turing building, in Italy, which is sometimes used for exhibitions. The considered building consists of 29 rooms, 4 main corridors and 34 sets of IoT sensors and actuators (Figure 4). In order to investigate our approach we address four research questions. The first two questions are centered around the algorithm and its levels of granularity and distribution:

- **RQ1**: what are the best cells sizes to divide the building surface, and how does the size affect the evacuation times and computational delays?
- **RQ2**: does running the algorithm in a time-decomposed way increase or decrease the computational and operational delays? What are the designed software architectures corresponding to these results?

The next two research questions are focused on the software system delays (using Queuing Networks):

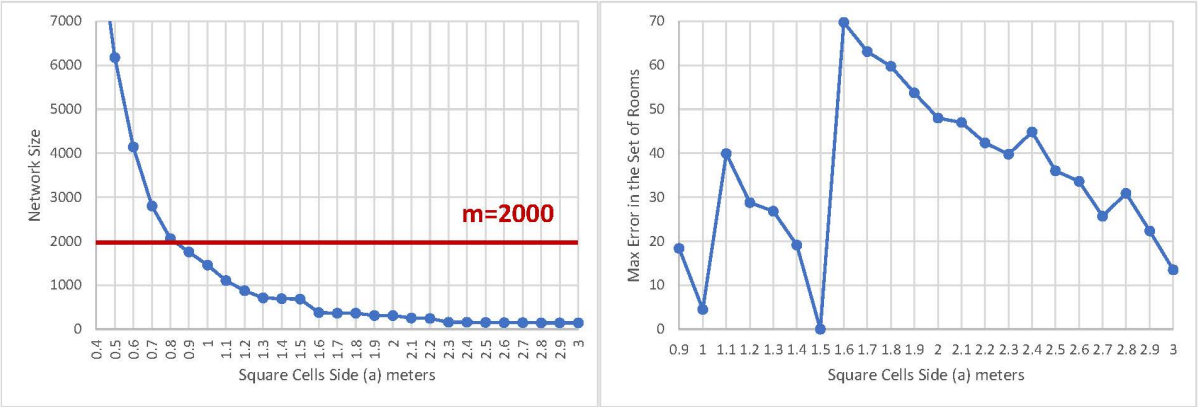

Figure 5. Optimal cell size: maximum error (right) and network size as a function of cell size (left).

- **RQ3**: what level of delay is tied up with each QN model adhered to architectural patterns?
- **RQ4**: what software architectural design reduces delays to make it usable for real-time applications?

Answers to RQ1: cellular approximation of physical space

We split each room in unit cells, each behaving as a (virtual) square room that can be traversed in a unit time slot. In practice, we embedded the building plan into a square grid as shown in Figures 6 and 8. To decide the cell size, we look at both the error introduced by room approximation and the number of nodes in the resulting graph G. The latter is in an inverse proportion of cell size (left diagram in Figure 5); the former varies irregularly with cell size (right diagram of Figure 5). We considered square cells up to 3×3 meters (the short edge of the smallest room) and allowed no more than 2000 nodes of G; then we selected the size that minimizes the largest error for all rooms. The reason of considering such a big maximum network size is to assess the impact of increasing the number of nodes on CPU time and consequently, on the software architectural pattern. As shown in Figure 5, 1.5×1.5 cells (Figure 8) give the best approximation (no error) and involve 687 graph nodes (Figure 9). With 3×3 cells (Figure 6) the error rises to 13.5 but G contains only 144 nodes (Figure 7). Summarizing, 3×3 leads to larger error but less CPU time; conversely, 1.5×1.5 causes larger CPU time but no error. We tested scenarios with both cell sizes in order to find the best efficiency/accuracy compromise.

Simulation. Simulations were first run for both cell sizes. The simulation code was written in the OPL language and problems were solved by CPLEX version 12.8.0. All experiments were run on a Core i7 2.7GHz computer with 16Gb of RAM memory under Windows 10 pro 64-bits. In all tests, we computed the minimum time required for 264 persons, randomly distributed in the building rooms, to reach a safe place. This datum comes from an experiment performed in the Alan Turing during the *the Researchers Night* event, when the IoT system recorded the simultaneous presence of 264 people in the building as a peak value. We solved problem (1-4) for $\tau = 1, 2, \ldots$ until a solution of value 264 was found.

To get a reliable model, some more parameters such as walking velocity under various conditions, door entrance capacities and room capacities must be set to numbers that reflect reality. We set these model parameters based on a literature review (Table 1).

Table 1. Evacuation Model Parameters

Model Parameter	Assigned Value
Walking Velocity	1.2 m/s (Ye et al. 2008)
Door Capacity	1.2 $p/m/s$ (Daamen and Hoogendoorn 2012)
Cell Capacity	1.25 p/m^2 (Uk Fire Safety)

Table 2 reports the number of evacuees at each τ and the computation time of each solution step. Computation is done for both *low-* and *high-resolution* networks (respectively, 3×3 and 1.5×1.5 cells). With the low-resolution network, we get the evacuation and CPU times shown in Table 2 left: in terms of evacuation, everyone has reached a safe place in 55 seconds; on the other hand, computation requires 2.33 seconds in the worst case, and is therefore

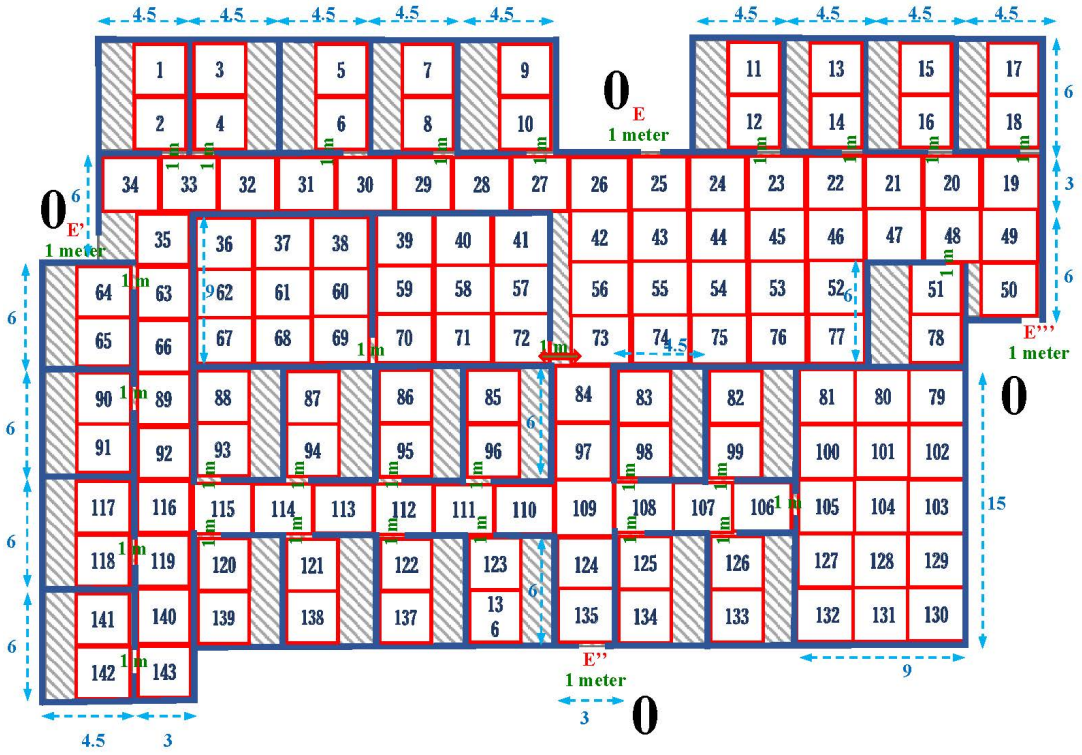

Figure 6. Plan embedding the Alan Turing building into square grids with a low resolution: 3×3 cells. The area that is not covered by cells (error) is shown in gray.

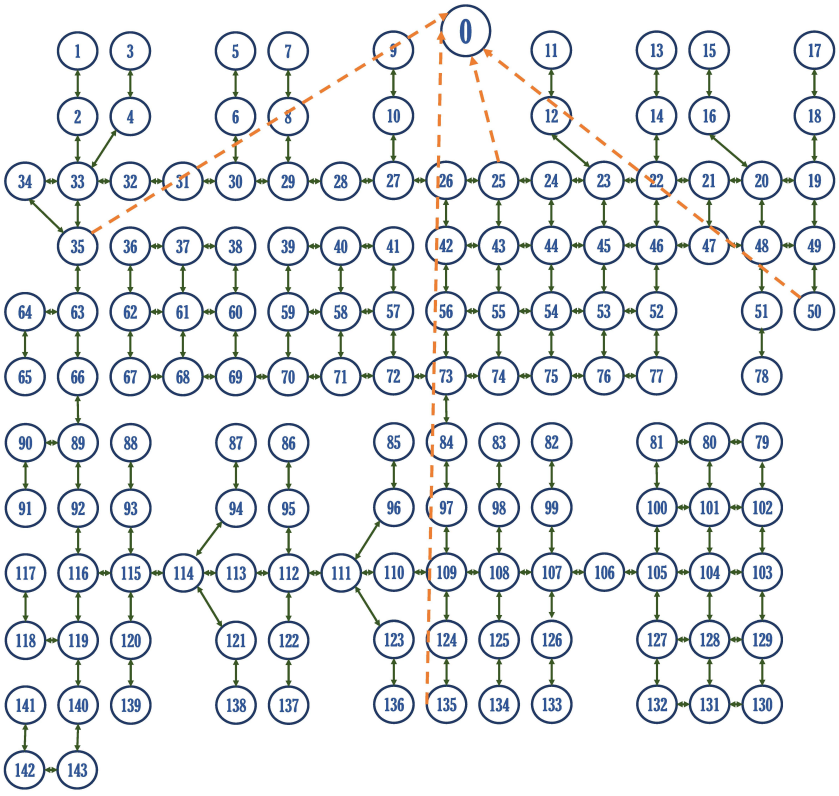

Figure 7. Network associated with the plan of Figure 6.

totally compliant with real-time applications. Evacuation and CPU times for the high-resolution network are reported in Table 2 right. We see that everyone has reached a safe place in 98'75". CPU time is now much larger (382.24 seconds in the worst case) and the model appears inappropriate for real-time use, unless additional computational resources are deployed. Hence we can conclude that sufficient accuracy is obtained using the low resolution network.

Answers to RQ2: Time Decomposition

Table 3 gives the number of evacuees at each τ and the computation time of each solution step corresponding to time-decomposed networks (collaborative P&S). With a time-decomposed simulation of 3×3 cells, we obtain the evacuation and CPU times in Table 3 left: in terms of evacuation, everyone has reached a safe place in 75 seconds, however computation requires 0.58 seconds in the worst case, and is therefore compliant with real-time applications. Compared with continuous simulation (central P&S) of the same case that is presented in Table 2 left, whilst CPU time is now significantly reduced, the optimal evacuation time is increased by 36 percent. Looking at the time-decomposed simulation results for 1.5×1.5 cell (Table 3 right), CPU time is decreased by at least 123 percent (being 3.11 seconds in the worst case) and the evacuation time remained constant.

Hence, for a high resolution time-decomposed network: whilst the operational delay remains constant, the computational delay improves significantly. However total response time should be observed since the quicker sampling rate tied up with high resolution may cause a negative impact. For a low resolution time-decomposed network: whilst the computational delay decreases, the evacuation delay (that has a priority over all other delays) increases: so that running the algorithm in a collaborative architecture is not recommended, regardless of melioration/deterioration of total response time.

Taking into account the result of this subsection and keeping evacuation time and CPU time as inputs, the following subsection practically assesses, in terms of total response time (delay), the quality of proposed architectural patterns with respect to four different scenarios, resulting from the different combinations of architectural patterns designed to handle emergency situations:

Figure 8. Plan embedding the Alan Turing building into square grids with a high resolution: 1.5×1.5 **cells.**

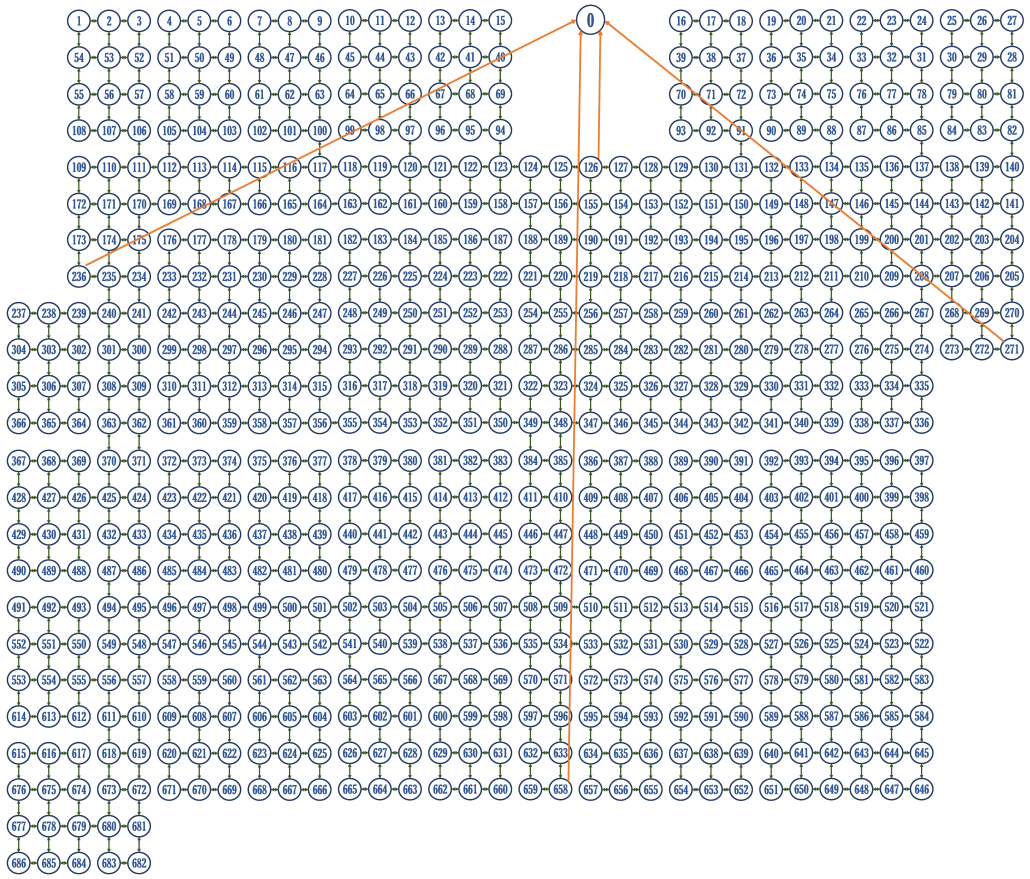

Figure 9. Network associated with the plan of Figure 8.

1. *Centralized with High Resolution (Centralized-HR)*: the critical situation is handled by a continuous simulation of the algorithm, (on a single controller) and physical space is divided into 1.5×1.5 cells.
2. *Centralized with Low Resolution (Centralized-LR)*: the critical situation is handled by a continuous simulation of the algorithm, (on a single controller) and physical space is divided into 3×3 cells. Therefore, again all tasks are routed to a central controller.
3. *Collaborative with High Resolution (Collaborative-HR)*: the situation is handled by a time-decomposed simulation of the algorithm, (on collaborative controllers) and physical space is divided into 1.5×1.5 cells. This means that the two available controllers are intermittently chosen as the destination of routed tasks.
4. *Collaborative with Low Resolution (Collaborative-LR)*: the emergency situation is handled by a time-decomposed simulation of the algorithm, (in a collaborative way) and physical space is divided into 3×3 cells. Thus, one of the controllers handles the situation for *odd* and the other for *even* time slots.

Answers to RQ3: Total Delay Assessment using Queuing Networks Parameterization

In order to realize the software architectures resulting from algorithm simulations, we exploit the QN of Fig. 3 that we have previously introduced, with the four different sets of input parameters needed to model the software architectures resulting from algorithm simulations.

Sense tasks (by CCTVs) are generated at a certain rate (i.e. every 2.5 seconds for high resolution and 1.25 seconds for low resolution networks). These rates are the monitoring frequencies, and is the time taken for an individual to cross a single cell in our crowd monitoring algorithm. Such time intervals represent a key-value, due to their impact on the overall evacuation delay.

Exponential distributions are used to define CPU times. Table 4 reports the means of such distributions for our case study, which have been estimated in several ways. Our focus is on evacuation, i.e. *CriticalPlan-HR* and *CriticalPlan-LR*, which have been estimated by formulating the evacuation handling problem within CPLEX. Other parameters are set as follows:

- Service time distribution means for sensors, networks and actuators, have been obtained by modelling the IoT system for the Alan Turing building with CAPS, our simulation framework (Muccini and Sharaf 2017). CPU times for sensors, actuators and networks, have been calculated in terms of transmission and propagation delays (*td* and *pd*, respectively).
- Service time distribution means for controllers refer to SMAPEA task types. *Sense* tasks have zero CPU time since they do not introduce additional computation for controllers, hence they just need to be transformed into *Monitor* tasks.
- As shown in Table 4, *Monitor* and *Execute* tasks are equal and have the same order of magnitude of *Analyze*. To avoid further complexity, we ignore formulating optimization models for such task types, by setting arbitrary values as follows: we assume that aggregating raw data (i.e. *Monitor*) and building a list of atomic actions to execute (i.e. *Execute*) are less demanding than interpreting monitored data (i.e. *Analyze*).

Table 4. SMAPEA Task Types and CPU Times for case Study

Simulation. We assess the total delay corresponding to each IoT architectural pattern design based on the flow algorithm, for the case study. The response time (delay) that is analyzed is the mean time spent from starting the sampling to the time that actuation ends.

Table 5 reports, for each scenario, the overall system response time (in seconds) in the second column and the architectural design decision in the third one (useful to answer RQ4).

Table 5. Experimental results.

Pattern	System response time (s)	Architectural design decision
Centralized with HR	*System saturation*	Unfeasible (real-time requirement)
Centralized with LR	*1.5085*	Feasible
Collaborative with HR	*26.5597*	Unfeasible (real-time requirement)
Collaborative with LR	*0.5864*	Unfeasible (non-optimal)

Answers to RQ4: Architectural Design Decision. Experimental results show that, in LR, the Collaborative pattern minimizes system response time. However, this pattern does not satisfy the precondition that minimizes operational delay, i.e. optimal evacuation of people from the building. Thus, one can argue that a Centralized pattern should be imposed when working in a critical mode. The drawback is that, managing critical cases with Centralized increases system response time in critical mode by more than 200% with respect to Collaborative. Therefore, the solution can be using HR network. However, HR does not allow the system to fulfill a real-time requirement, due to two factors: *i)* working in HR requires much more CPU time; *ii)* the sampling rate doubles when working in HR. Both factors contribute to a significant performance worsening which might lead to system saturation (as for Centralized-HR).

As a result of the considerations above, *only one pattern could be adopted, i.e. Centralized-LR*.

It is worth noticing that, in order to face the sampling rate for HR (i.e. 1.25), while satisfying the precondition that minimizes operational delay, the CPU time of the controller in Centralized pattern should have the same order of magnitude of the controllers in Collaborative-LR. For example, with a CPU time of 0.5016667 (i.e. the same as Collaborative-LR), Centralized-HR would show a system response time of 0.6535 seconds (i.e. 11.5% Collaborative-LR). As a second example, with a CPU time of 2.0164557 (i.e. the same as Collaborative-HR), Centralized-HR would experience continuous saturation that might lead to a system response time in the order of hours.

CONCLUSION

This work uses the Queuing Network concept in order to model the IoT architectural patterns for emergency evacuation, and assess the patterns' corresponding delays. The architecture has a core computational component in the form of network flow, which supports the design decision by providing the model with expected operational and computational delays. Preliminary evaluations using data from a real case, and an *ad-hoc* IoT infrastructure showed the suitability of a centralized software architecture based on a low resolution division of the building surface.

ABSTRACT

Natural hazards can generate damages in large inhabited areas in a very short time period. Crisis managers must plan interventions very quickly to facilitate the arrival of the first emergency. In a crisis unit, experts visualize heterogeneous visual representations of spatio-temporal information, in order to facilitate decision-making, based on various types of screens, i.e. laptops, tablets, or wall screens. Visualizing all this information at the same time on the same interface would lead to cognitive overload. In this paper, we assume that it could be of interest to provide innovative co-visualization models and tools, to bring hazard, geospatial and climate information together, in a shared interface. We propose to explore spatial and temporal multiplexing tools within a dedicated geovisualization environment, in order to help expert decision-making. The proposition is implemented with the case study of a tsunami event in the Caribbean sea.

Keywords

geovisualization, multiplexing tools, crisis management.

INTRODUCTION

Natural hazard management remains a major issue for populations and authorities. It relies on the capacities and the possibilities that scientific and operational have to simulate, predict and prevent natural phenomena in order to protect the impacted inhabitants and infrastructures. Decision-making processes can be complex and mostly depend on quickly transmitted information, based on massive raw data coming from sensors and geophysical models: this information is then often graphically represented as graphics and maps, enabling visualizations of the territories affected by an event, the dynamic evolution of this event in space and time, and its various possible impacts. In a crisis unit, the goals of the experts are to lead emergency and people security: they rely on information, coming from various sources, sensors, and other emergency centers, displayed on different screens, i.e. laptops, tablets or wall screens, variably arranged in the room, to take the better decisions (Cf. Figure 1).

Figure 1: Inside a crisis management unit (Photo Credit PREDICT Services[1])

For instance, when facing a tsunami event, emergency information is transmitted in a raw text format and are combined with pre-computed event forecast models to extract and derive the expected spatial extension and the related potential impacts. Figure 2 presents the example of a raw alert message in text from the Pacific Tsunami Warning Center (PTWC) (2-a) and one of a possible derived cartographic representation (2-b). At the same time, other information need to be visualized, in order to assess the dangerousness of an event, its extension and dynamics, for instance: meteorological information, i.e. wind, local and worldwide pluviometry at the time and the trends for the past two weeks, seismologic activity, etc.

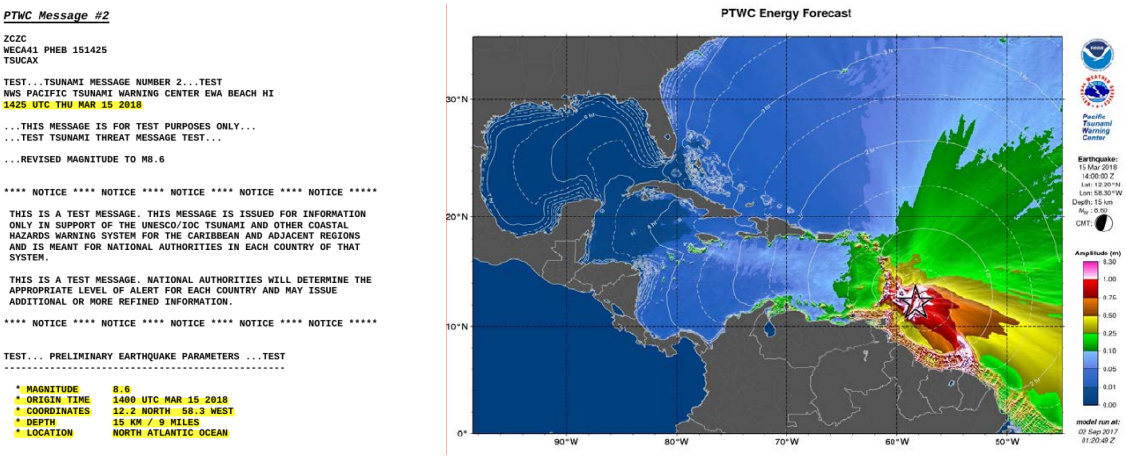

Figure 2: a) PTWC raw alert message and b) Maximum amplitude map for the Caribbean and Adjacent Regions (PTWC, 2018)

This research initially emerged during various visits of crisis units, where wall screens are used to represent heterogeneous spatio-temporal information useful for crisis management. During these visits, we observed that a lot of data are displayed on wall screens at the same time, in 2D or 3D, whatever spatio-temporal extents and scales. However, we have noticed several functional limits for the co-visualization and the navigation of information displayed on wall screens.

First of all, the representations displayed on a wall screen were independent one to each other, which did not allow an efficient cross-over between representations, and could generate too many unnecessary interactions with the representations. Independence and hermeticism of the representations (often provided in raw format by web services) prevented to display this information on a unique representation. Furthermore, a temporal interdependence exists between representations, which is fundamental in a crisis management context with strong temporal constraints. For example, synchronization between tsunami arrival, hourly weather conditions, and evacuation times to a safe place can not be considered separately. Moreover, the possibility of anticipating by taking advantages of the temporal relations between representations proves to be invaluable for crisis experts.

In the context of a catastrophic event, decision makers and experts in a crisis unit have to face significant temporal constraints, while acting on potentially vast areas. Wall displays offer a solution to co-visualize the various representations useful for decision-making, but at the same time, the difficulty of combining these

[1] http://www.predictservices.com

representations can amplify these constraints. It therefore seems necessary to identify geovisualization tools and methods to manage co-visualization of heterogeneous representations in crisis units. In this context, we assume that advances in Geographic Information Sciences could benefit crisis managers to better navigate, combine and synchronize information displayed on wall screen in crisis units.

Geographic Information (GI) sciences have facilitated the development of geovisualization design and use, enabling experts to conduct more elaborate actions for risk prevention and crisis management (Van Oosterom et al., 2005; Konecny et al., 2010). While *mapping* is a graphic representation of geographical spaces and phenomena more used to communicate and mediate, *geovisualization* regards the way data may be visualized based on data interaction, to lead to *visual analytics* capacities, i.e. to infer spatio-temporal knowledge from data exploration (Keim et al. 2008). Geovisualization issues mainly concern the handling of heterogeneous spatio-temporal data visualization and the design of suitable graphic choices when representing uncertainties and spatio-temporal evolutions and their adaptation to the potential final users (experts, public authorities, populations). Nevertheless, the development of geovisualization tools for crisis management remains complex because of the emergency context and time pressure, of the increasing amount of available data, and of the risk of a cognitive overload instead of the expected cognitive support. In crisis management units, in the usual way, in order to avoid these problems, information is split on several screens to facilitate their access and reading. Based on these observations, we have been wondering if another organization of graphic interfaces could be useful and relevant in order to support sophisticated cognitive processes of knowledge inference and decision-making about crisis management, coming from a facilitating co-visualization of heterogeneous spatio-temporal data. *Co-visualization* refers to the methods and tools to bring representations together, in a shared interface *(*Hoarau and Christophe, 2017). We assume that this visual data integration will better support visual analytics and could help in the earlier steps of decision-making in a crisis management context.

In this paper, we propose to initiate this research by a proper design experiment step to explore the potentialities of spatial and temporal multiplexing tools, associated with a dedicated geodata visualization environment. Our long-term purpose is to provide a suitable visual support for knowledge inference and decision-making on crisis management in the case of natural disasters. In the first step of this long-term research, we focus on the issues related to the proposition of interface tools design, which are our first contribution to solve the on-going research problem: user studies have not been conducted in this first step, because a proper design needs to first approach issues of how to visually integrate data and representations. We present the advances in geovisualization, and especially in co-visualization of data and graphic representations, and the visual possibilities enhanced by multiplexing tools, in our crisis management context. Afterwards, we propose a generic model to better co-visualize the geospatial and thematic data, based on various points of view that could be displayed in a same graphic interface. As an applicative use case, we consider a tsunami event in the Caribbean sea, with a focus on the Martinique island, with the help of an existing detailed scenario proposed as part of the crisis exercise *CARIBE WAVE 18* (PTWC, 2018). We detail the scenario and the dataset used to simulate the event. Finally, we demonstrate the implementation of multiplexing tools to handle heterogeneous data to better co-visualize information on a tsunami event.

ADVANCES IN GEO-VISUALIZATION & CO-VISUALIZATION FOR CRISIS MANAGEMENT

Geovisualization refers to the "theory, methods and tools for visual exploration, analysis, synthesis, and presentation of geospatial data" (MacEachren & Kraak, 2001). As an interdisciplinary domain between GI sciences, geography, information visualization, image processing and computer graphics, geovisualization provides conceptual approaches, methods and tools to interact with geospatial data. Through this capacity to let the users explore the data and their representations, geovisualization tools aim at inferring knowledge and supporting visual reasoning (Yi et al. 2007). Nowadays co-visualization may benefit from the advances in the Human-Computer Interaction (HCI) scientific domain, providing spatial and temporal multiplexing tools to manipulate data 'together'. In order to improve the usability of co-visualization tools to manage data in space and time, the main leads undergoing research are the following ones: the improvement of the perception of the dynamics of a phenomenon and the design of smooth navigation between data and representations.

Spatio-temporal geovisualization

Geovisualization has widely considered issues related to the representation and the interaction with spatio-temporal data (Andrienko & Andrienko 2005, Andrienko et al. 2008, amongst others). The first main approach is to animate the spatial or/and temporal dynamics at stake, in a continuous or pseudo-continuous manner (Andrienko et al., 2008; Keim et al., 2008). Many applications have been experimented, the water level rising

simulation (Marcy et al., 2011; Nicholls et Cazenave, 2010; Yang et al., 2014), tsunami and marine submersion prevention (Allen et al., 2010), the modeling and visualization of currents and tides (Mengguo et al., 2000), the monitoring of sandbanks trajectories (Gierlinger et al., 2015) and seabeds (Tateosian et al., 2014), or the real-time representation of maritime traffic (Etienne et al. 2012, Marine Traffic[2]). These spatio-temporal animations are more and more used, thanks to the increasing rendering capacities of computers, in order to serve fluid and continuous animated visualizations. Nevertheless, even if animations are very useful to improve the global perception of a spatio-temporal phenomenon and its general patterns, such as demonstrated in a user study of geovisualization and assessment of a flood crisis (Leskens et al., 2015), it is mostly difficult to detect changes and to monitor a specific aspect of the phenomenon (Rensink et al., 1997). These previous work show that a dynamic visualization is a better way to understand, but also suggest that several points of view are required to observe and analyze a spatio-temporal phenomenon.

Co-visualization techniques from Geographic Information (GI) Sciences

Co-visualizing heterogeneous data raises issues on how it is possible to visualize data together, sharing the same interface side by side, overlapping each other, or being hybridized or merged in one new image. Map design researches have addressed for instance the design problem of visually mergin an ortho-image background with an abstract topographic map (Hoarau, 2012; Raposo and Brewer, 2013). While merging data, legibility issues appear, implying issues in graphic semiotics and its related visual variables, initially described by Bertin (1983), extended, revisited and experimented, by MacEachren (1995), Boukhelifa et al. (2015), Carpendale (2003), Slocum et al. (2009), Perin et al. (2014), amongst others. Issues on colors and color contrasts (Christophe, 2011; Harrower and Brewer, 2003; Patterson and Kelso, 2004; Patterson and Jenny 2013; Thyng et al. 2016 amongst others) may be also addressed in this co-visualization context, such as rendering techniques to variously blend geographical layers (Porter and Duff, 1984; Hoarau and Christophe, 2016; Lobo et al. 2015). The unique use of the transparency to blend data may cause visual cluttered information not legible and not usable: blending data require specific techniques mostly to handle contrasts (Hoarau et al., 2013; Murphy 2015). Therefore, the design of continuum of data and graphic representations has been explored as 'a series of pictures, iteratively reduced in representation from its referent' (Medley and Haddad, 2011). In GI sciences, the design of cartographic continuum aims for instance at navigating smoothly, between a map and orthoimagery according to the parametrization and interpolation of colors and textures to enhance photorealism (Hoarau & Christophe 2017) or smoothly between various representation scales to manage visual attention (Dumont et al., 2017). Managing progressive transitions between levels of abstraction allows navigating between different levels of abstraction in a same visualization, according to the distance from the image center or the saliency of rendered objects (Semmo et al., 2012), or according to the scene depth (Semmo and Döllner, 2014). Another example consists in generating masks according to relevant geographical objects and scene depth, in order to highlight specific objects as soon as the users perceive them (Trapp et al., 2011).

Multiplexing techniques

Navigating in large information spaces using zoomable user interfaces is a research question that has received a lot of attention in the Human-Computer Interaction (HCI) community, based on three main interface schemes: pan & zoom (Wijk and Nuij, 2003), focus+context and overview+detail (see Cockburn et al., 2009 for a comprehensive survey). The implementation of navigation techniques from HCI based on these schemes leads to a wide range of tools supporting multiplexing (Bottger et al. 2008; Brosz et al., 2013; Jakobsen et al. 2013; Reilly and Inkpen, 2004), i.e. tools conveying multiple information at the same time: such as magnifiers, lenses, swipes, or enslaved views (Appert et al. 2010; Pietriga et al. 2010; Pindat et al., 2012; Karnik et al., 2009; Lobo et al., 2015), evaluated in (Lobo et al., 2015). These spatial multiplexing tools may be divided into:

- Juxtaposition methods, i.e. two types of data are displayed in the same environment, but one besides the other, or one up the other: multiviews, overview and detail, split screen, portal.
- Superimposition methods, i.e. two types of data are overlaid, some of them may be hidden and visible with the help of an interface tool: mash-up, translucent overlay, swipe, dragmap (Ware & Lewis, 1995), lenses, as Smart Lenses (Thiede et al., 2008), Jelly Lens (Pindat et al., 2012), Detail Lenses (Karnick et al. 2010) amongst others (see Tominski et al., 2014 for a wider survey about lenses).

Co-visualization of heterogeneous data based on multiplexing techniques

[2] https://www.marinetraffic.com/en/ais/

Because of the amount of heterogeneous data that have to be handled, visualized and cognitively processed, together, in the same time, in a crisis unit, we may take advantages of the parallel advances in geovisualization and in HCI: they provide a strong state of the art to go further in the co-visualization of heterogeneous spatio-temporal data, based on multiplexing techniques for crisis management. A combination of juxtaposition methods, i.e. multiviews, overview and detail, and of superimposition methods, such as lenses, could allow to render the region of interest or any subregions, according to these constraints:

- With different input information: topographic, thematic regarding the event, climate, textual data, sociodemographic;
- With various points of view on the event: representation of hazard, potential issues, and elements at risk;
- At different time steps: before, during of after the event;
- At different spatial scales: international, regional, local, urban;
- For any natural event: tsunami, flood, water level raising, etc.;
- For distinct objectives: monitoring, evacuation, etc.

Taking into account these multi-dimensional constraints for the co-visualization of information in a crisis unit supposes the development of a generic model for the management of heterogeneous graphic representations.

GENERIC MODEL TO VISUALIZE INFORMATION IN VARIOUS WAY

To improve the co-visualization of heterogeneous data in a crisis context, we argue that the intended information to represent and the way it is displayed on various screens (wall screens, laptops, tablets, etc.) must be preliminarily identified. For example, in a crisis unit, at the beginning of an event, some information have to be visualized onto a wall screen, such as the source of the hazard, the impacted areas, alert messages, or climate data. This information must be displayed, at different scales (according to the spatial extension of the event) to make it possible for the operator to view the representations at different levels of detail. This raises both:

- User Interface (UI) issues: How to efficiently organize information displayed on the screen? Which tools can be used to better represent information?
- Geospatial issues: What kind of spatio-temporal (ST) relationships exist between representations? How to mash-up heterogeneous datasets with different scales and styles ?

A generic metamodel for interface handling

We propose a generic model to describe entities used in a particular hazard context (e.g. tsunami or flood). In this model, we need to consider interface issues, such as co-visualization of heterogeneous datasets. At the highest level, we have to manage the three concepts of interfaces, frames and scenes and their relationships, as modeled in Figure 3.

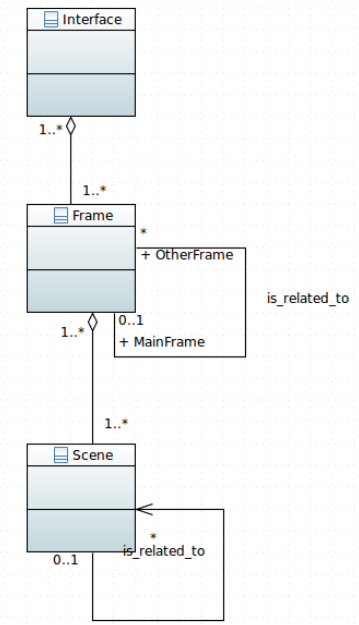

Figure 3: Generic metamodel of interfaces relationships interaction in a co-visualization framework (UML diagram)

An *interface* allows the users to interact with the information within a dedicated support (wall screens, tablets, etc.); a *frame* is a 2D visualization space inside the interface where contextual information is displayed; and a *scene* is a static or dynamic representation at one scale and for one particular time (before, during of after the event). In the context of crisis management, an interface must allow the experts to:

- Co-visualize heterogeneous, cartographic and thematic data (weather, alert message, topographic data, etc.);
- Hide / show / combine relevant information for the user;
- Put forward a frame or a scene that is considered as the main one, at a certain time t;
- Interact with data through multiplexing tools.

Interfaces are composed by frames and interaction components. Each frame constitutes a 2D visualization space in which different scenes are represented. Frames can be represented by windows, popup, widget, or any component of a GUI which allow displaying cartographic or thematic information. Frames can be related to each other. In particular, one frame is dedicated to be the main for displaying the most relevant scene for the operator at one time. This main frame can have some links with the others (e.g. zoom of a particular place, thematic information for a particular placemark, etc.). Spatial and temporal multiplexing tools can be used at this level, such as juxtaposition of several frames (multiview, split/merge, etc.), superimposition (dragmag, mash-up, etc.), or temporal synchronization of frames. In the frames, we have to represent one or more *scenes*, corresponding to a particular *spatial scale* (region, local, urban), at a particular time (synchronized with the event time). Scenes can be related to each other.

A model to manage scenes

At the scene level, we have to manage the graphic representation, the different link between them and the associated dataset. The Figure 4 presents a conceptual model (UML formalism) to describe the interaction and the relationships between entities at this level.

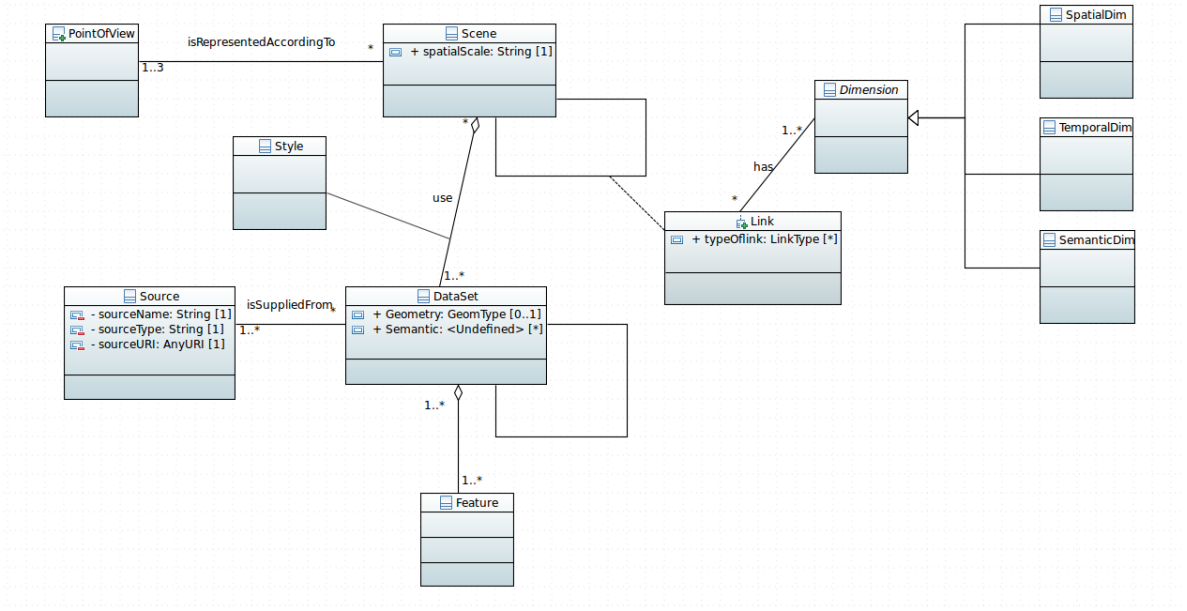

Figure 4: Scene level model (UML class diagram)

A *scene* is represented according to a *Point of view*. In our context, we consider diverse points of view: *Hazard, Potential Issue and Risk*. The *hazard* refers to the direct or indirect consequences of a catastrophic natural phenomenon. It can be amplified with other phenomenon, such as additional and cumulative rainfall for instance. *Potential Issue* contains information about people or infrastructures potentially exposed to the phenomena. *Risk* is the intersection between hazard and potential issues (e.g. submerged roads, destroyed buildings, etc.). For one scene, several *spatial or thematic datasets* are needed to graphically represent the information. A *style* depending on the scale of representation and the dataset used to display the information is applied. Datasets are supplied from different *sources* (databases, geoportal, etc.). Finally, spatial, temporal and semantic links can exist between scenes: for example, alert messages and estimated intensity of the hazard can be synchronized. These relationships will guide the use of multiplexing tools, to better combine the information to be disseminated. For instance, at the *hazard* point of view, data about the prediction of the impacted area can be easily found, and at the *potential issue* point of view, data on the impacted population in the same area are available. Lenses would potentially be helpful to see a specific aspect of the phenomenon (scale, data or view change) or of the impacts (affected population or infrastructures) or of the complementary thematic data (rainfall evolution, etc.) and to show how to reach quickly some refuge sites.

TSUNAMI CRISIS SCENARIO AND UNDERLYING DATASET

The crisis scenario is based on the Barbados earthquake scenario from the *CARIBE WAVE 18* exercise (PTWC, 2018). It relays on a rupture of a fault segment along the Caribbean coast of Barbados, occurred at 14:00 UTC, causing an earthquake with an 8.6 magnitude. The epicenter is located at the coordinates Long : 58.30°W, Lat : 12.20°N. With this scenario, the southern segment of the Lesser Antilles ruptures to create a tsunami. Expected impacts for this event are determined from pre-computed tsunami forecast models. For instance, Figure 5 shows tsunami travel time and water heights off the coast. Tsunami forecast models indicate a significant tsunami along several coasts in the Caribbean Sea. Threat messages and enhanced graphical products will be disseminated to officially designated agencies. The initial alert is disseminated at 14:05 UTC.

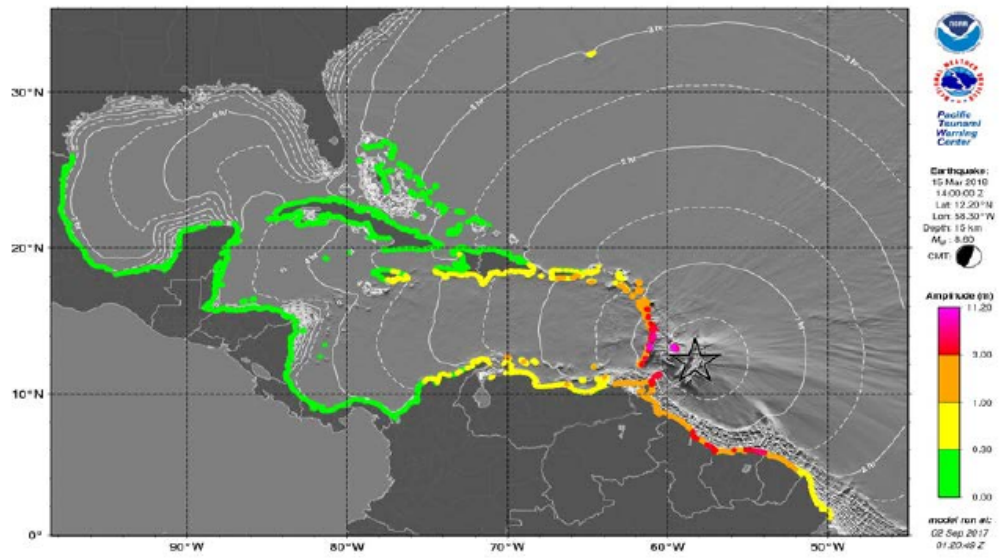

Figure 5 : Coastal tsunami amplitude map for the Caribbean and adjacent regions (PTWC, 2018)

The first tsunami threat message issued by PTWC is based on the earthquake magnitude (8.3 reevaluate in the second message) and the tsunami travel times (Figure 5). The other messages are based on tsunami wave forecasts that indicate the levels of threat that have been forecast and to which countries or places they apply. The messages cover a period of time between 5 minutes and 7-hours from earthquake origin time. The end of the event is scheduled at 18h00 UTC (PTWC, 2018). Based on this scenario, experts, in a crisis unit, and during the crisis period, have to manage emergency and people security for the french islands of Caribbean region, and in particular the Martinique island.

Figure 6 : PTWC Threat Message N°1: On the left, information are provided about the earthquake, on the right each line represents the estimate times of arrival of the Tsunami wave for different towns.

Table 1 describes our proposition of required information and multiplexing tools, according to three relevant spatial scales, regional, local and urban, and their related associated tasks: alertness, risks assessment and evacuation. For each spatial scale, several datasets are necessary to achieve these tasks: the row "Information to display" gives the relevant required information for each spatial scale, for all the points of view (Hazard, Potential Issues and Risk):

Spatial Scale	Regional ◄——► Local ◄——► Urban		
Associated task	Alertness	Risk assesment	Evacuation
Information to display	Base Map + Épicenter information, Tsunami Travel Time, PTWC Messages,	Base Map + **Hazard**: submerged area + coastline water hight **Potentiel Issues**: Buildings, roads and population **Risk**: Refuge sites, area to evacuate **Weather**: Rainfall	Base Map + **Hazard**: Submerged area **Potential Issues**: Buildings, roads, population and boats **Risk**: Refuge sites, population and boats to evacuate
Multiplexing tools associated	**Spatial multiplexing**: *Swipe*: wave progression **Temporal multiplexing**: TTT *animation*.	**Spatial multiplexing** *Mash-up:* weather and topographic information **Temporal multiplexing** Rainfall *animation*	**Spatial multiplexing**: *Split-Merge*: Risks information *Lens*: ≠ Point of view

Table 1 : Datasets and multiplexing tools used according to the three spatial scale and their related tasks.

- At the regional spatial scale, the task is “alertness”: the experts need to have a global vision of the event and its probable consequences. A base map of the whole region with the location of the epicenter, and the PTWC alert message are needed. Additionally, the Tsunami Travel Time (TTT) and the earthquake information must be displayed upon request. Data used at this level are extracted from the PTWC alert message.
- At the local spatial scale, the task is “risk assessment”: the experts have to see information for the entire island to decide where to dispatch the rescues first. Thus, they need information about the three viewpoints:
    - For the *hazard* point of view, experts need to know the probable local tsunami height, in order to derive submerged areas. Water heights are extracted from the PTWC alert message and pre-computed tsunami forecast models. Submerged areas are locally derived using LITTO3D Digital Terrain Model.
    - For the *potential issues* point of view, populations and infrastructures impacted by the tsunami have to be quickly identified. Infrastructures (e.g. buildings, roads) are extracted from the BDTOPO topographic database, and population density are derived from INSEE databases.
    - For the *risk* point of view, priority evacuations and secure areas should be identified, based on refuge sites and evacuation areas.
    - Additionally, rainfall at different periods of the crisis must be available to evaluate a potential amplified risk. Rainfall representations are generated from METEO FRANCE data.
- At the urban spatial scale, the task is “evacuation”: the experts need to plan the evacuation of people and boats. For this, they have to display the same type of information than at the local level but with more accuracy and reliability details.

We propose some multiplexing tools that can be associated with the scene, at each spatial scale, in order to help the experts in their decision-making:

- At the regional level, spatial and temporal multiplexing tools, such as swipe or animation, could be used to display more efficiently the wave progression and the Tsunami Travel Time.
- At the local level, spatial multiplexing tools can be implemented for mashing-up topographic, weather and temporal information to animate the rainfall.
- At the urban level, lenses and split/merge tools could be used to display risks information with different points of view.

IMPLEMENTATION : A TSUNAMI GEO-VISUALIZING PROTOTYPE USING MULTIPLEXING TOOLS

We implement the prototype using the Java language and two libraries: ZVTM (Pietriga, 2005) which is dedicated to the display of 2D representations on several screens (laptop, tablets, wall screens), and JavaFX to manage the interface[3].

Architecture of the prototype

The architecture of our prototype is described in Figure 7 and contains three major packages: one dedicated to the ZVTM library, one to the interaction with a PostGis database where data are stored (topographic or statistic data for example), and one dedicated to the Graphical User Interface (GUI). This last package is based on the Model View Controller (MVC) pattern.

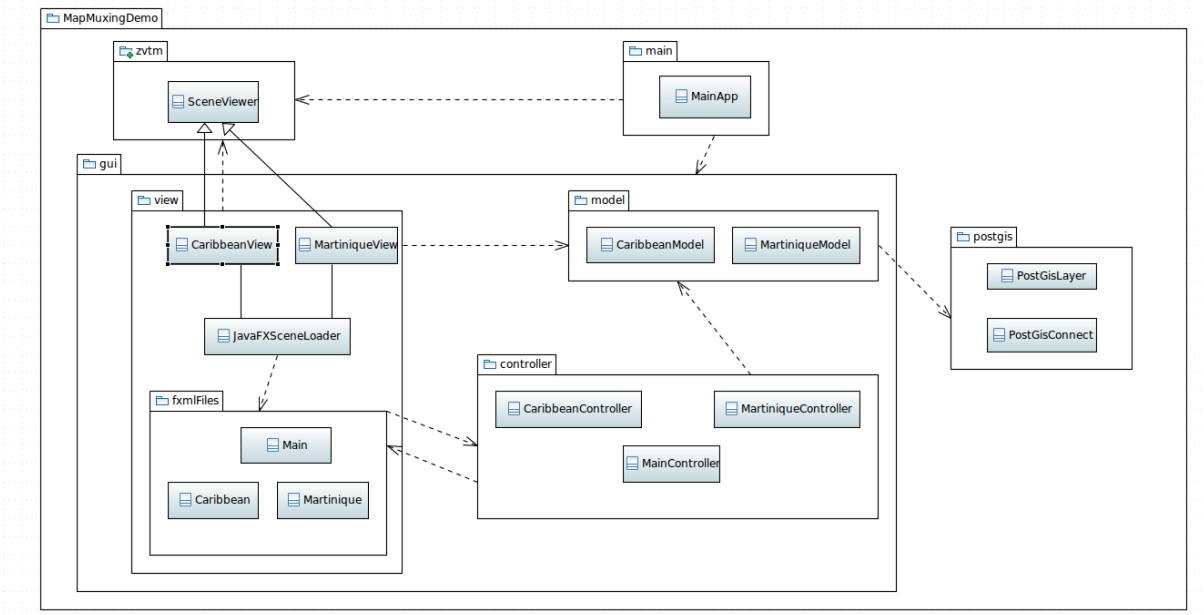

Figure 7 : Architecture of the prototype (UML package diagram)

Crisis unit user scenario at the regional level, the Caribbean region

We propose the following crisis unit user scenario, at the regional level, illustrated in Figure 8, when all of the frames are displayed: the screen is divided into several frames containing 1) a scene about Caribbean region for the hazard point of view on the left side, 2) the PTWC alert message on the right side (the message changes each time a new message is received), and 3) an overview to locate the scene in a largest region, on the bottom right side. This scene is composed by a tile map from the region (that can be changed by a menu), and some additional information about the earthquake (e.g. location and magnitude). The experts can see more information about the earthquake in an alert popup (4), by clicking on the epicenter placemark (5) or via a menu.

[3] http://www.oracle.com/us/technologies/java/050862.pdf

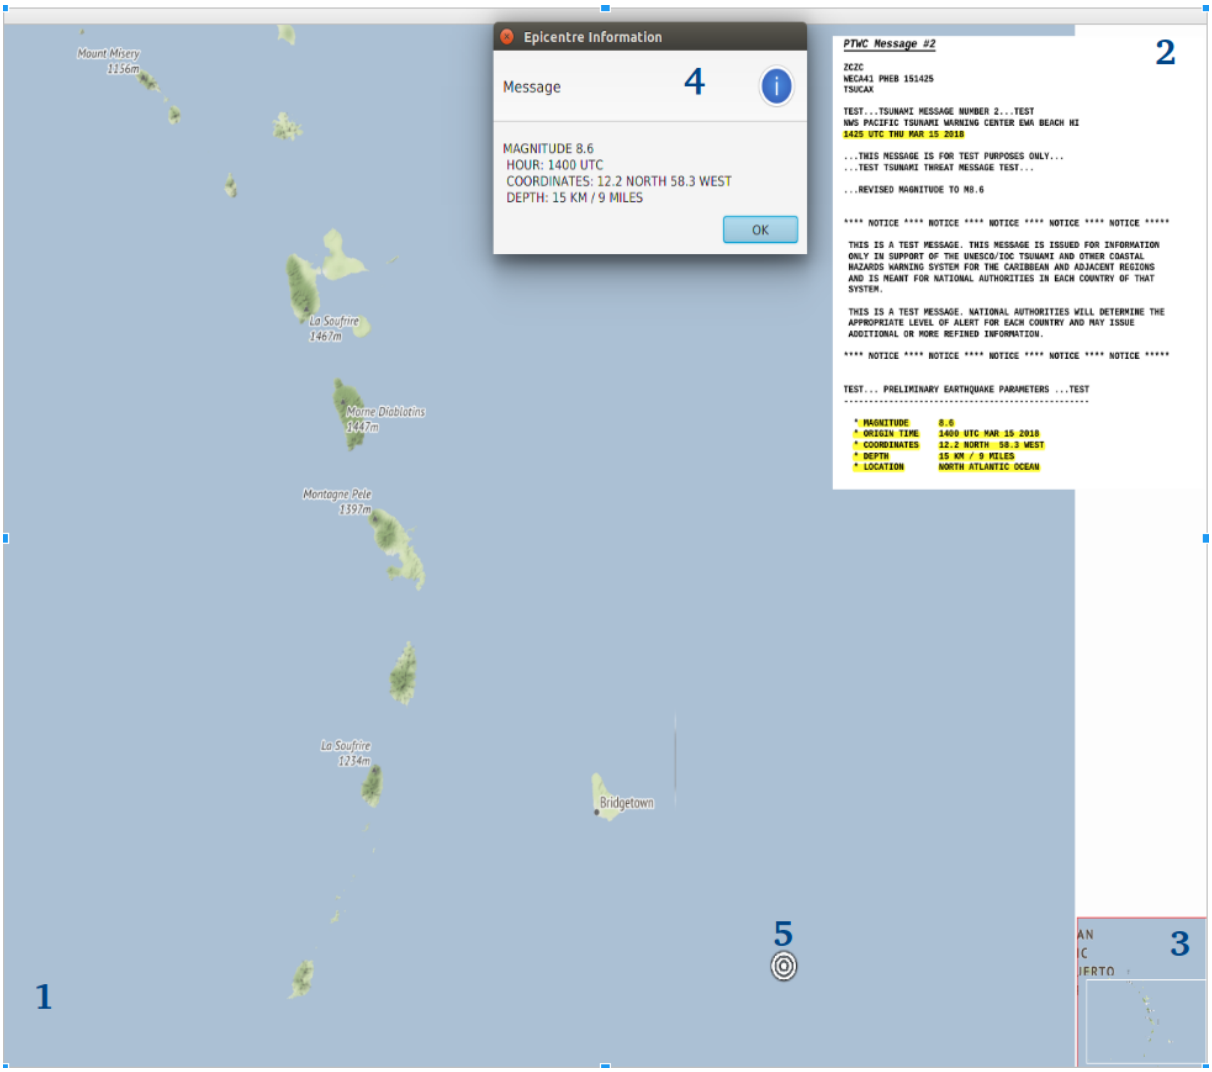

Figure 8 : Frames to be used for a user scenario at the regional scale: 1) Caribbean scene for the hazard point of view, 2) PTWC alert message, 3) Overview of a largest region, 4) Epicenter information, 5) Epicenter placemark

Additionally, experts can see via a menu, the Tsunami Travel Time (TTT) and the maximum predicted water height of the coast. This information gives the estimated time of arrival of the wave for all the Caribbean islands. Thus, they can decide to click on the Martinique island to see more information, and to decide where to dispatch the rescues. This action triggers the opening of a new frame on the Martinique scale.

Crisis unit user scenario: local level

The interface of the prototype is arranged in such a way that the frame of the Caribbean is not masked by the one of the Martinique (Figure 9). However, the main window is now the one of Martinique (but it is still possible to put forward the Caribbean one).

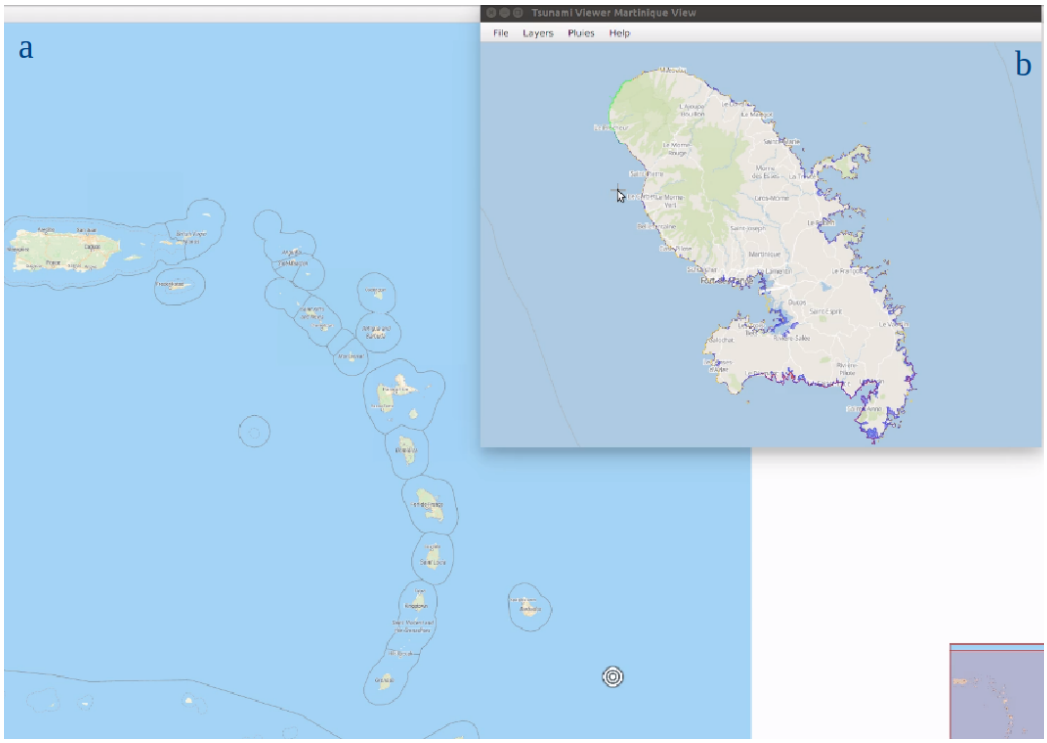

Figure 9: Space arrangement of the interface, with two frames at different scale: a) Regional scale, b) Local scale

The first frame displayed at the *Martinique* level is the hazard point of view (Figure 10a). At first sight, the experts can see the location of the main submerged area (colored in blue), and the water heights colored from green (low hazard) to red (significant hazard). By a menu, they can switch to the different viewpoints to navigate into scene from Hazard, Potential Issues or Risk. Figure 10b shows Potential Issues such as boats and buildings (in gray), and 10c shows the area to be evacuated (in green).

Figure 10: Martinique different scenes with: a) Hazard viewpoint, b) Potential Issue viewpoint and c) Risk viewpoint

Additionally, the experts can see the rainfall for each hour of the event (from 14h to 18h, figure 11b and 11c) or through an animation (Figure 11a). Rainfall accumulation for all day is also available. We use Meteo France semiology[4] to represent rainfalls, where in our simulation, light blue is less than 1mm and purple is higher than 10mm.

[4] http://www.meteofrance.com/previsions-meteo-france/simulations-numeriques-meteorologiques/france

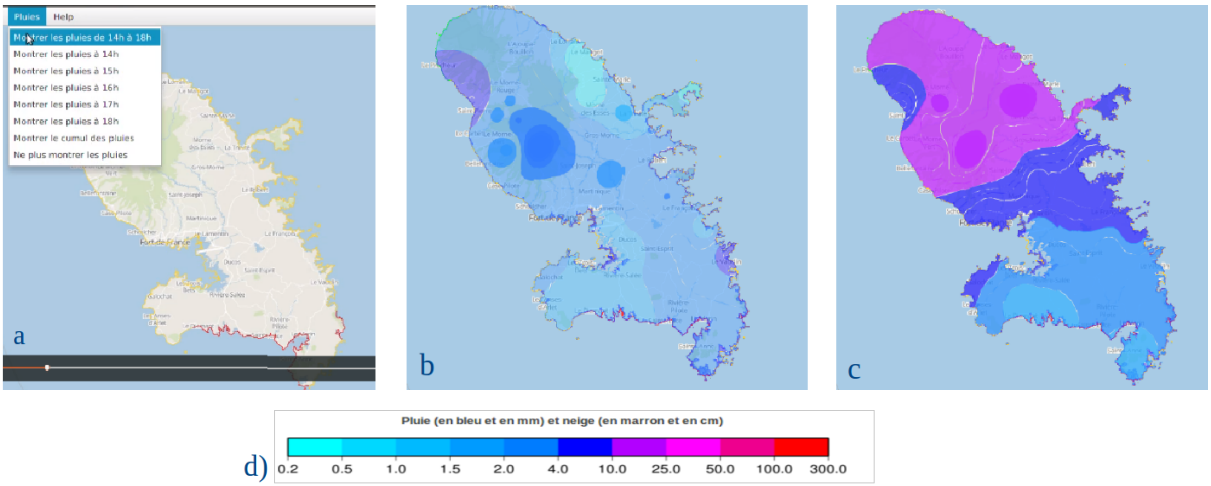

Figure 11: Rainfall animation during all the event (a), rainfall at 14h00 UTC (b), rainfall at 18h00 UTC (c) , and Meteo France scale semiology for rainfall display (d)

With all this information, the experts may notice that some strategic areas such as *Fort de France* town, the south of the island and the Atlantic ocean south coast will be more impacted by the tsunami than the north of the island. Thus, they have to zoom to these areas to check the potential issues and make the right decisions to keep people and boats safe. To illustrate this scenario, experts decide to click on the south of the island to see more details about the city of *Le Marin*.

Crisis unit user scenario: urban level

A new frame opens a display of an urban scene according to the hazard viewpoint. This new frame is located at the bottom left of the screen, allowing the visibility of both regional and local frames into the entire interface space (figure 12).

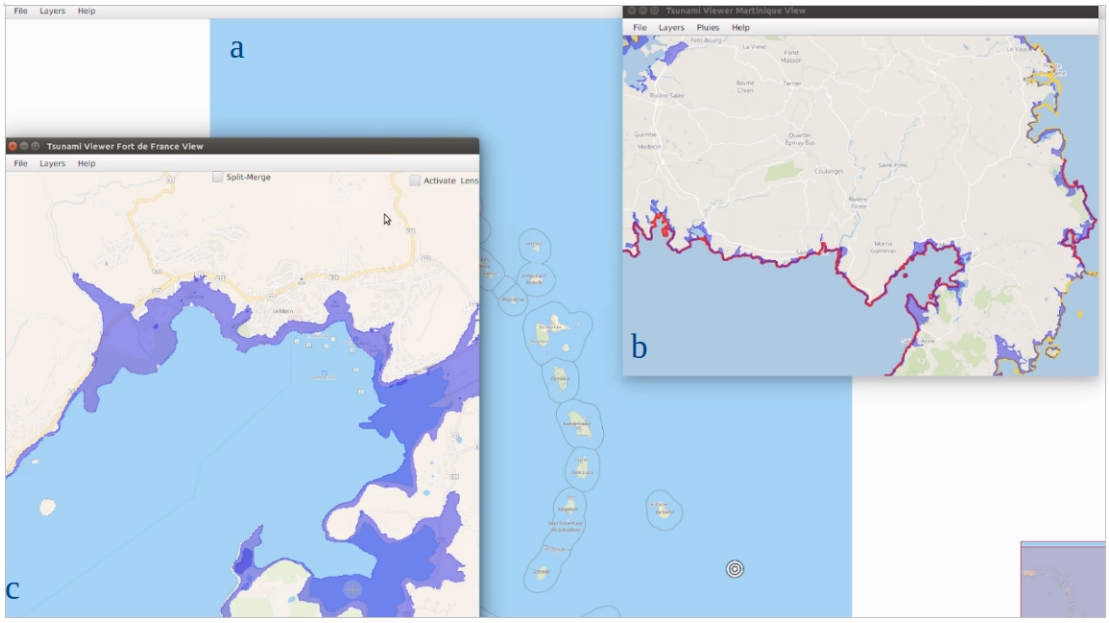

Figure 12: Frame spatial arrangement to see all scales : a) Regional level, b) Local level and c) Urban level

At this level, the experts may have to organize the pedestrian and boat evacuation. For that, they have to explore data from the three points of view (Hazard, Potential Issues and Risk). First, they may want to see data from two viewpoints in a single aggregated scene to assess which potential issues are impacted by the tsunami and evaluate how many people and boats to evacuate. To achieve this task, we propose to help the experts by the use of lenses multiplexing tool where one point of view is seen as the context and the over, inside the lens as the focus. Figure 13 gives an example of how we can use lenses at the urban level: in Figure 13-a, the *Potential*

Issue viewpoint is the focus inside the lens (showing people, road, buildings and boat that might be impacted by the wave), and the *Hazard* viewpoint is the context where we can see, the submerged area. In Figure 13-b, the context represents the *Potential Issues* and the focus is the *Hazard*. This example shows that the use of lenses can be potentially helpful in a crisis management context.

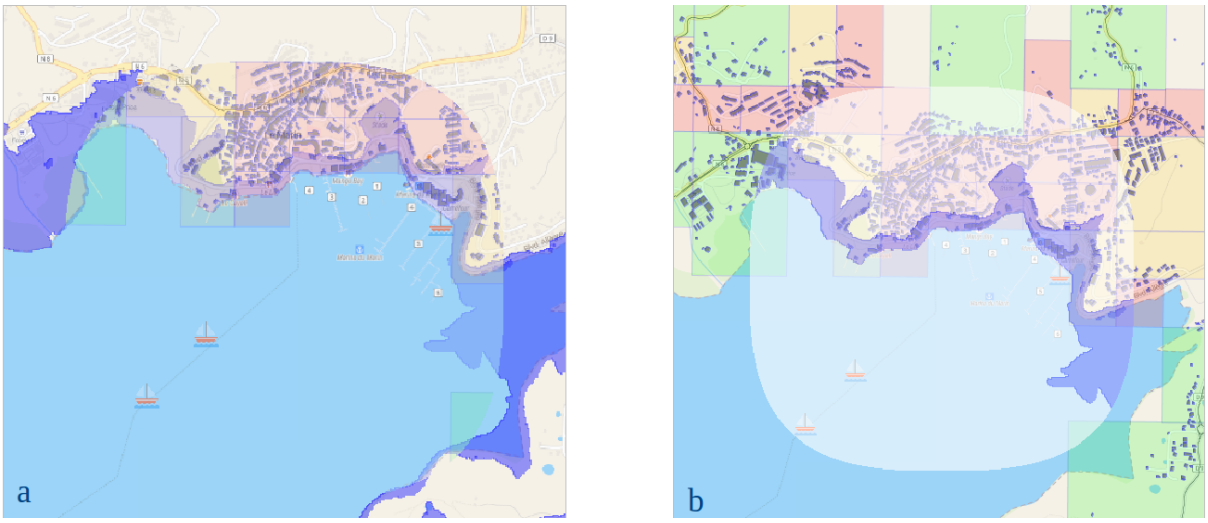

Figure 13 : Using lens to show different points of view into the same scene: a) Focus=Potential issues viewpoint, Context=Alea viewpoint; b) Focus=Alea viewpoint, Context=Potential issues viewpoint.

Additionally, the experts want to focus on the risk viewpoint to plan the evacuation. In this scene, superimposed datasets are displayed to the experts such as the population to evacuate (from green to red depending on the number of people impacted), submerged roads (in red), location of the refuge sites, or even boats to be evacuated offshore (Cf. Figure 14).

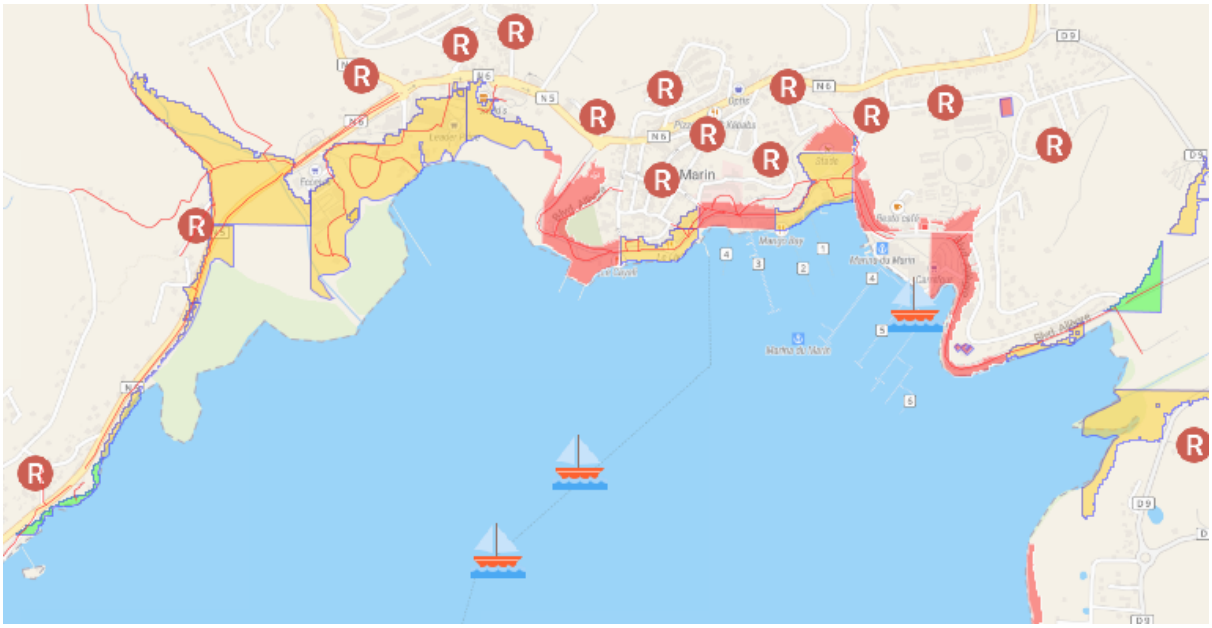

Figure 14 : Superimposition of several datasets for the risk point of view in the same scene

Visualizing all this superimposed information can lead to cognitive overload and is not efficient for the experts to perform their analysis in order to facilitate decision-making. To help the experts in this task, we propose to use a splitting multiplexing tool to break up the risk information into three distinct scenes: boats to evacuate, impacted population and submerged roads (Cf. Figure 15).

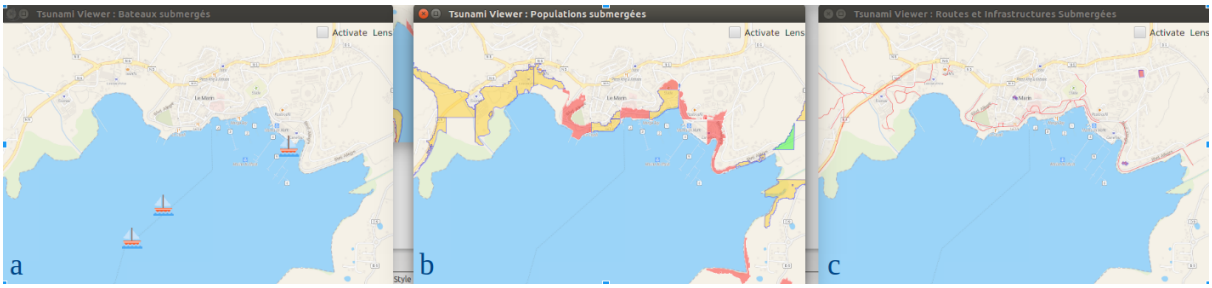

Figure 15 : Juxtaposition of scenes for the risk point of view by using a split/merge tool: a) boats to evacuate, b) impacted population, c) submerged roads.

By using this feature, the experts can focus on one major risk at a time, while keeping a view on other risks. With a menu button, the experts can easily switch from the merge to the split view. Using a split/merge multiplexing tool allows the experts to choose between aggregate or separate dataset. The separation reduces the graphic overload associated to the risk representation, and allows also experts to work collaboratively on different aspects of the crisis management. Additionally, expert can use a lens into one view to see for instance other information available (e.g. the refuge sites). We can easily assume that the use of a splitting multiplexing tool associated with a lens would be useful at the risk viewpoint to plan evacuation and lead people security.

DISCUSSION

The proposed model to manage multiple representations, as well as the developed prototype, already provide a formal framework for the co-visualization of information. Even if this contribution has not been completed by user tests, it offers potential answers to three limitations observed during our visits in crisis units:

- The difficulty to navigate efficiently from one visual representation to another,
- The difficulty of combining visual representations to extract new information,
- The impossibility of synchronizing spatio-temporal representations.

First of all, given that the proposed model formalizes the spatial relations between frames, it facilitates navigation between scales (as shown by the application example between Caribbean and Martinique representations), as well as the co-visualization of information on the same scale at the same time, using spatial multiplexing tools (for example using lenses).

Secondly, the formalization of spatial and semantic relations between scenes in the proposed model is supposed to facilitate the combination of information to deduce a new one. This has been illustrated by the crossing of hazards and issues to deduce elements at risk, but it was also observed in another visit on the intersection between atmospheric pressure and temperatures to deduce precipitations. As a perspective, it may be judicious to perform a user test in order to assess the capabilities offered by spatial multiplexing tools, such as lenses, to extract information inherited from multiple representations.

Finally, the model also proposes to formalize temporal relations between representations, which can be added to the spatial and semantic relationships already described. If the current model is conceptually able to link multiple representations by temporal relations, the operational implementation of these relations within the prototype is not yet effective. This question also raises issues related to the visual interpretation of the combination of animated phenomena. Indeed, it can on the one hand allow a crisis manager to anticipate (by observing the evolution of a phenomenon and by extending it cognitively), while also being able to disturb its capacity of decision-making because of the potential visual overload implied by these animated evolutions.

The current progress of this work leaves us to think that the field of crisis management can benefit from advances in terms of geo-visualization, and more particularly multiplexing techniques (spatial and temporal) to better manage heterogeneous representations used in an emergency and decision-making context. For this purpose, this work must be enriched with real uses cases experiments, in order to evaluate the benefits of the developed tools and methods to improve co-visualization of information for crisis management.

CONCLUSION

In this article we propose to explore spatial and temporal multiplexing techniques in order to improve co-visualization between visual representations of heterogeneous spatiotemporal data. This project is born during the visit of several crisis units. During these visits, we observed that many cartographic representations were

displayed on wall screens in order to facilitate the process of decision-making. However, we identified that these representations remained independent, which made navigation between representations difficult, and that the information represented remained difficult to combine, as it was often transmitted through raw data flows. If the visualization of these different representations could thus prove benefits in a context of crisis management, we could note that the lack of interdependence, and the impossibility of combining this information could also prove to disturb crisis managers. Therefore, we propose in this article (1) to elaborate a generic model allowing to formalize the relations (spatial, temporal and semantic) between representations, (2) to explore spatial and temporal multiplexing techniques in order to facilitate the co-visualization between heterogeneous spatiotemporal data, (3) to implement the model and the multiplexing techniques within a prototype software.

To illustrate the functioning of this prototype, we used a case study on a tsunami in the Caribbean region. Information on this scenario is coming from the *CARIBE WAVE 18* crisis exercise. This case study proved to be relevant to illustrate how the prototype works, since a tsunami can have catastrophic consequences over large areas in a very short time, which leads crisis managers to plan interventions on different areas. In terms of geovisualization, it involves experts to navigate between different scales of representation, and to combine different points of view (Hazards, Potential Issues and Elements at Risk). The proposed prototype, which includes a model for the formalization of the spatial relations between representations, associated with multiplexing techniques (spatial and temporal), offers a first contribution to manage these multi-dimensional constraints associated with the co-visualization of information for the crisis management.

Improvements still need to be integrated in these developments, particularly on the handling of the temporal dimension between representations, in order to allow experts to anticipate the consequences of a phenomenon in its dynamics characteristics. In addition, user tests should also be conducted in order to validate the benefits of the spatial and temporal multiplexing techniques in a crisis management context.

Obviously, this work leaves us to think that the field of crisis management can benefit from the advances in the fields of Geovisualization and Human Computer Interactions to better manage the co-visualization of information in a crisis management context related to natural disaster events.

ACKNOWLEDGMENTS

This research was funded by the french ANR MapMuxing program (ANR-14-CE24-0011-01). We want to particularly thank Meteo-France Martinique team who provided the climate data used for the prototype.

ABSTRACT

In this paper, we propose a method for understanding the semantics of mobility (mainly related to lifestyle) patterns based on stay point detection from tracking data. The method identifies the context (trip purpose and visited point of interest) of tracking data by using large-scale data collection infrastructure. We evaluate our method with a tracking dataset in Birmingham (European project SETA) generated by 534 users from September 2017 to September 2018. To this end, we compare insights from the tracking data with check-in mobility in social media. The results show that both data capture rich human lifestyle features related to the visited point of interest. Our study provides solid evidence that lifestyle patterns from tracking and social media data can indeed be useful for understanding and gauging the level of disruption after a crisis, as it is possible to check the deviation of habits from normal conditions and post-crisis.

Keywords

lifestyle patterns, mobility patterns, semantic annotations, semantic mobility.

INTRODUCTION

Disaster severity and frequency trends have risen significantly in recent decades. Understanding human mobility, specifically lifestyle patterns is crucial for crisis responders and policymakers in determining effective strategies for disaster response, especially recovery or evacuation plans (Wang and Taylor, 2016). These lifestyle patterns are related to spatial and temporal regularity. Spatial regularity means a person is going to similar places or point of interest (POI); temporal regularity can be considered as when a person visits the same POI at a similar time of the day. Natural disasters such as earthquakes, storms, etc. are serious threats to urban areas affecting daily lifestyles because such events can devastate public infrastructure usually visited by people. Adjusting lifestyles to deal with crisis events can be problematic. Therefore, understanding human daily life pattern changes such as trip purpose and use of public infrastructure (shopping malls, food places, stations, etc.) will enable decision makers to monitor and analyse the impact of any disaster in the urban area, providing advantages for risk assessment, preparedness, emergency management and plans for recovery or reconstruction actions primarily related to the needs of citizens, such as where to obtain supplies of food and clothing.

Recently, technologies have been developed to capture human mobility data. The movement of people may be tracked and recorded in real time easily using wireless and sensor technology. Apps created by big companies such as Google, Apple, and Facebook collect our daily patterns of regularity related to place and the time spent there. Furthermore, with the increased popularity of social media, a large amount of check-in data can also be used to capture human mobility. Learning and understanding this data can help to analyse lifestyle patterns related to a crisis event. However, the accuracy, sparsity and semantic representation of tracking data pose challenges in understanding lifestyle patterns. Raw tracking data in the form of a time sequence of locations are not easily understandable without semantic representation.

Human mobility analysis has been applied to support crisis management using crowdsourcing (Ludwig et al., 2017), GPS data (Song et al., 2017), and social media (Xiao, Huang and Wu, 2015). Furthermore, effective models for simulating and predicting human movement after a crisis have been proposed (Song et al., 2015, 2017). However, there is still a lack in previous studies related to understanding human mobility to support

crisis management. Most are concerned with specific mobility data. They only use tracking data (GPS trajectory), transportation networks, CDR or social media, but do not integrate these data to give more insight into daily urban life patterns. By incorporating these data, habit deviation from normal and post-event, the changes in crowd mobility, levels of disruption after an event can be assessed accurately to support crisis management. If mobility and distribution patterns can be efficiently identified then post-crisis risk can be minimalised, crisis responders or rescue resources will arrive on time, understand what the population needs, how the different part of a city are connected and provide better evacuation plans. Specifically, the research uses GPS trajectory data only focused on motorised mobility (ex: using taxi trajectory) and does not discuss other types of mobility (walking, running, cycling, etc.). It does not explain detailed semantics of mobility such as the associated behaviour to the mobility, trip purpose or how the population use the POI.

This work aims to identify semantic mobility patterns in the metropolitan area from two datasets: tracking and social media data. The tracking data collected by apps (iOS and Android apps as a part of the European project SETA, http://setamobility.weebly.com/) that track multimodal mobility patterns in three cities (Birmingham, Santander, Turin). Since social media data relationships could explain 10%-30% of all human movement (Cho, Myers and Leskovec, 2011), we compare the patterns in tracking data with check-in patterns found in social media data. 'Check-in' refers to the specific time and location of a particular user shown by use of online social applications.

In this study, we present a method to build semantic mobility patterns from tracking data. We develop a model to discover trip purpose and important places in people's daily life based on stay point. The model will allow the analysis of human daily lifestyle patterns, when or where people use public infrastructure such as shopping malls, food places, stations, etc. Furthermore, knowledge of everyday patterns allows understanding of the citizen's needs (where they get supplies (e.g. food, clothing), where they go at the weekend, how the different parts of the city are connected, etc.). Specifically, it also shows and gauges the level of disruption after an event, as it is possible to check the deviation of habits from a normal situation and post-event. This detailed information is very useful for decision makers or policymakers.

In summary, the contributions of this paper are:

- We study an important and challenging problem of understanding human lifestyle patterns in tracking data records. We build context annotations that help bridge the gap between raw tracking data and surrounding contexts and hugely enrich our understanding of mobility data.
- Different from existing studies on human mobility for crisis management which do not consider detailed semantics of mobility, we propose a semantic model to capture meaningful user activity based on stay points and type of location visited.
- We conduct experiments on large-scale mobility datasets in Birmingham (534 users in tracking data and 116,468 users in social media).

Below, we discuss related work and challenges in understanding human mobility in crisis events. Next, we describe heterogenous datasets used in this research. We present a method for identifying human semantic mobility in the system overview and framework section. The results of our experiment are discussed in the Results and Discussion section. Finally, we conclude the paper and provide some directions for future work.

RELATED WORK

A number of studies have been made on how mobility patterns can be utilised to supporting crisis management by applying techniques such as crowdsourcing, GPS data, and social media. Many studies have employed the content of social media such as tweets to identify irregularities in human movements or communication before, during, and after disasters (Hong, Fu, Torrens and Frias-Martinez, 2017; Kumar and Ukkusuri, 2018; Xiao, Huang and Wu, 2015). Other researchers have proposed a general model to identify human post-crisis movement patterns based on mobile GPS data (Song et al., 2015, 2017). Call Detail Records (CDR) have also been used by researchers to explore communication behaviour changes caused by disasters, especially in particular locations where resources for evaluating mobility behaviours are rarely available (Hong, Mashhadi and Frias-Martinez, 2018). While these studies present in-depth investigations of large-scale human mobility, they often focus on specific types of disaster without considering other potential considerations in the aftermath of crises such as the dynamics of population lifestyle in the affected area (how the citizens use POI in the affected area).

Another stream of work developed a model to predict human mobility during or after a crisis. Song et al (Song et al., 2015) proposed an effective model based on a Hidden Markov Model to predict human mobility following disasters, the Great East Japan Earthquake and Fukushima nuclear accident, based on GPS records, news, and

transportation networks. Recently, a deep learning framework was developed to predict regular and irregular human mobility during rare events in the city from historical GPS data (Fan et al., 2018). These prediction models, however, usually lack semantic understanding of mobility because they did not consider transportation mode - stay, walk, bicycle, car, train - and were not associated with other context data such as POI, weather, or event information which could provide detailed knowledge to boost prediction accuracy.

The most similar work to this paper examined a process to annotate raw tracking data with some contextual sources. Adding semantic annotations is a key for human mobility analysis, especially finding behaviour patterns from tracking data. Point-of-Interest Extraction (PIE) Algorithm annotated stay points in indoor activities by defining parcel polygons and polygons-of-interest (de Graaff, de By and van Keulen, 2016). Furthermore, a framework which combined trajectory segmentation (move or stop) with contextual information (OpenStreetMap[1] and Ordnance Survey UK[2]) examined the type of place visited by the volunteered GPS trajectories (Siła-Nowicka et al., 2016). Other works also studied the function of each region (zones) in a city using a topic modelling approach based on taxi trajectories and POI data (Yuan, Zheng and Xie, 2017). The method annotates functional zones with semantic terms by calculating an average POI feature vector (rank POI category in a zone) and frequently observed mobility pattern in each zone. In addition, research related to mobility based on check-in location in social media has also been conducted. Constructing a tourist travel diary in Hongkong based on POI check-in obtained detailed trip and contextual information reflecting tourist activities (Vu et al., 2017). Chao et al analysed college community patterns in Wuhan based on geotagged Weibo messages (Yan et al., 2018).

HETEROGENEOUS DATA SOURCES

In this work, we employ various data sources to build semantic understanding of human mobility to support crisis management; they can be summarized as follows:

- **Tracking Data:** We collected tracking data from thousands of users in Birmingham, Santander, and Turin from September 2017 - September 2018. As a case, we use tracking data from 534 users in Birmingham. The SETA apps have been distributed to the citizen with some social economic category (a specific type of population). Users are voluntary and entirely aware that they are being tracked for research purpose. Data were collected and managed by large scale architecture that provide query processing, integrated processing, Reliability, Data Privacy, and Security. The framework and architecture for data collection were discussed in the previous research (Ciravegna et al., 2018)
- **Social media data:** We extracted check-in data in Birmingham, UK from the geo-located tweets (Twitter) of 116,468 users from September 2017 to September 2018.
- **POI database:** We built a POI database based on data from Foursquare[3] and google places[4]. The data contain information about POI, such as name, location, POI category, opening times.
- **OpenStreetMap Database:** We used the UK OpenStreetMap database to map tracking data with potential stay points.
- **Postcode database:** We used the UK postcode database to map stay points with the nearest postcode.

SYSTEM ARCHITECTURE AND FRAMEWORK

In this section, we describe the system architecture for developing a semantic understanding of human mobility from tracking data to support crisis management. As explained above, the framework and data collection infrastructure has been discussed in previous research (Ciravegna et al., 2018). Therefore, the following system architecture (Figure 1) focuses on the data processing method.

[1] https://www.openstreetmap.org/
[2] https://www.ordnancesurvey.co.uk/
[3] https://foursquare.com/
[4] https://cloud.google.com/maps-platform/places/

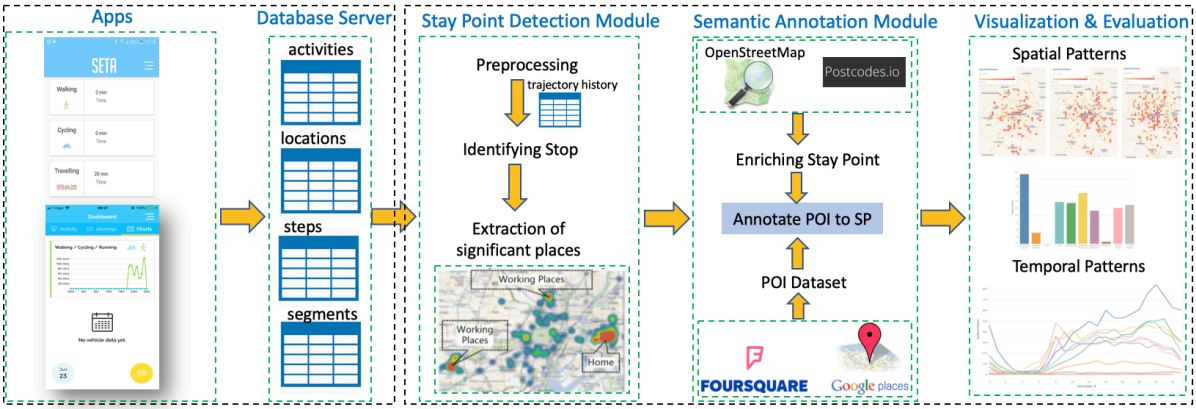

Figure 1 System Architecture & Framework

Our framework comprised four components: Data Collection Tool; Stay Point Detection Module; Semantic Annotation Module; and Visualization and Evaluation module. The detailed description of each part is explained in the following sub section.

Data Collection Tool

The SETA app is a mobile application that monitors a person's movement and presents a summary and breakdown of their day so that a user can track their level of mobility. The app tracks vehicular and active mobility to allow the next analysis related to lifestyle patterns such as stay point or trip purpose that refer to the points of interest. This application captures data from mobile phone sensors, such as accelerometer, GPS (location), and pedometer (steps). Data from multiple sensors are analysed and combined to produce segments of activity such as walking, cycling, and running, including step counts, time of activity started and ended, and individual locations (latitude, longitude).

The apps fuse individual tracking data, sent to the server and immediately stored in a database. The final dataset collected is extracted, validated, analysed and filtered to form tables which store data about activity, locations, segments, and steps.

Stay Point Detection Module

Real tracking data are often not accurate, due to noise, missing, or incomplete data. Processing this low-quality data will lead to poor results. The pre-processing step is performed to provide clean and valid data to obtain useful features. Any duplicate record is removed, the timestamp locations checked with excluded locations with the same timestamp. The pre-processing step also does temporal alignment by aligning raw data (activities, locations, steps, and segments) captured from different phone sensors into one history table. The alignment process classifies locations into activity segments based on the location timestamp. All locations between activity segment start time and end time are classified as one location segments and then the activity is attached to the location. The segments categorised in 6 activities are Vehicle, Cycling, Stationary, Other, Walking, and Running.

Stay point is the set of geographical points where a person stays for a while within a certain distance threshold. In general, stay point can be represented as a set of consecutive GPS locations $L=\{l_m, l_{m+1}, l_{m+2}, \ldots, l_n\}$ *where* $\forall_i$, $m< i\leq n$, $distance(l_m, l_n)\leq dthreshold$ *and* $|duration(l_m, l_n)|\geq tthreshold$. The distance between two geographical locations is computed by using the Haversine formula and the time span between two location points is defined as stay duration. Stay point plays a major role in adding a context or semantic meaning to trajectories. Identifying the stay points allow us to segment the trajectory to be a stop or move, determine mode transition e.g. walking to bus, and infer trip purposes by associating it with POI information.

We develop an algorithm based on the PIE algorithm (de Graaff, de By and van Keulen, 2016) and the algorithm proposed by Li et al (Li et al., 2008) to obtain stay points from tracking data. The procedure to acquire stay points from tracking data can be seen in algorithm 1 (see Figure 2).

Algorithm 1 Stay Point Detection

INPUT:
1. *UT* = list of user trajectories {<lat,lon,t,seg>, <lat,lon,t,seg>, ...<lat,lon,t,seg>}
2. *eps*, the stay point distance threshold in meters
3. *t*, the stay point duration threshold in millisecond

OUTPUT:
1. SP = {sp_1, sp_2, ..., sp_m} the list of stay points
2. Clustering of Stay Point
3. Home Place

begin
  for each user **do**
    //Remove inaccurate locations that greater than the average of accuracy
    listLocationsPoints = $\{l_p \in UT \mid l_p.a \leq avg(a)\}$

    //Get candidate stay points for each day
    listCandidateStayPoints = *getCandidateStayPoints (listLocationsPoints, eps, t)*

    //Cluster candidate Stay Point by applying DBSCAN and generate centroid
    listStayPointCluster = *getClusterDBSCAN (listCandidateStayPoints)*

    //Generate summary of stay point (occurrence, days, duration)
    listSummarySP = *generateSummarySP (*listStayPointCluster*)*

    //define some significant places: home, SP1, SP2, SP3, etc
    defineHomePlace(stayPoints, summarySP)
end

Figure 2 Algorithm to extract stay points

The algorithm works by retrieving a sequence of locations for each user trajectory. The inaccurate locations are removed based on the average of location accuracy in the data. The stay point candidates for each user are generated by considering the distance and duration threshold parameters. We also consider the type of location segment in deciding stay point candidates. The '*stationary segment'* means that users stop in certain locations for a certain time based on segment timestamp. We focus only on the stay point where the user stays for equal to or more than to 5 minutes and not give much attention to shorter stay points such as traffic light stops, traffic at roundabouts, etc.

The stay point candidates are location clusters which consist of one or more stop locations. Even though the most inaccurate locations are already previously removed, the stop locations could contain locations outside of the POI. Therefore, we utilise DBSCAN algorithm (Ester et al., 2008) with parameter *eps=30 meters* and *minPts=5* to get more accurate locations in the stay point and get a better centroid of the cluster based on remaining stay point locations.

For spatial and time regularity, we record features such as frequency, day, arrival time, leaving time, and stay duration to produce a summary of user stay points. We also create Origin-Destination matrices based on stay point to get detail journey of the user. We use this summary to detect Home place and extract other significant places. Home is considered the place where a person spends most of his/her time. Therefore, the rules for defining Home are:

i. The most frequently visited place with the most total duration of visits.
ii. The start and end location for every day.
iii. There should be at least 5 stop locations per week in the stay point.

We aggregated and clustered stay points for each user by temporal features (time, day) and spatial features (POI category, postcode) to understand human lifestyle patterns. Knowing daily patterns of citizens is critical to allow us in measuring the level of disruption after a crisis, as it is possible to monitor the deviation of the habit before and after the event. Figure 3 shows the distribution of stay points (on weekdays and weekends), with the sizes of the circle indicate number of stay points at the POI.

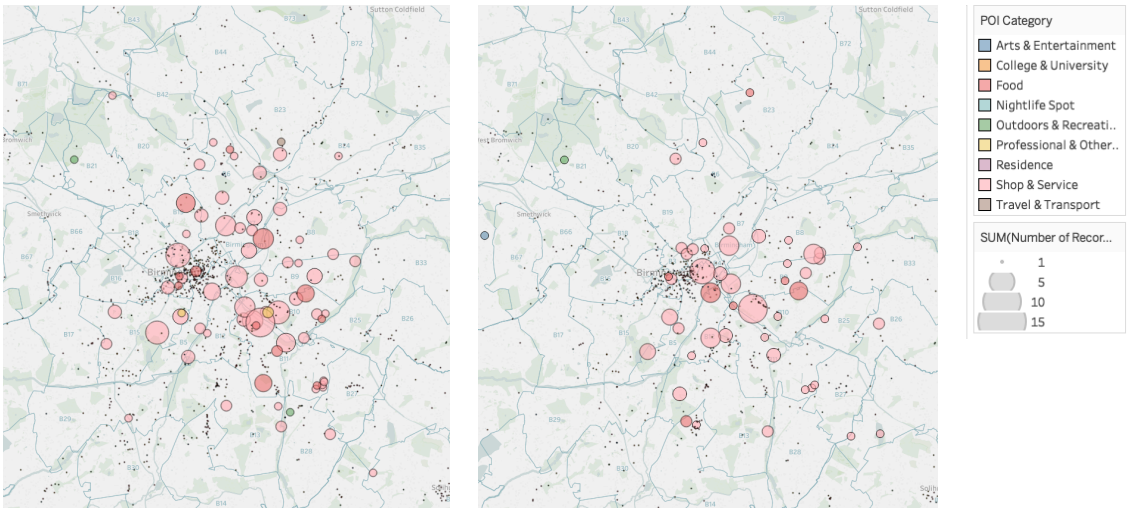

Figure 3 Distribution of stay point for weekdays (left) and weekend (right)

Semantic Annotation Module

Semantic annotation is a process of adding context to the stay point so we can classify it to the certain POI. We want to analyse which POI motivated stops in the stay point during the trip. There are two subprocesses to semantically annotate the individual trajectories: enriching stay points with additional data from OpenStreetMap and postcode.io[5]; and finally, annotating POI to the stay point.

To get more meaningful knowledge about activity label, we enriched stay point with related contextual information, such as OpenStreetMap and postcode. We mapped the stay point to the OpenStreetMap data by exploiting the information around the stopping place to get POIs nearby, land use, or amenity information. We utilized spatial relationship features supported by the PostGIS[6] database to determine if a stay point was entirely inside another geometry (polygon) or within the specified distance (maximum 100 m) of points or polygons representing the POIs. If this condition was fulfilled, then we assigned a name of POI nearby, land use, and amenity information (the nearest POI within 100m is assigned to the stay point which is not inside of another polygon). We also assigned postcode information to the stay point based on the nearest postcode.

The last process in building semantic annotation to the stay point is classifying stay point to the POI.

The POI dataset enables us to model the functionality of each area in the city. POI dataset gives some information about the venues, such as name, category, coordinate, opening times, and a bounding box. We built POI dataset based on data from Foursquare, OpenStreetMap, and google places. The POI dataset comprises 10 categories: *arts & entertainment, college & education, event, food, nightlife, outdoors & recreation, professional, residence, shops travel and transport*.

We queried foursquare Places API to collect POI information in Birmingham city with bounding box [{'south west': '52.381054, -2.033649', 'north east': '52.608707, -1.728858'}]. To cope with a limited request in the API, we used the technique introduced by Fei et all (Fei Wu, 2016). For each search query, the API returns at most 50 POIs. We performed recursive steps by partitioning the Birmingham map into smaller grids (four partitions for each iteration) if a query on the map or current grid returned 50 POIs. As a result, we obtained 19122 POIs. Figure 4 shows the distribution of POI categories in Birmingham City.

[5] http://postcodes.io/
[6] https://postgis.net/

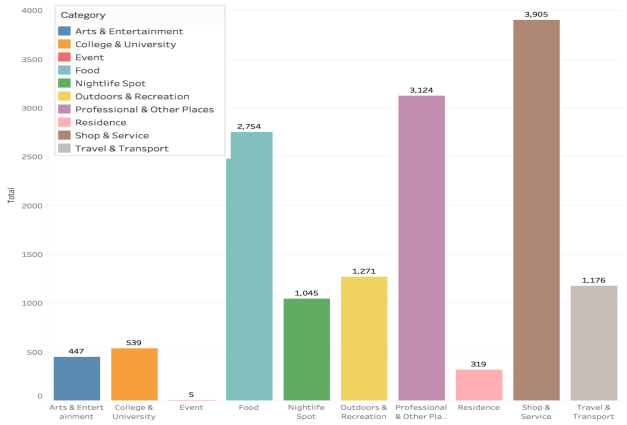

Figure 4 POI distribution in Birmingham, UK

Based on the defined POI dataset, the stay point is annotated with POI category. Home stay points located in residential areas are excluded from further analysis. The semantic annotation rule is applied by combining the distance-based method and contextual information previously found from OpenStreetMap. Other stay points are annotated with the POI based on the nearest distance, highest similarity POI name to the stay point and the arriving time in the range of POI opening times.

The algorithm to build semantic annotation to the stay point can be seen in the following algorithm (Figure 5).

Algorithm 2 Annotate Semantic SP

INPUT:
1. *SP*= list of significant places {<list stay point>,...}, *SSP=summary stay point {<summary SP>}*
2. *OpenStreetMap Data*
3. *POI database*

OUTPUT:
1. SSP = {sp_1, sp_2, ..., sp_n} the list of semantic stay points

begin
for each SP **do**
//enrich the stay points with postcode
SSP=getPostcode(stayPoint centroid)

enrich the stay points with OSM by considering spatial relationship
SSP = enrichStayPoint(listSummarySP)

$$\left\{ \begin{array}{l} sspI \in SSP \mid distance(sp, polygon) = 0 \vee distance(sp, polygon) < eps \vee \\ \qquad\qquad\qquad\qquad distance(sp, point) < eps \end{array} \right\}$$

//Add semantic to the stay points by considering same name and nearest POI
If not Home and not Land-use residential:
SSP=getSemanticSP(SPname, arrivalTime, POI Database)
end

Figure 5 Semantic annotation algorithm

Visualization and Evaluation Module

Semantic POI finds in the tracking data are visualized via a faceted browsing interface. We show the statistic on how the population in Birmingham used POI in the city and visualized the spatial distribution in the map. We also use this module to visualize POI check-in from social media. Such information is very useful for identifying the distribution of population during an emergency and therefore the number of people affected in each area.

EXTRACTING POI CHECK-IN FROM SOCIAL MEDIA

Location-based services in social media applications facilitate people sharing their check-in places (Cho, Myers and Leskovec, 2011). The check-in information contains geotagged venue and its geolocation attribute which are very useful in identifying human movement behaviour. Mobility pattern can be understood from social media data by extracting check-in tweets to get information about activity purpose. The activity purpose is inferred based on the category of the visited POI appearing in the tweet. Furthermore, the spatial distribution of popular places is represented by considering the total number of check-ins for different POI category and the popularity over time for those POI categories is considered as temporal distribution.

In this paper, we use 2,876,645 geotagged tweets from 116,468 users in Birmingham, UK from September 2017 to September 2018. We recorded geo-located tweets using Twitter search and streaming API[7]. After collecting this dataset, we selected the subset of tweets containing check-in word and Instagram. As a result, we obtained 43,971 check-in tweets for our analysis. Based on our observation, we extracted the check-in tweets by defining the strategy below:

i. Check-in tweet contains check-in words: ["I'm @", "I'm at", "I am @", "I am at", "arrived at", "arrived @", "I am in front of", "I'm in front of", "I'm going to", "I am going to"] followed by POI name.
ii. POI name in the check-in tweet is matched with POI name in POI database if:
    a. the distance between the geotagged tweet and POI coordinate is within 100 meters and
    b. the similarity between POI name is large or equal than 0.8. We use Lavenshtein distance[8] to compute the similarity between POI name.

Another rule applied to obtain check-in tweets was to utilize Instagram links found in the tweets. People publish their status on Instagram when they check-in to one place and this status links to their Twitter account. The Instagram content includes POI name without check-in word pattern. The text in the tweet will contain the Instagram link. Therefore, we extract the Instagram link in the Twitter and crawl the link to obtain a POI name where the user checks in. Then the matching rule in point ii is also applied to define the POI name. We also consider the POI opening time to validate the POI name. The example content of Instagram link can be seen in Figure 6 below.

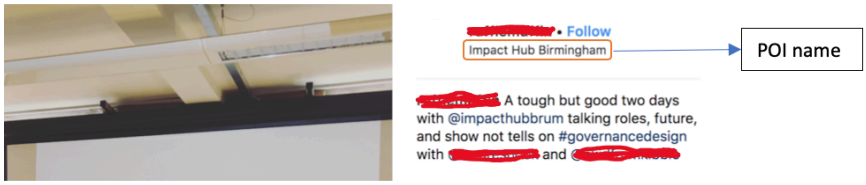

Figure 6 Example Instagram content link in a tweet

RESULTS AND DISCUSSION

In the following section, we present key findings derived from tracking and social media data. We demonstrate the capability of our method to capture rich information about human lifestyle patterns. Approaches were applied to analyse the behavioural characteristics of users in Birmingham from two perspectives: temporal pattern and spatial pattern analysis.

The tracking information was collected from 534 users in Birmingham during September 2017 to September 2018. The users were part of the population with certain characteristics related to a social-economic indicator such as income, ethnic community, medical condition or mental well-being. All tracking users were anonymous, and a single person could represent multiple users of the SETA app. Based on the framework implementation on tracking data, we found 72% (389) of users had more than 10 stay points and 50% (275) of users had between 10 and 38 stay points. Meanwhile, geotagged social media data were collected from Twitter users in Birmingham in the same period. We obtained 44,225 check-in locations in Birmingham with average 4 check-in locations per user (minimum=1, maximum=1680). Figure 7 shows the distribution of stay point or check in locations per user.

[7] https://developer.twitter.com/
[8] https://en.wikipedia.org/wiki/Levenshtein_distance

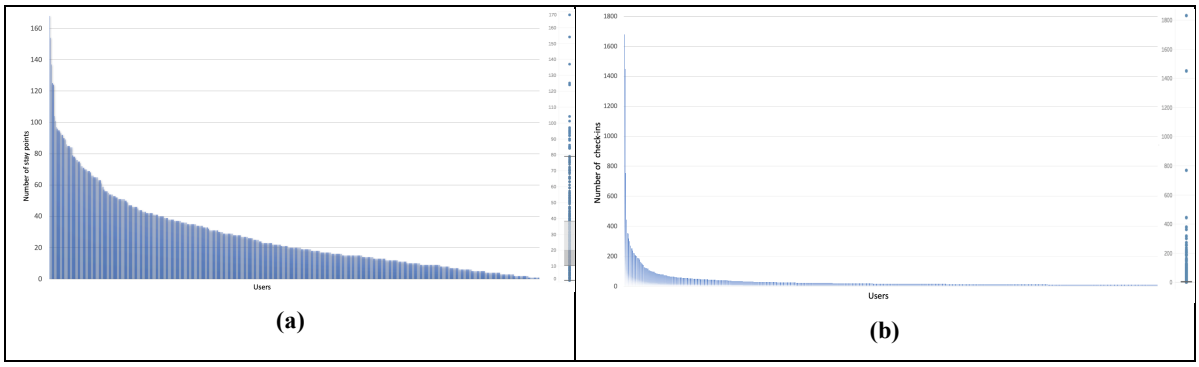

Figure 7 Number of stay point or check-in location per user. (a) tracking data (b) social media

Figure 8 shows the POI distribution for tracking and social media data. Overall, trend activity based on POI category visited by the user was very different. As can be seen, Shop & Service-related activity was the highest among user in tracking data. The remaining activities (Professional & Other places, Outdoor & Recreations, and Food related activity) follow with big different gaps. In contrast, activity patterns in social media were more uniform. Arts & Entertainment related activity was the most frequent and other activities (Food, Nightlife, Outdoor & Recreations, Professional & Other Places, Shop & Service, Travel & Transport related activity) had similar levels of popularity.

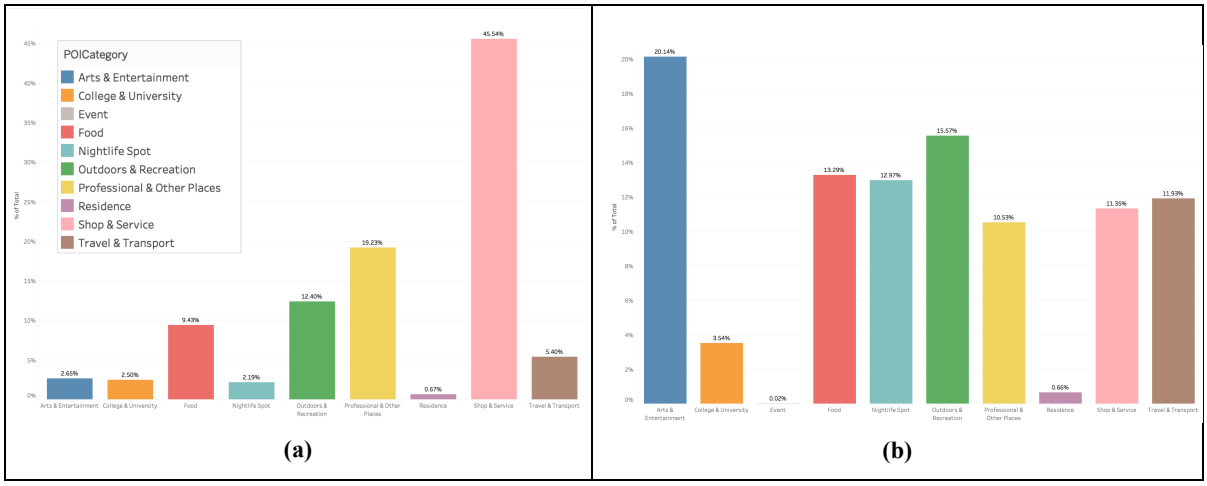

Figure 8 Statistic POI distribution (a) tracking data (b) social media

The following subsections discuss the temporal and spatial pattern results obtained from tracking and social media data.

Temporal Mobility Patterns

We extracted time (arrival time in tracking data and check-in time in social media) when users followed the activity. Figure 9 shows the number of stay points and check-ins per day. As can be seen, this pattern presents a glimpse of the active time of the user in tracking and social media data. Clearly, both users tended to follow their activities in the morning at 7 am. There is a major peak between 12 and 17 in tracking data that indicates most users followed their activity in the stay point at this time. In social media, the pattern reached a peak between 17 and 21 pm; this means that most users tended to post their activity information after office hours.

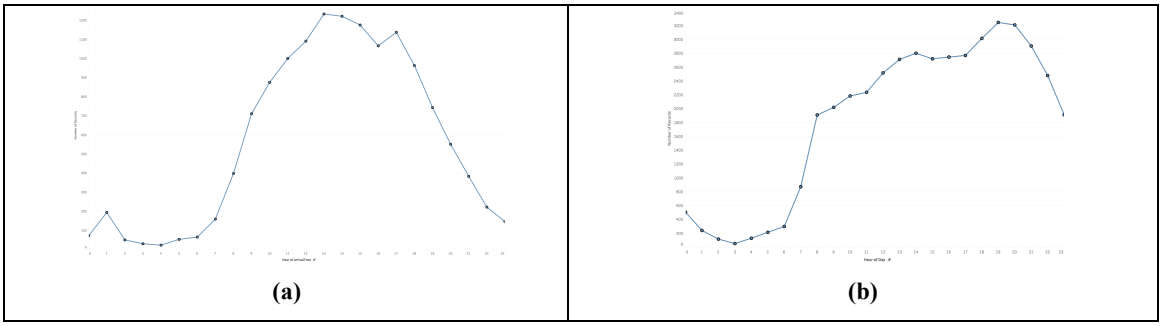

Figure 9 Time distribution of (a) tracking data and (b) social media

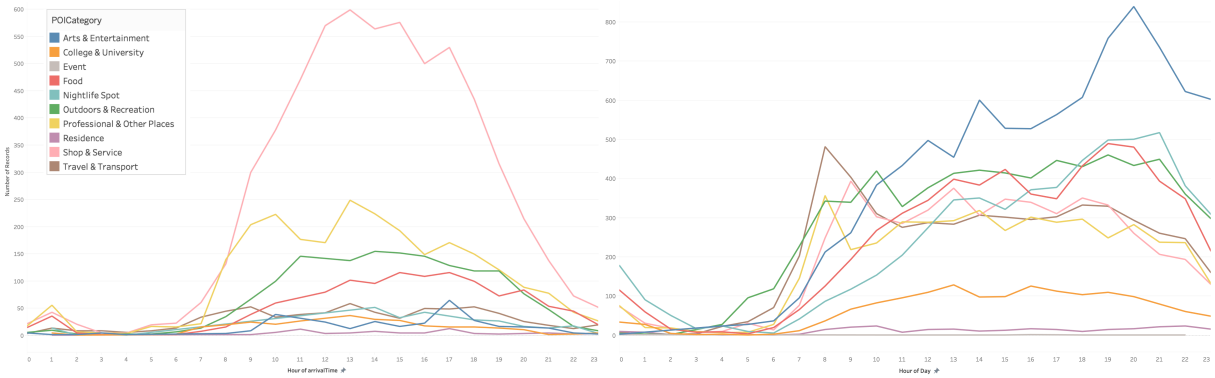
The temporal pattern indicates time-varying popularity where a place may be of interest to people. To reveal detailed temporal mobility regularity, we investigated the distribution of visits for POI category at different hours of the day. We aggregated the number of stay points or check-ins for each POI category in each hour of the day (see Figure 10). The weekly pattern of these visits was also examined and can be seen in Figure 11.

We observed that activity purpose had a pronounced impact on the time of activities. For instance, we can see that food-related activities in these two datasets had three distinct peaks around noon (12-13 pm), evening (15 pm) and early night (17-19 pm). Nightlife activities were more popular during afternoons and nights and peaked around night (21 pm) as these visits mostly constituted going to bars and nightclubs (even though, nightlife activity was not common in tracking data). Furthermore, we can see that activity related to professional places was increasing significantly in the morning (after 7 am) and remained steady between 8 am - 17 pm. This shows that this activity was mostly in a working place or school. Similarly, outdoor and recreation-related activity also remained constant between 6 am - 19 pm.

As pointed out above, shop and service-related activities were more dominant for tracking users (Figure 10(a)), increasing significantly in the morning (9 am), peaking around afternoon (13 pm), and dropping steadily until 17 pm. This pattern decreased dramatically after 17 pm. Using semantic stay point, we identified most of those places were the Shopping centre, Shopping Park, or supermarkets. This indicates that most users bought their supplies, such as food, clothing, etc. at this time. Most of the users also went to eat at food outlets or fast food restaurants between 13 and 17 pm. Professional & other place related activities rose sharply in the morning - at 8 am (going to work), reached a peak at 13 pm (back to work places after rest breaks) and fell gradually around 18 pm. Furthermore, the pattern shows that more people visited parks, leisure or sports centres around 11 am - 17 pm. Nightlife and Art & Entertainment related activities were less popular in tracking data at only 4.8% of all activity.

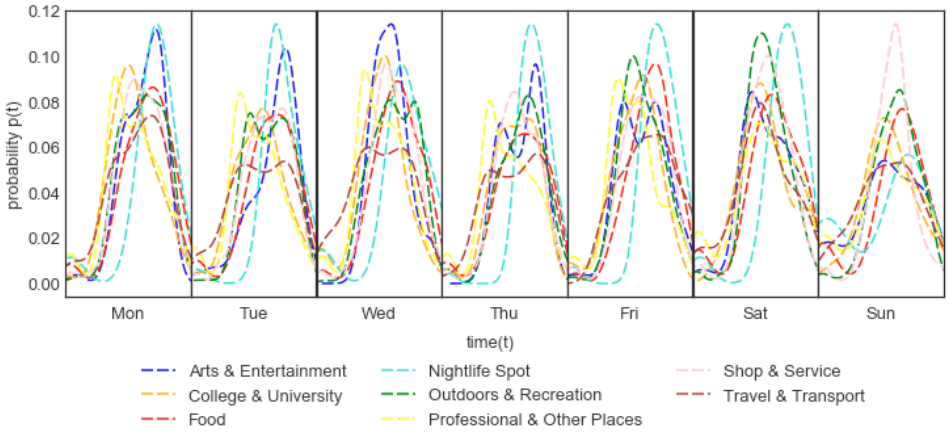


(a) **(b)**

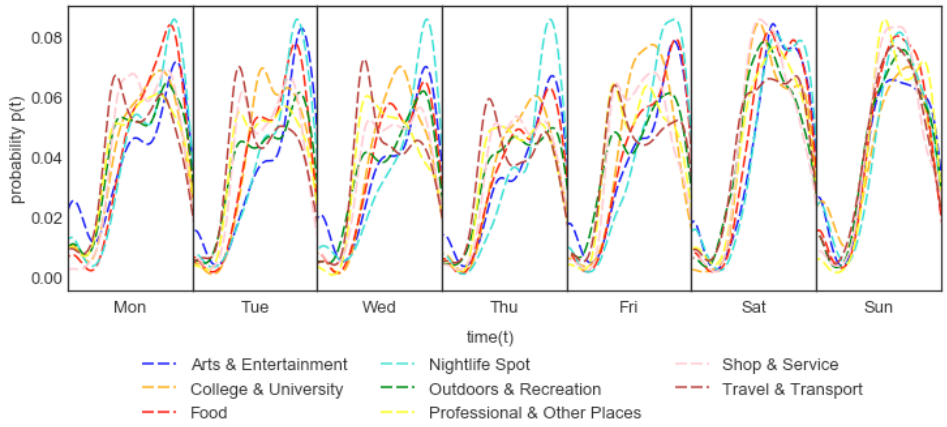
Figure 10 POI popularity over 24 hours in a day. (a) tracking data (b) social media

Figure 10(b) shows the activity patterns in social media were more comprehensive than tracking data. More people visited Art and Entertainment places around 14 pm and between 17 - 22 pm (after office hours) as these activities mostly involved attending an event in such places (Birmingham arena, The Genting Arena, O2 Academy, etc.). Shop and service-related activities fluctuated between 8 am - 19 pm and peaked around morning (9 am), and noon (13 pm). This activity was mainly conducted in food markets, shopping plaza, or shopping mall and some service places. Travel and transport activity reached a peak at 8 am when people were going to work, remained steady between 11 am and 18 pm, and decreased gradually after 18 pm when people finished working. Furthermore, most people bought food (eat and drink) in a restaurant or cafe at lunch (13 pm) and dinner time (19 pm - 20 pm).

Figure 11 shows the stay point or POI check-in density for every day in tracking and social media data. As can be seen, art and entertainment, and nightlife related activity was more popular on weekdays, and shopping activity was more dominant at the weekend. In social media, weekly patterns suggest that art and entertainment and nightlife related activity was dominant on weekdays after 12 pm, whereas shopping and recreation trips were predominant at the weekends. Users in social media also tended to post their activities from travel and transport places in the morning on weekdays. Similarly, tracking users visited art and entertainment and nightlife places on weekdays. Most users followed shopping & service, outdoors and recreation related activities at the weekend.



(a)



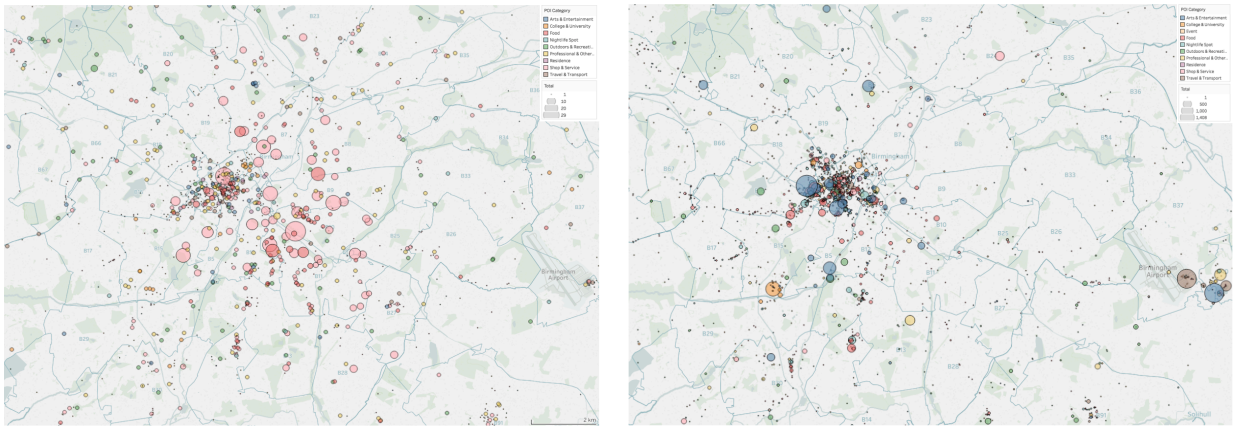
(b)

Figure 11 Temporal POI Check-in densities every day for a) tracking data b) social media data

Based on the temporal pattern results explained above, we can see our method has the capacity to capture detailed lifestyle patterns from tracking data and social media. Different patterns in tracking and social media data were obtained related to when users followed the activity and the type of POI visited. Clearly, most of the activity in tracking data was carried out between 9 am - 17 pm. During this period, the trend of activities (except shopping and service-related activity) showed small changes. In contrast, most users in social media tended to post their activity at a particular time: in the morning when they were starting an activity, during their lunch break and after working hours. Related to type of POI, most users in tracking data followed a routine activity by visiting the same place of POI several times (shopping in a specific kind of supermarket, etc.). Social media users posted their activity when attending an entertainment event, shopping in the plaza or mall, or eating in a restaurant. The POIs visited by user in social media were sparser than in tracking data.

Spatial Distribution of Popular Places

The current section demonstrates that our method can be used to visualise popular POIs in the city. The popular places visited by the citizen from tracking and social media data are generated by counting the total number of stay points or check-ins for each POI. The density for each region corresponds to the number of stay points or check-ins to that POI. Figure 12 and 13 show a visualisation of the spatial distribution of stay points and check-ins in the Birmingham area. The sizes of the circle indicate the number of stay points or check-ins at the POI.



(a) (b)

Figure 12 Spatial POI Check-in densities every day for a) tracking data b) social media data

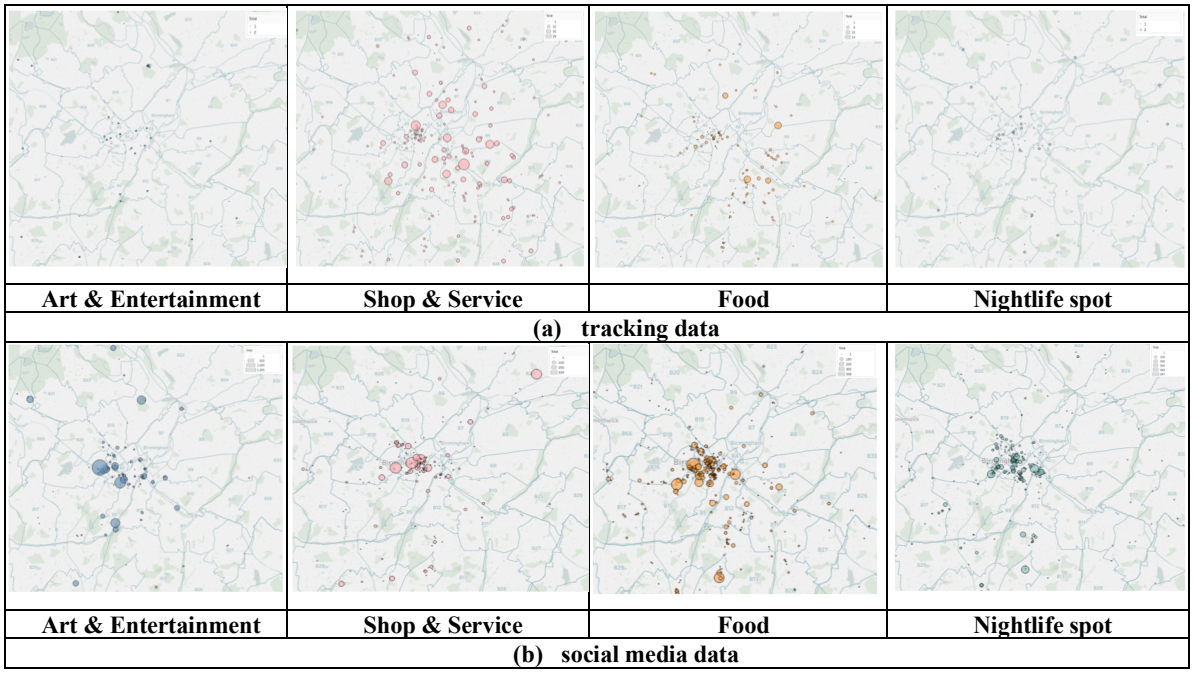


Figure 13 Spatial POI Check-in density for some POI Categories

As shown in Figures 12 and 13, popular places differed depend on activity purpose (POI category). The most active POI in tracking data was shopping and service places and few places had very high numbers of people who usually visited for eating, entertainment and nightlife purposes. Whereas in social media, other places such as art and entertainment, food and nightlife spots were also active POIs in the city. Clearly, there were more check-ins for eating, entertainment and nightlife activity in social media than in the tracking data.

Furthermore, stay point and check-in distributions look different for various activities. For example, the distribution of stay points for shopping and service-related activity and other (art and entertainment, food, nightlife) related activity look very different. Distribution of shopping and service-related activity in tracking data spread (scattered) in the city, where those places were shopping centres or supermarkets. Probably, people shopped in these particular places according to the proximity of the POI to their home. While, the distribution of activity from social media was more concentrated in the city centre, it was sparser and spread among different types of POI.

The analysis above highlights the significant differences between patterns in tracking and social media data. Users in social media were random (more variable) since data collected from all active users on Twitter who posted tweets in the Birmingham City area. Furthermore, social media usually contain features of sparsity and uncertainty. Spatial-temporal data provided by geo-located tweets are typically sparse due to the high interval

between two consecutive tweets in the spatial dimension. Activity found in social media is often occasional and discontinuous. Users in social media tend to share their geotagged tweets related to an interesting event, exciting moment or express their experience when they are in certain places with/without other people.

In contrast, tracking data provide regular/routine detailed activity conducted in daily life. Therefore, some places were visited several times. Shopping activity was the dominant activity where most places visited by the user were the shopping centre, shopping park, or supermarket. Users in tracking data were not random. As explained above, the apps were used by part of the population in the city with a specific social economy or medical condition characteristics. Therefore, we did not have the largest number of users in the parts of the city where they were the largest part of the population; there does not seem to be a close correlation between tracking user distribution and population size. Nevertheless, the results show that we are able to track citizens with some characteristics, capture the rich context of human lifestyle, and model their lifestyle patterns based on visited stay points. The lifestyle patterns show the power of analysis that clearly explains that these citizens are a part of the population in the city.

Understanding daily lifestyle patterns of the population enables decision makers to understand citizen needs, such as where and when they get supplies (e.g. food), and how the different parts of the city are connected. Monitoring these patterns allows us to understand, learn, and gauge the level of disruption after an event, as it is possible to check habit deviation from normal conditions post-event.

CONCLUSION

In this paper, we have presented a framework to build an understanding of mobility lifestyle patterns from tracking data. Even though the method has not yet been used during a crisis, our result shows that the stay point annotation from tracking data and POI check-in from social media can effectively explain daily life patterns in the city especially related to the usage of public infrastructure, such as shopping places, food, nightlife, etc. This detailed information is very useful for monitoring and learning how the population behaves (deviation of habit) before or after a crisis or gauging the level of disruption after an event.

We note several limitations within our study. The tracking data used are constructed from parts of the population in a specific category in the city and not incorporate data from some representative portions of the population (i.e., people who do not own mobile devices or do not register for a GPS service cannot be incorporated into this study). Therefore, the patterns found are related to certain types of people more likely to have a specific condition (related to social economic indicator). However, we are confident that the tracking data, which offer movement behaviour for the approximately 534 people included in the database, are reflective of part of the population lifestyle patterns. Furthermore, ambiguities in defining home and working place (to distinguish people having fun or working in pubs during the night; people who live and work in the same building (ground and 1st floor) are concerned to be future work to improve our algorithm. The third limitation of our study is the context of mobility only considered the stay points. Therefore, we are concerned to improve our method in future work, especially related to the number of the population examined and analysing the changing patterns of mobility regarding other semantics, such as large events or environmental conditions.

ACKNOWLEDGMENTS

The activity has been generously funded by a number of bodies: the European Commission as part of the SETA European Project (contract no. 688082); in England through funds from the national health system; from the University of Sheffield; and the National Centre for Sports and Exercise Medicine (NCSEM)

The authors would like to express their gratitude to the Indonesia Endowment Fund for Education for the research dissertation grant.

ABSTRACT

The number of smartphone applications to alert and inform the population in a risk situation in France is too large and these solutions are still unknow by the population. This study proposes an evaluation protocol based on various indicators, which take into account the capacity of the applications to send a targeted alert, their attractiveness, the ability of individuals to emit information and number of hazards considered. The results obtained on 50 applications deployed in France show that very few of them meet the objectives of the alert, in the sense defined by civil security, because of a single-risk approach, a unique sense of communication, and the low acceptance of these solutions by citizens.

Keywords

Alert, smartphone application, major risks**.**

INTRODUCTION

The combination of unpredictable hazards with climate change and increased exposure of populations makes territory more and more vulnerable (Kelman, 2011; Vinet *et al.,* 2017). The physical extent of the disaster makes it very hard for residents or affected human to react in timely fashion. Significant research and development efforts are required to create or improve systems to predict natural disasters, and to efficiently alert humans at the earliest possible time through different communication channels (Carley *et al.*, 2015; Choy *et al.*, 2016; Lindsay, 2011; Matveeva, 2006). The purpose of the alert is to warn citizens against a threat, a danger (Linardi, 2016) so that

citizens can make decision and take action for safety (Daupras *et al*., 2015; Sorensen, 2000). Due to its shorter temporality, the term "alert" differs from the term "warning" which takes into account forecasting and hazard monitoring. Thus, the alerting tools goals are: 1) spreading alert messages to citizens to inform them on the nature of the danger and its intensity; 2) advise citizens about actions to undertake.

In this paper, we focus on a specific alerting tool, smartphones applications, in order to measure the potential effectiveness of these solutions to play a role during alerts. Such solutions represent considerable scientific interest in the way this tool impacts our environment (Barr *et al*., 2015; Brownlee and Liang, 2011), our economy (Poushter, 2016) and our displacements (Adoue, 2015): in 2015, 3.7 billion people have a smartphone in the world. During a crisis, smartphone apps change the way in which people interact (Goodchild, 2007 ; Laurila, 2013 ; Slingsby *et al*., 2013), especially during alerts (Chatzimilioudis *et al.,* 2011 ; De Longeville *et al*., 2010 ; Douvinet *et al.,* 2017 et 2018 ; Fajardo et Oppus, 2009 ; Kouadio, 2016). Mostly, smartphone applications have the potential to improve the accuracy and timeliness of information over events in progress, to improve planning and alerts and communications between institutions and humans (Slingsby *et al.,* 2013): 1) they can locate citizens in real-time and communicate with them; 2) they can generate a "two-ways" interaction between users and decision centers, in an ascending logic (Goodchild, 2007); 3) smartphones messages and signals are moreover more understandable than sound signals (alarms) or shorter signs.

The development of smartphone applications to alert in the case of disasters has greatly increased since the years 2010 (namely after the seismic damage that has occurred in Haïti or after floods in Brisbane, Australia). In France, these tools are gradually being used since 2014 (Kouadio, 2016; Douvinet *et al.*, 2017). French government has launched its own app dedicated to alerts at the national level in June 2016, especially due to the increasing risk of terrorism since 2015. SAIP® app (*Alert and Information System for the Population*) has nonetheless been abandoned in May 2018, due to several missed and false alerts. In parallel, specific alert applications have been displayed since 2015 at the local level (in several municipalities like Nîmes, Nice, Hyères, Athis-Mons, etc.). In addition, private companies have massively engaged in the development of these solutions on an international scale (operating in the world, like ELERT®, Qwidam®, Signalert®, WeatherAlert®, etc.) in order to cover all hazards and probable related dangers. In many cases, applications results from public-private partnerships and need significant human and economic resources, and a major political decision to develop them.

In France, the massive creation of smartphone applications cause a high competitive logic between stakeholders involved, and a strong confusion for citizens who struggle to find their way in the face of the diversity of solutions. All available solutions present variable criteria and characteristics, especially in terms of the communication mode, the price, the spatial coverture, etc. Thus, it remains difficult for citizens, stakeholders or scientists, to know the best solutions. This has the consequence of increasing the gap between citizens who want efficient and operational emergency applications, and institutions that are reluctant to invest digital tools (Vogel, 2017).

In the scientific literature, most of the studies are focused on the technical capabilities of applications (Fragkiadakis *et al*., 2011; Chatzimilioudis *et al.,* 2011) rather than how the content is perceived by the public (Lindsay, 2011). Furthermore, the social appropriation of smartphone applications is still poorly and insufficiently documented (Bopp *et al*., 2019; Douvinet, 2018). Thus, comparing several smartphone applications available in France since few years, this article supplies two contributions. First, we experienced a retrieval method to classify and hierarchize the "good from the bad smartphone applications" proposing to alert users to natural risks. A "good application" simultaneously corresponds to the need to attract attention and deliver an instructional message (DGSCGC, 2013). The method has been designed to "put oneself in the shoes of a future user", to go beyond standard indicators that are limited to measures the internal efficiency of applications and are insufficient to explore how humans play a major role during crises. Second, we wish to select the applications with the high scores and discuss the opportunity to develop them in France. Such a choice might impulse major political changes, as sirens remain the priority for the French government in charge of alerting the population facing disasters since the end of the 2nd World War (Vogel, 2017; Douvinet, 2018).

The paper is organized as follows. Section 2 presents the data collection and the main elements used to implement the evaluation. Section 3 presents the obtained results through the evaluation of 50 applications displayed in

France. In section 4 and 5, the benefits and limits of the evaluation tools as well as the results are discussed, and conclusions are drawn in Section 6.

METHODS AND DATA COLLECTION

The basic elements needed for the evaluation are explained here and a functional description of each indicator is introduced. Applications have been uploaded in March 2018 *via* specialized search engines (Google Play®, Play Store®) using keywords: alert, risk, SOS, warning, disasters, hazards, etc. Every application has been rigorously tested and only applications allowing the sending of an alert to a risk have been retained.

Our evaluation method is first based on four major indicators identified using the scientific literature and experiences feedback. A "good" smartphone application for the alert must be regarded according to (1) its potential to alert and inform the user in case of disasters (with the postulate that such information is relevant); (2) its potential to allow interactivity between users and the decision center; (3) its potential to take into account all the existing hazards on the France territory (to permit adaptation to various situations); (4) its potential to be attractive to prevent users from deleting them.

The potential of alerting and informing users

French authorities define the alert as a signal intended to warn citizens of a danger, imminent or in the process of producing its effects, which may affect their physical integrity and requires the adoption of a reflexive backup behavior (DGSCGC, 2013). Then, the alert process is expected to: 1) be intrusive, with a clear and short message that breaks with usual information; 2) be targeted, by defining an alert zone; 3) trigger an immediate response to exposed populations (Douvinet, 2018). In this sense, a good application needs to support people in the affected area to take the correct actions (Kouadio, 2016). First, applications can send a push notification, an interruptive message that appears on the screens even if the application is closed, that corresponds to the interruptive character and intrusive expected alerts (Tang *et al*., 2013). Secondly, applications allow geolocation of users. Precious during crisis management, the "location-based mobile telephony services" (Aloudat *et al*., 2014) allows the sending of a targeted alert to citizens located in the potential area of the hazard, provided that they agree to communicate their position. Smartphone applications have other capabilities in improving the dissemination of alert messages and their understanding thanks to hazards visualization in real time on map interfaces or the possibility to relay alerts through Social Medias.

The potential of interactivity

Humans have a better perception of risks when they have been integrated in the design and preventive phase (Gaillard *et al.,* 2010; Garcia, 2012). Citizens are empowered to observe and transmit data through the Internet, connected objects or crowdmapping (Becker and Bendett, 2015; Riccardi, 2016; Ziemke, 2012). In addition, decision centers need to quickly acquire accurate information in times of crisis (Villela *et al*., 2018). A good smartphone application may allow citizens to interact with warning systems (Budhatoki *et al*., 2010; Horita *et al*., 2013; Okolloh, 2009). Interactive applications allow users to detect all "weak signals" revealing disasters in progress (Kouadio, 2016). In this sense, a single "top-down" broadcast communication mode, coming from the decision center to users, is less relevant than a "bottom-up" mode of dissemination from the user to the decision center, or than a "peer-to-peer" mode enabled by a mesh network deployment.

The multi-hazard dimension

The multi-hazard concept refers to the fact that different hazards may threaten the same element and that one event may trigger others (Liu *et al.,* 2017, Nadim and Liu, 2013). Consequently, a smartphone application developed to alert people facing to a single hazard is limited. In France, 12 major risks are identified and defined by the authorities as "the threat to human people and his direct environment (…) whose gravity is such that society is absolutely overwhelmed by the immensity of disaster" (DGSCGC, 2013). Eight natural risks exist (flood, earthquake, volcanic eruption, movement of land, avalanche, forest fires, cyclone and storm) and the other four

are anthropogenic risks (nuclear risk, industrial risk, transport of hazardous materials, dam failure). Although the distribution of hazards is very heterogeneous in France, an application developed throughout France must take into account these 12 major risks. Thus, the app will be adapted to various situations that users can face. We don't take into account here cascading effects between hazards considering that humans need to be alerted whatever the spatial distribution of hazards.

The potential of attractiveness

The attractiveness of an application is a key parameter to its general use. The user is able to determine (during its first use) if one application is useful or not for him (Adoue, 2015). If two applications present similar functionality, the quantity and quality of information provided and its ergonomic aspect are determinant in the user choice (Adoue, 2015). The color choice is particularly decisive in the user's appreciation of the app (Weinclich, 2014). Some researchers then aim to ensure compatibility between the characteristics of users, the technical products, and the systems in order to facilitate their use (Barcenilla and Bastien, 2009). Attractiveness is a fuzzy parameter involving user experiences on the product. Poorly studied in the scientific field, the user experience requires evaluating both pragmatic qualities (usefulness, usability) and hedonic qualities (stimulation, identification perceived by users on the product (Hassenzahl, 2004; Väätäjä *et al.,* 2009). In our research, without being able to assess such user qualities, it is only possible to look at the pragmatic qualities of applications. The usefulness of apps can be assessed through various offered functionalities: interactive cartography and usefulness of information (such as real-time traffic or weather, presence of information and instructions on risk, etc). The usability can also be checked with the presence or absence of advertising and detected bugs. Price of apps is also a parameter of this indicator.

How to convert qualitative criteria into quantified indexes?

Figure 1 details the methodology used to evaluate applications. The four indicators are defined by a certain number of settings ranging from 0 to 1 and weighted according to their importance.

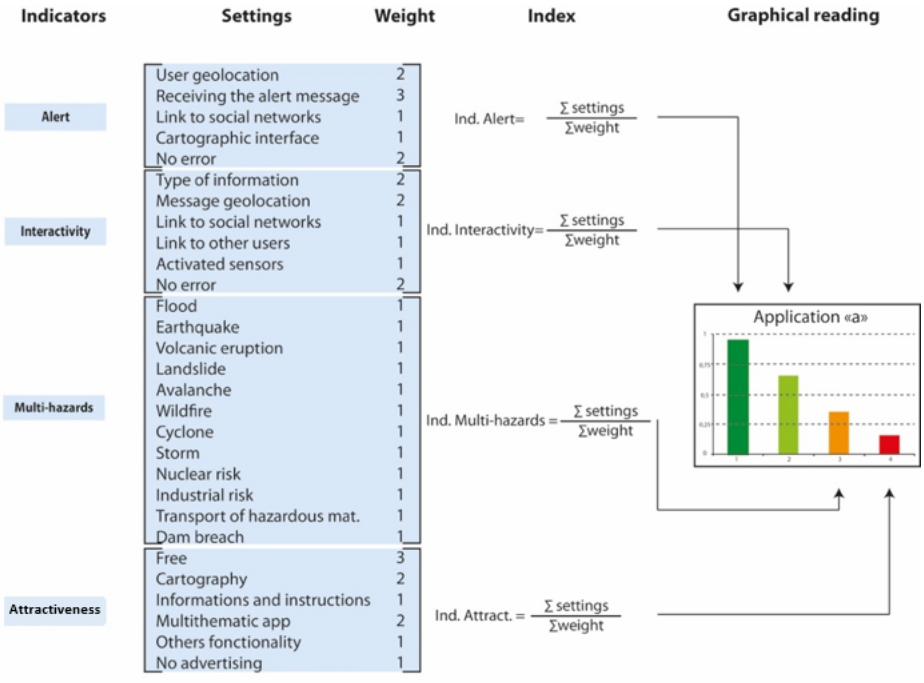

Figure 1. Indicators and selected settings to define them.

With this methodology, each criterion can be measured in the same units, and differences in values on different criteria are comparable and can be offset (Serre, 2005). Settings were weighted with a simplified point rating system (1, 2 or 3), according to the literature review. Therefore, such a method emphasizes the importance of

application functionality in the field of alerts (Shan and Lai, 2015, Shih *et al*., 2013), including the issuance of information by users (Chatzimilioudis *et al*., 2012) and the attractiveness of applications (Weinlich *et al*., 2014). Finally, the sum of the settings was aggregated and ranged from 0 to 1 to propose an index per indicator. The four indexes obtained make the classification easier between applications. One graph finally presents the results obtained for all indicators, to avoid an excessive loss of information with initial setting an increasing color refers to the obtained values. This method fits directly into the main principles of the *Multi-criteria Hierarchization Methods* (MHM), invented by Saaty (1984) and which can now be distinguished according to the objectives and points of view (Maystre *et al*., 1994).

RESULTS

This method was first tested on four applications and experimented on fifty applications dedicated to alerting humans in case of disasters. The selected sample renders the compilation of a wide variety of functional applications available in France possible.

Detailed results for each indicator

Surprisingly, the attractiveness globally performing well for all applications, whereas the alert, multi-hazards dimension or interactivity indicators are heterogeneous (Table 1 and Figure 2). The high average (0.64) and the minimal variation for attractiveness (0.45) are explained by the fact that 35 applications are free, 34 allow the visualization of a disaster on maps and 23 complete alert messages with behavior guidelines and information. Only 11 free applications contain advertising and some apps have features to directly contact relief or reassure loved ones. The calculated average for the alert indicator (0.58) and dispersion of values are explained by the fact that geolocation and reception of the message have been weighted: 36 applications allow the geolocation of users, including 32 automatically, and 25 use the push notification. 22 applications allow interactions with other social media and 36 are related to a mapping of a disaster in real time. 36 do not present any error or malfunctions during the test phase, whereas the quality of reception disturbs the performance of others (14). The calculated average for interactivity (0.29) is weakest, and highest standard variations are explained by the fact that only 20 applications allow current relations between users and decision centers. Some of them (17) activate at least one predefined sensor (digital camera or voice recorder), but only 7 allow comments within social media and only 11 allow users to exchange information with other users. But 18 applications present malfunctions in the information sending test phase, including 13 applications where these malfunctions have a strong impact on the quality of information sending. The multi-hazard is also discussed: 23 applications are multi-hazard but only 11 take into account all the hazards related to a major disaster in France. 14 tested applications focus on a single hazard (mainly in the case of earthquakes or floods). 7 applications do not take into account any of the 12 hazards selected in this study. Most solutions (Table 2) consider natural disasters (79.4%) and rather than anthropogenic disasters (20.6%).

Table 1. Detailed results for each indicator.

	Alert	Interactivity	Multi-hazard	Attractiveness
Average	0.58	0.29	0.64	0.64
Mode	0.56	0.00	0.08	0.60
Decile 1	0.00	0.00	0.00	0.45
Decile 9	0.89	0.78	1.00	0.90

Table 2. Hazard taken into account by the applications.

Type of disasters	Number of app	Type of disaster	Number of apps
Flood	30	Snow avalanche	19
Cyclone	25	Volcanic eruption	18
Storm	24	Landslide	16
Earthquake	24	Industrial risk	12
Wildfire	21	Dam break	11

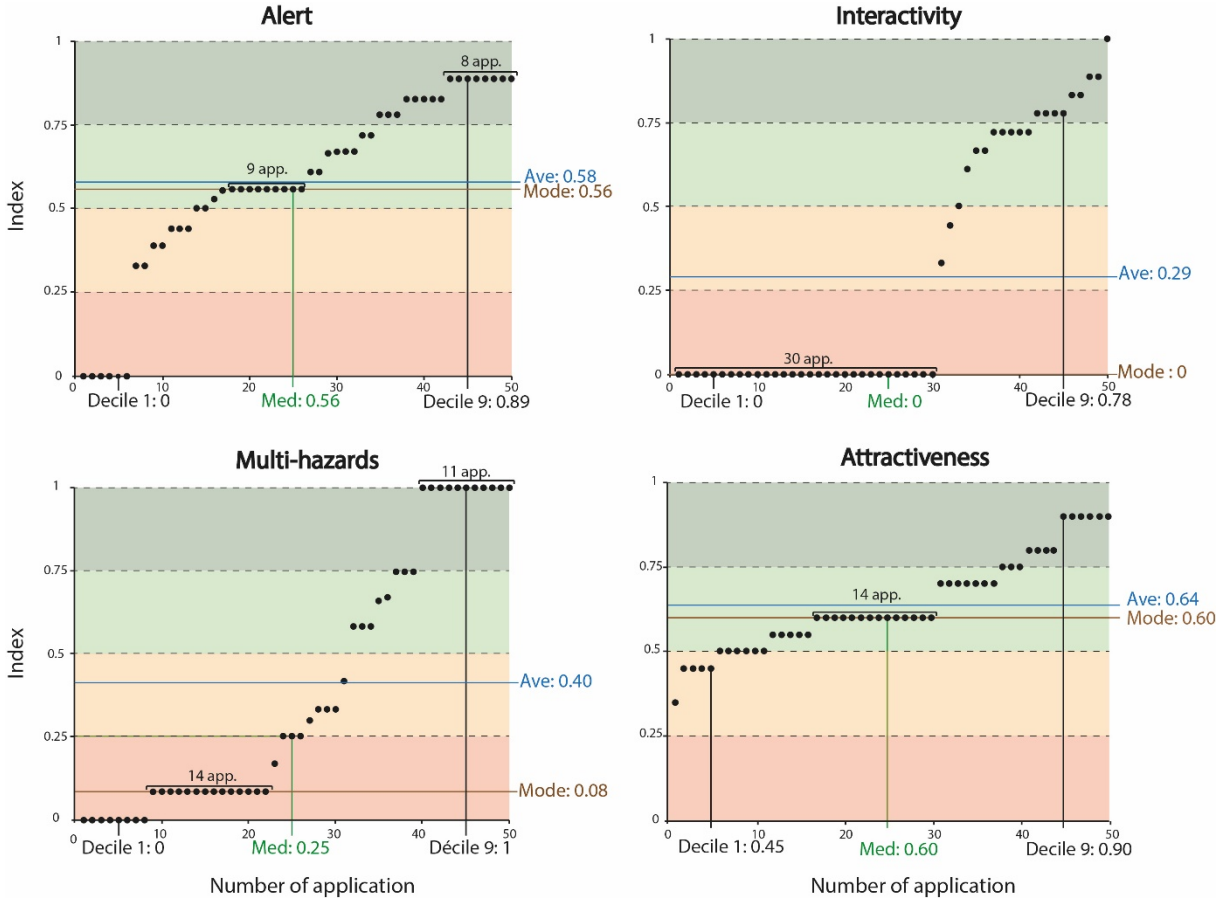

Figure 2. Ranking of results for the four indicators.

Global overview

The overall evaluation (Figure 3) provides additional lessons. Only 4 applications have their 4 indexes greater than 0.50 whereas 34 apps have at least one zero index. 3 applications present a global index greater than 3.00, while 28 applications have a global index of less than 2.00. Consequently, a few applications are really considered effective at alerting humans, but their number appears limited. By classifying these 50 applications, we obtained a curve with regular ascendancy. The standard deviation equals 0.35 and deciles 1 and 9 are not in extreme values (respectively 1.14 and 2.69). Applications are mostly private (34 applications) and companies aim at democratizing their own products as widely as possible (Douvinet *et al.,* 2017). Hence a high prevalence of applications that can be used on a global or continental scale: over the 25 displayed at global or continental levels, 21 are managed by private entities (Tables 3 and 4).

Table 3. Nature of hosting structures for applications.

Managing structures	Number of app	Global index
Institutional apps	16	2.01
Governement	*4*	*2.26*
Local	*5*	*1.91*
Non-governemental organisations	*7*	*1.86*
Private companies	34	1.87

Table 4. Type of spatial deployment for the 50 studied applications.

Spatial coverture	Number of app	Global index
Local level	5	2.09
National level	20	1.72
Continental level	9	2.05
In the world	16	1.70

The 5 applications obtaining the best results are shown in Table 5. These applications are multi-hazard, participative, and so present a good potential to be an effective alert tool for humans in the case of a disaster. Some others have a good evaluation for only one indicator, but insufficiently take into account the complexity of the alert process and its interactivity. The interactions between all stakeholders is therefore crucial as it currently leads to a certain reverse hierarchy of information: the latter, until this point confined in top-down stream (only going from the authorities towards the population) must now take into account bottom up and horizontal streams, ranging from the users to the authorities or between users (Coyle *et al.,* 2009; Douvinet, 2018).

Table 5. Values obtained for the five best applications.

Tested applications	Alert index	Interactivity index	Multi-hazard index	Attractiveness index	Global index

Figure 3. Classification comparing the 50 applications according to all calculated indicators.

LIMITATIONS

In this paper, we evaluated the effectiveness of smartphone applications in case of disasters. As research on this matter is still at an early stage, more studies need to be done to develop the calculation of weighted settings and to quantify the performance of people in using such solutions.

Several limits could be stated in our study. The choice of the weighting coefficients has a significant influence on the results. Thus, if we remove the weighting of settings, giving each one an equivalent weight, we obtain a variation of values ranging from -1.09 to 0.97 (figure 4), which is high for global indices between 0 and 4. However, the weighting is based precisely on results from the scientific literature, and not giving weight to certain criteria would therefore make no sense.

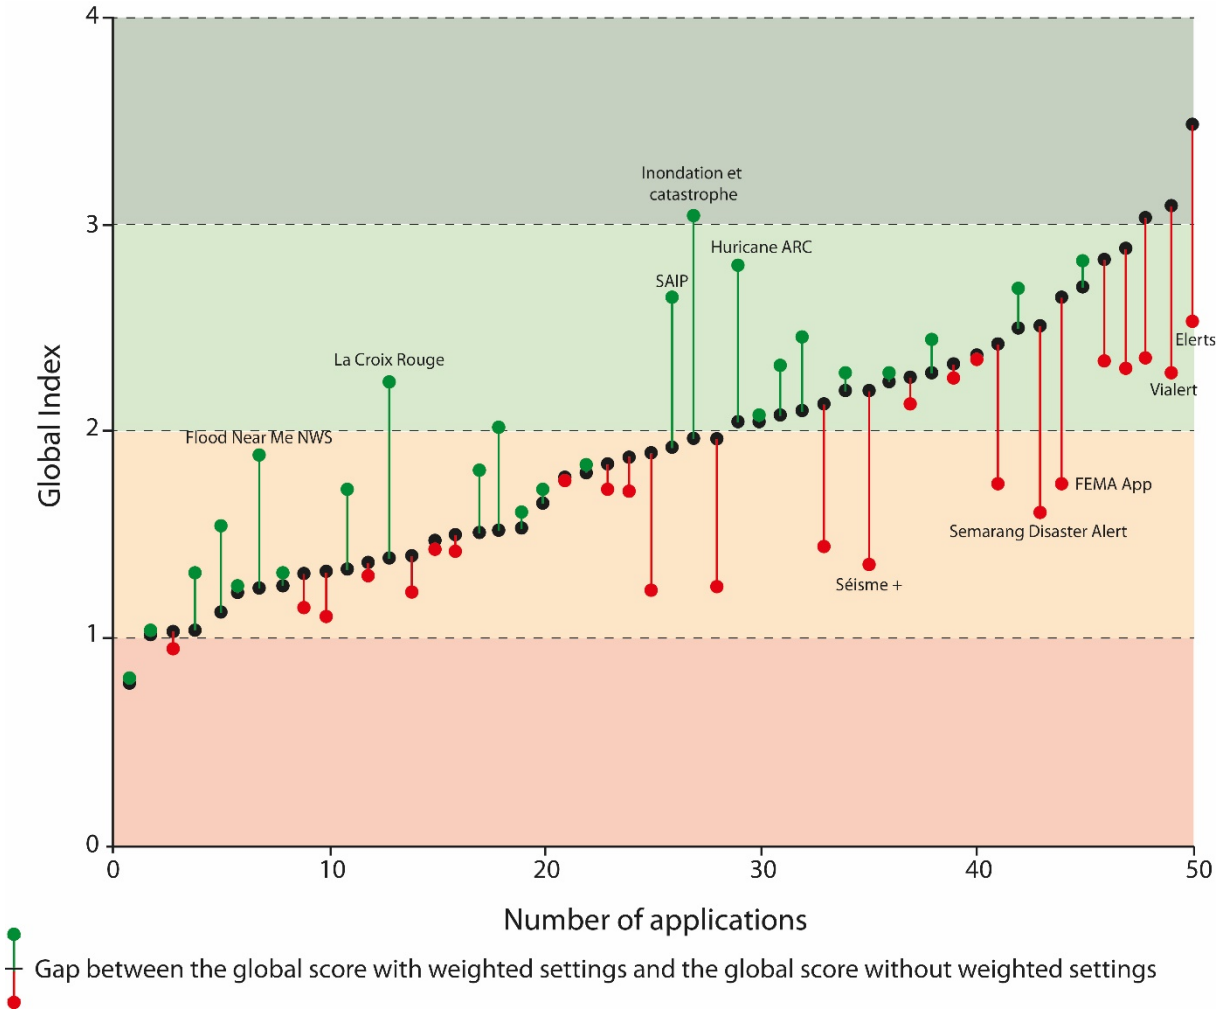

Figure 4. Gap of results between weighted and unweighted settings

Many applications do not obtain good indicators, regardless of the calculation method. This work suggests that many of them do not really answer to the main objectives retained for alerting humans in case of disasters.

Another limit is the quantification of the response phase behavior of people (Lindsay, 2011). It seems to be not useful to create a ready-for-use smartphone application without ensuring training and support. Downstream information has already shown its inefficiency, both in the fields of prevention and alert in France (Vinet, 2010). As such, we must avoid keeping the same thinking scheme. Moreover, without real appropriation of these new means by the citizens, applications could disappear as fast as they emerged (Douvinet, 2018).

Due to a lack of data, this work did not assess how application managers proceed to send an alert or process information from users. Some managers make the choice to automatically switch information from official organizations in the forecast of hazards (Météo-France, Vigicrues, BRRM, etc.). Other managers set up an on-call duty team to process all the information in real time. But this information is not available for all evaluated applications. The download number was also not taken into account because of confusing data: download ranges on Google Play® are too wide and there is no information on removing applications by users.

DISCUSSIONS

Clearly, this work has well shown that the studied solutions do not reach their objectives and it undoubtedly adds further misunderstanding for citizens. This is paradoxical because, the pervasive aspect of smartphone makes it possible to hold cross-cutting discussions between various stakeholders (citizens, institutions and associations) and facilitates quicker information. The faster signals may be detected (for example, pictures showing damages), the faster managers may be able to trigger emergency response actions and the sooner they may be able to support citizens and provide relief to victims. But a problem remains to be solved: citizens can spread false or wrong information through applications and the Internet. False information are spread "significantly farther, faster, deeper, and more broadly than the truth in all categories of information" through Social Medias (Vosoughi *et al*., 2018). However, mass participation in crowdsourcing tends to rectify the place of false information in Social Medias (Alexander, 2014). Several groups are attempting to increase the veracity and the accuracy of crowdsourced data (like "Hacker Against Natural Disaster") and "the cost of responding to a false alarm is far less than not responding" (Riccardi, 2016).

In France, authorities are unable to use this technology because of institutional regulatory protocols that are not designed to manage such fast-paced timescales (Vogel, 2017). The establishment of "community managers" by the crisis center is a first step but remains insufficient. This issue must be solved to dramatically improve warning systems. In the field of smartphone applications, the collaborative aspect could be improved in three stages: 1) before a disaster occurs, awareness campaigns, collection of data, and training for citizens-sensors should be carried out, which could lead to selection or specialization of "citizen monitors" (a specific role entrusted to each users according to their abilities) ; 2) during the crisis, collecting information in real-time would be greatly facilitated by upstream training, aiming to only pass reliable information on. Therefore, monitors could also turn into "stakeholder", able to move by following guidelines taught in the upstream phase and to act within the area where the crisis is occurring. Guidance provided by a rescue center in real-time is also a possibility; 3) downstream of the crisis, there is a need of taking into account the evolution of the crisis, witnessing and enabling institutional aid to improve training, intervention and crisis management processes. These steps aimed at strengthening the prevention of human and material damages during current or exceptional disasters. This method requires much more support than mere data collection applications such as crowdsourcing or crisis-mapping (Douvinet *et al*., 2017). It is crucial to recommend the use of real-time operational systems, awareness and training measures.

Otherwise, to enhance applications uses, there is an urgent need to sensitize the citizens to commit the "internet of things" and organize training exercises (Gisclard, 2017). In that respect, smartphone applications boost discussions around resilience, which defends the idea that a population must be autonomous (it may be isolated in times of danger), united and involved before being able of using the existing tools. However, in places where the perception of risk is low, the Cell Broadcast might be more appropriate than an application to alert citizens. Cell Broadcast is a message sent to cell phones in a predefined area and does not require the download of an application (which requires a minimum of risk culture). This means does not allow interactivity between users and crisis managers but it allows to alert effectively and quickly a large number of citizens. Smartphones are also expensive objects, less used by old and less graduated people and dependent on the Internet network. Thus, these tools increase territorial and social disparities and their use must be done in addition to other means of alert.

CONCLUSIONS

This study evaluated a method to classify and compare different smartphone applications dedicated to alert in France. The application evaluation was focused on four points: 1) their ability to alert users; 2) their ability to be interactive; 3) their ability to take into account the 12 majors risks identified in France; 4) their attractiveness.

Surprisingly, few of them really reached the original objectives, while many claimed to be as such. Many applications have limited potential because it doesn't take into account the possibility of interactivity enabled by smartphones. We must give citizens the ability to interact with alerting means. This criterion is a prerequisite for the implementation and appropriation of smartphone applications by citizens (Coleman *et al*., 2009; Gisclard, 2017). Moreover, many studied solutions have a vision of the hazards which is limited to the scale of their territory. These results reflect two restrictive choices made my managers. Firstly, they not consider citizens as an actor able to observe and communicate during crises. Secondly, they forget the fact that a territory is often subject to various risks, and that more complex or unpredictable phenomena (cascading effects, simultaneous risks) can occur there.

Our results need larger-scale debate. It raises this specific question: it is necessary to multiply the solutions at local scales, for increasing the understanding of dangers by residents, or does the French government have urgently to display a new national smartphone application, even after the issues observed in the use of SAIP® during two years? Our results in this work highlight large-scale solutions because local solutions present more problems in their software and functionality, and induce inequalities between territories and humans. Whatever the discussions arise from the type of indicators, the nature of retrieval method or the weighted coefficients allocated to several parameters, this work argues that the high number of applications strongly induces confusion and concurrence between stakeholders implicated in the alert process. In the same time, the emergence of numerous smartphone applications reveals a lack in the actual political choice carried out by the institutions. Finally, the institution must take into consideration connected objects to develop systems different from the sirens which remain the main tool used in France.

ABSTRACT

The impact of landslides is determined by the previous state of vulnerability and susceptibility present in a community. Vulnerability is related to physical aspects and susceptibility is defined as the propensity or tendency of an area to be affected by the occurrence of a given hazard. Knowledge of geography allows us to characterize and measure some of these factors. For example, in landslides called huaicos in Peru, these are related to the existence of a slope and soil type of the hills favorable to the loosening of land masses, as well as the increase in rainfall and the presence of streams. The use of UAVs (Unmanned Aerial Vehicles, commonly called drones) for the identification of susceptibility zones is presented in this paper. The result is positive for using the georeferenced data to identify potential landslide flow using as unique criterion surface slopes.

Keywords

Susceptibility mapping, disaster prevention, landslides, drones.

INTRODUCTION

Within the mitigation stage, decisions are made taking a strategic perspective to reduce the potential impacts of a disaster or to avoid it; thus, risk analysis is normally part of this stage (Altay and Green III, 2006; Leiras et al., 2014). Vulnerability and susceptibility maps become enormously important, because it allows knowing in advance, where the most exposed and dangerous areas are located. These tools support elaborate qualitative and quantitative information, such as: forecast impacts post disasters, evaluate options of preventive intervention, risk control planning (using elimination, isolation or reduction strategies), guide where the investment of infrastructure to mitigate vulnerability must be made, determine the sociodemographic characteristics of the

threatened territory (MINEDU, 2015). Nowadays, vulnerability maps are widely used by various public organizations, non-governmental organizations and companies to track, evaluate and manage the different risks to which they are exposed.

Risk mapping is the presentation of the results of risk assessment on a map, showing the levels of expected losses which can be anticipated in specific areas, during a period, because of disaster hazards. The risk is defined as the combination of the probability of an event and its negative consequences (UNISDR, 2009). The latter is related to expected losses such as fatalities, persons injured, damage to property, and disruption to economic activity, etc. caused by a hazard (Coburn et al., 1994). Risk assessments include: a review of the technical characteristics of hazards such as their location, intensity, frequency and probability; the analysis of exposure and vulnerability including the physical social, health, economic and environmental dimensions; and the evaluation of the effectiveness of prevailing and alternative coping capacities in respect to likely risk scenarios. This series of activities is sometimes known as a risk analysis process (UNISDR, 2009). Zhao and Chen (2015) present a methodology for the risk assessment (see Figure 1). The process of risk assessment is based in a mesh spatial representation, where an entire region is divided into a few fine spatial meshes with a specific risk value. The procedure considers both hazard sources and risk targets (hospitals, schools and commercial centers, etc.). For each mesh, the risk level is calculated considering the severity and vulnerability level. The severity measures the intensity and frequency of the hazard. The vulnerability measures social indicators, such as population and its structure, the accessibility of emergency resources, etc. Mapping and disaster assessment can improve the provision of timely and accurate support for activities such as evacuation, sheltering and distribution (Rodríguez-Espíndola et al., 2016).

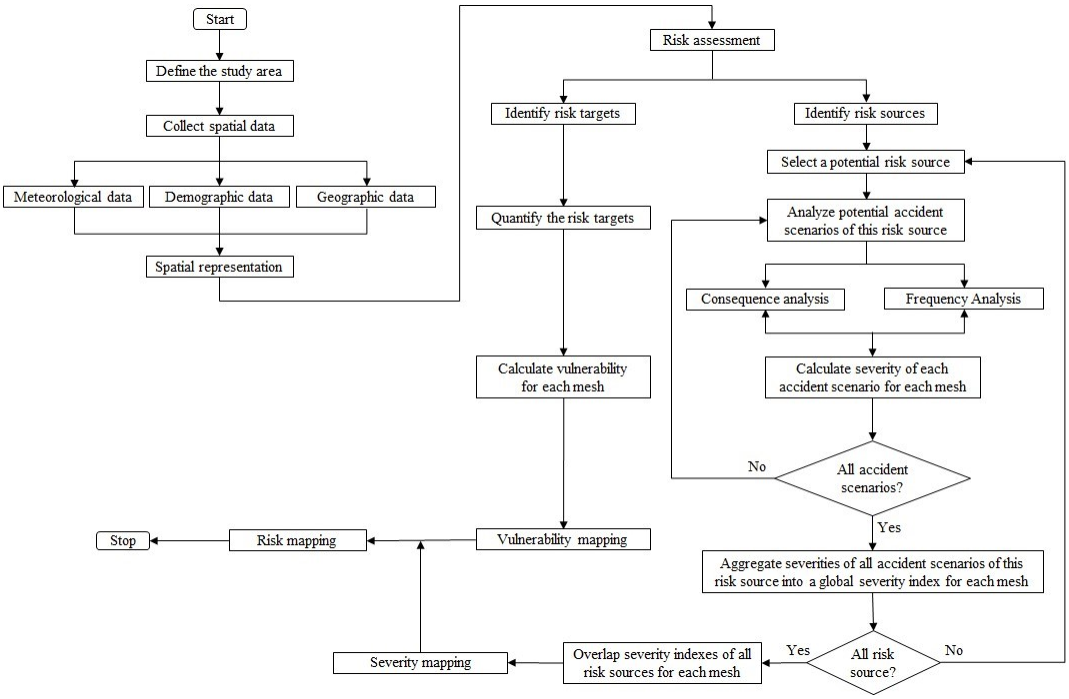

Figure 1. Flowchart of risk assessment and mapping (Zhao & Chen, 2015)

According to Lewis (2004) "vulnerability" is related to physical aspects and "susceptibility" to a previous weakness of capacity to manage it. In many cases, it is necessary to settle for a qualitative classification in terms of high, medium and low; or explicit statements concerning the disruption likely to be suffered (Coburn et al., 1994). Susceptibility is defined as the propensity or tendency of an area to be affected by the occurrence of a given hazard (Ayala-Carcedo, 2002). The categories used for a susceptibility analysis can be (Rauld et al., 2015): (1) Very High; there are very favorable conditions and there are several recorded events, (2) High; there are favorable conditions and there are sporadic events recorded, (3) Moderate; there are some favorable conditions and / or practically no catastrophes of danger and (4) Low / Null; no favorable condition to some event. Hence, susceptibility and vulnerability mapping are considered one of the most important steps in disaster risk reduction because it identifies elements (areas and communities) propensity to be affected by a disaster, they are important for disaster risk management planning (Isma'il and Saanyol, 2013).

Hazard risk vulnerability mapping is considered one of the most important steps in disaster risk reduction because it keeps identifying vulnerable areas to be considered into plans for disaster risk management (Isma'il and Saanyol, 2013). Next level to risk maps are the susceptibility and hazard maps as expression of the probability of occurrence of a certain event in a location and period of time, the higher level corresponds to maps that take into account not only the phenomena themselves and their probability but how they affect people and goods (exposure) and its economic, psychological and social valuation, or in terms of the degree in which they are affected (vulnerability); finally, the product of the hazard, elements at risk valuation and vulnerability results in risk assessment (Fernández et al., 2013).

Different tools are available to make susceptibility and vulnerability maps; we have the traditional ones related to cartography, topographic and geographic, which make maps of the location of the threats (plate tectonics, mountain streams, soil types, etc.). Others include new technological tools available today with mobile communication devices such as those with a geographic system integrated with GPS, remote sensing and fuzzy logic to generate a real-time evaluation or simulation to determine the presence of contaminating sources of impact (Corwin et al., 1996). Vulnerability mapping is also done in the frame to understand social vulnerability and to more easily identify areas of vulnerable population (IWR, 2013).

However, technology still has limitations and obstacles, such as the case of digital cartography, whose main challenge is to achieve preventive analysis of threats, based on reliable approximation of data from different hazards on the same space (Perles and Cantero, 2010). As well as an important amount of high-quality data to be able to analyse and elaborate valid and reliable vulnerability maps (Esteller et al., 2002). To overcome some problems mentioned, the use of drones is proposed as an alternative to play an important role, in obtaining data and information related to the mapping of vulnerabilities in a territory exposed to threats. This advanced equipment of hardware and easy manoeuvrability allows the capture of large amounts of information thanks to the various integrated sensors (Ramírez et al., 2013).

To acquire situational awareness of the disaster an accurate map and 3D model of the affected terrain can be obtained using aerial images and photogrammetry techniques. Such images have been obtained using drone technology in two phases using different kind of aircraft: fixed wing and multirotor. Each one is used for specific missions depending on the type of mapping required.

The paper is organized as follows, first the theoretical framework based on the understanding of geographic information systems (GIS) will be presented, then the systems of drones for the use of disaster monitoring, shortly after the contribution of this work, which is the development of maps of vulnerability and prognosis of some affected areas for the study area. Finally, the discussion and conclusions parts, adding proposals of future works of investigation, are presented.

GEOGRAPHICAL INFORMATION SYSTEM (GIS)

Rodríguez-Espíndola et al. (2016) show the capabilities of Geographical Information System (GIS) for disaster management and the analysis potential flooding scenarios to provide information for an optimization model of location and distribution. The work is applied to two real-world floods in Mexico. The results provide evidence that including GIS analysis for a decision-making tool in disaster management can improve the outcome of disaster operations by reducing the number of facilities used at risk of flooding. Cutter (2003) highlights the applications of GIS to the emergency response cycle, citing examples from natural hazards and suggests some important research areas based on the needs of the disasters and emergency management. Other studies on information systems applications, vulnerability and risk mapping in humanitarian logistics can be found in the literature: Chen et al. (2018); Hu et al. (2016); Isma'il and Saanyol (2013); Kumar and Anbalagan (2015); Muthukumar (2013); Özdamar and Ertem (2015); Tomaszewski et al. (2015). GIS applications in Disaster Management are progressively turning into a necessary component of disaster and emergency management activities in many parts of the world. The spatial dimension of geospatial data makes it exceptionally critical for decision-makers in the different phases of emergency management operations. It is important for policy makers to have the right information to permit them to react, mitigate and manage catastrophes (Abdalla, 2016).

DRONE SYSTEM IN DISASTER RISK MANAGEMENT

Unmanned Aerial Systems (UAS) have considerable potential to radically improve monitoring. UAS-mounted sensors offer an extraordinary opportunity to bridge the existing gap between field observations and traditional air and space-borne remote sensing, by providing high spatial detail over relatively large areas in a cost-effective way and an entirely new capacity for enhanced temporal retrieval (Lin et al., 2016, Manfreda et al., 2018, Tanzi et al., 2014).

Elaboration of vulnerability maps by drones have numerous benefits to support decision-making for reducing

the vulnerability of communities, through utilisation of information to mitigate or reduce the impact of social disasters (Ismail-Zadeh and Cutter, 2015), and taking care of vital infrastructure such as electricity, water, transport, health and safety (Sandholz, 2018). Other ones applied in poor communities and their surroundings are the monitoring and execution of action plans, the simulation of models for the prevention of disasters, improvement in the precision and quality of urban-environmental planning and the relatively fast speed of data is collected (UNEP-DHI Partnership, 2017).

Based on experience from the authors, who deal with drone projects in different applications related to agriculture, cartography etc. (GISANT, which is the Unmanned Aircraft Systems Research group at Pontifical Catholic University of Peru, PUCP, http://investigacion.pucp.edu.pe/grupos/gsant/ and the National Telecommunications Research and Training Institute, INICTEL, a research group from National University of Engineering, UNI, http://didt.inictel-uni.edu.pe/didt/index.php/grupo-de-procesamiento-de-senales-e-imagenes-g-psi/) with the support the Crisis and Disaster Management group at PUCP, an interinstitutional and multidisciplinary (industrial, electronic and mechatronic engineers) research group to deal with this project was created. Three main phases are proposed to run a drone-mapping project. The first phase of the drone-susceptibility mapping project involves the acquisition of data from a wide area perspective, to swiftly acquire information on a large scale. For this task, a fixed wing aircraft is used. Images are acquired and are processed using of the shelf software to obtain 3D models and mapping. These maps will be crucial to detect affected areas by potential landslides; these specific sites need to be properly mapped in more detail, for which the second phase is put into operation. The second phase involves the use of multirotor aircraft which can fly lower and acquire detailed data to assess the situation and provide the necessary information for relief decision making. A final third phase relates the processed image information with previous threat conditions as cliffs, unsteady slopes, type of soil, presence of ravines, etc. which create susceptibility conditions and let identify potential affected by future landslides to be triggered by the increase of raining periods like El Niño phenomenon.

SYSTEM OVERVIEW

According to the report of the National Emergency Operations Center, COEN (2017) in Peru, since January 14, 2017, heavy rainfall was recorded because of the presence of Coastal El Niño, affecting the districts of Lurigancho-Chosica and Chaclacayo in Lima (Peru's capital), causing huaicos, affecting homes, communication routes, educational institutions and damage to the life and health of people. On March 16, 2017, at 4:30 p.m., the overflow of the waters of the Jicamarca ravine (Huaycoloro River) was recorded, and at 9:00 p.m., the overflow of the Rímac River was reported, causing the affectation of road bridges, housing, public places, communication routes and flooding in several sectors of the districts of San Juan de Lurigancho, El Agustino, Lurigancho-Chosica. On March 19 at 12:30 a.m., because of the intense rainfall, the Chillón River overflowed also, affecting cultivation areas in Carabayllo sector.

According to information found at the search engine service for information on disasters and their impact in Peru (see Figure 2), named the National Information System for Response and Rehabilitation, SINPAD (http://sinpad.indeci.gob.pe/sinpad/Estadistica/Frame_Esta_C7.asp) from the National Institute of Civil Defense of Peru, INDECI ; it was selected the town of Huatocay and its surroundings, in the district of Carabayllo as the study area because of 3450 casualties reported (see Figure 3). With the support of a seed fund of research by Penn University, researchers from UNI and PUCP, teamed up to design a humanitarian supply chain to 2017 Coastal El Niño affected communities from Huatocay. It was determined by the research group that the starting point would be to identify susceptibility areas to landslides. To carry out the field work, contact was made with the authorities and local inhabitants to receive support for the search of the appropriate places to be used for the drone flight work. Other benefits of the inclusion of authorities and residents in the realization of these works, are the transfer of knowledge and experience for disaster management, through the management of drone flight equipment, evaluation of areas of risk, control of existing threats, etc. The limitations for the development of this population inclusion strategy, to carry out the fieldwork has to do with the level of education and budget of the local authorities to carry out disaster prevention activities.

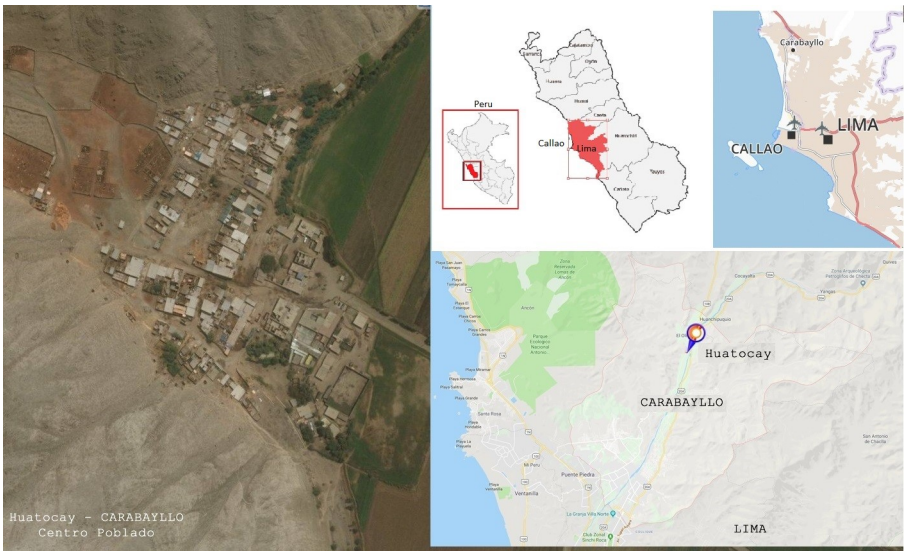

Figure 3. Huatocay location in Carabayllo, Lima region, Peru

Phase One: Fixed Wing Aircraft

The system features an 1880 - Skywalker aircraft frame. It is described as a flying wing UAV model made of highly dense foam and it has four main components: one fuselage, one elevon and two wings. Figure 4 shows the frame of the current prototype. This type of UAV has control surfaces on the wing as ailerons, horizontal and a vertical stabilizer on the tail as elevator and rudder to control roll, pitch and yaw during flight. The fuselage or main body was modified to house the Avionics, Propulsion and the Image Acquisition Systems components. Figure 5 shows an overview of the entire system.

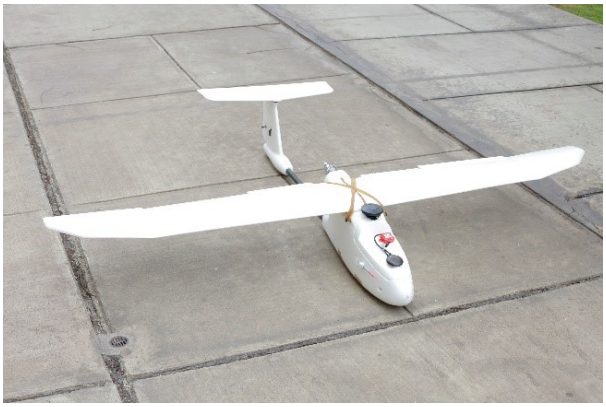

Figure 4. 1880 - Skywalker UAV model for multipurpose appliances

Avionics System

The Avionics System is built around the Pixhawk2 autopilot from Hex Technology Limited, whose tasks include the control of all the actuators of the UAV, reception of sensor information for state feedback for the system control algorithm, trajectory planning, and signal reception from the Ground RC Controller, among others. The Pixhawk2 controls each surface of the aircraft to follow the flight plan that is uploaded before each flight. The control algorithm used is based on PIDs that synchronize the movements of the electric servos on each control surface on the wings to follow the designated waypoints on the flight plan. Each waypoint has a known altitude, latitude and longitude coordinate that it is used to guide the UAV. For this purpose, the Pixhawk2 uses several important components, which will be described in the following paragraphs:

- A GPS Receiver, to get the UAV's geographical location and heading in the world.
- An Airspeed sensor, to get the current wind airspeed (and consequently the UAV speed) and calculate the altitude from pressure data.
- A telemetry radio, to inform a Ground Station about the status of the UAV and the mission.

- A RC Receiver, to get the RC signals from a ground controller for manual control of the UAV and to receive the command to start autonomous flight.
- An embedded IMU, for information regarding UAV attitude.
- An embedded barometer, to calculate the pressure altitude over sea level.

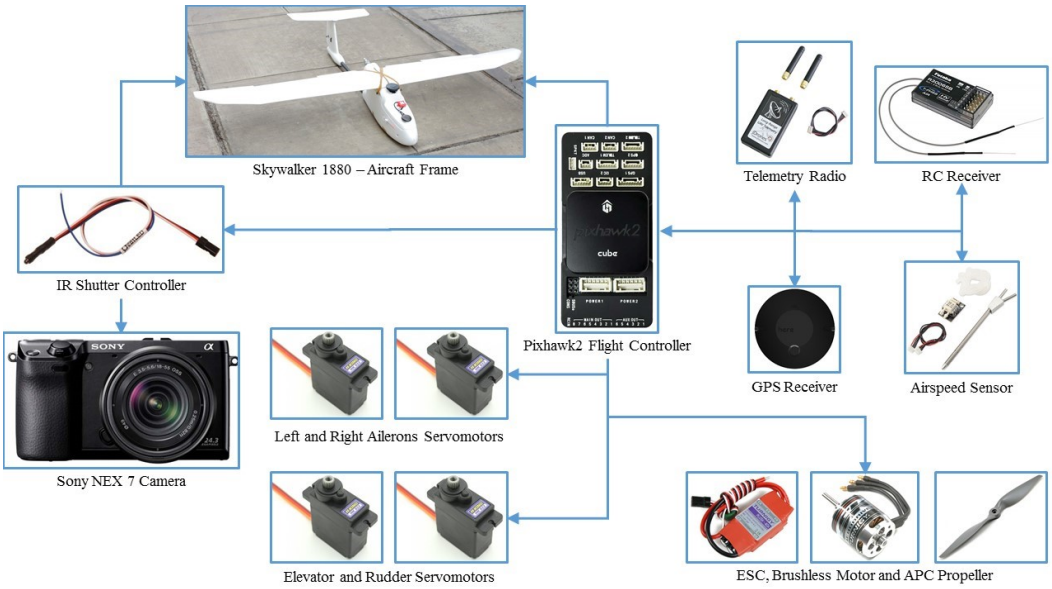

Figure 5. An overview of the fixed-wing UAV proposed system

Propulsion System

The Propulsion System is responsible for generating the thrust required by the UAV to move forward and control the speed of the aircraft, which is important to generate enough lift during take-off operations. Its main components are one Turnigy Motor ® 700KV brushless motor, one 4S – 8000mAh Li-Po battery and a 10″×7″ foldable plastic propeller.

Image Acquisition System

For the task of acquiring and storing images, a Sony NEX 7 camera is used to capture of 24.3 megapixels images. The Pixhawk2 navigation controller sends the necessary signal to trigger the camera.

Methodology for Data Acquisition and Processing

This part is composed of the following sub steps planning and operations: terrain inspection for take-off and landing operations, flight planning for trajectory, 3D reconstruction and surface flow model.

Terrain Inspection for Take-Off and Landing Operations

After arriving at the area of operations, the surrounding environment must be inspected to determine suitable terrain for the Take-Off and Landing Operations. A smoother land of considerable extension must be found to carry out a successful landing. Moreover, take-off operations, although not as dangerous as landing ones, require a place where the ground offers stable footing since, propulsion must be provided by a human operator, who must gain speed by running and throw the aircraft while the pilot activates the throttle.

Flight Planning (Trajectory Determination)

Test flights were carried out near Chillón River in Perú over two regions (76°58'58.713"W, 11°43'55.006" S) and (76°56'21.394"W, 11°42'28.940" S) on March 28, 2018. Each flight plan was made using the Mission Planner software considering a 75 percent overlap between images and flight lines. The terrain and weather are important factors to consider during the preparation of each flight plan. To overcome these difficulties, the flight plans are designed so that the UAV will fly alongside the direction of the wind and against it when the wind

speed is relatively low to save energy. To determine where the photos are to be taken along the trajectory, a distance-based system is employed, meaning that the cameras will be triggered each time the aircraft travels a determined distance inside the area of interest. This allows the images to maintain the desired degree of overlap since they are taken at regular position intervals, unaffected by wind speed or aircraft velocity. Moreover, flight trajectory is also determined by the image resolution of the camera. In Figure 6, the flight trajectory for the flying missions of two areas near Chillón River is shown. For these flights, a relative altitude of 150 meters was chosen, so to cover the entire area, the trajectory could afford to be sparse and with few lines for the aircraft to go through.

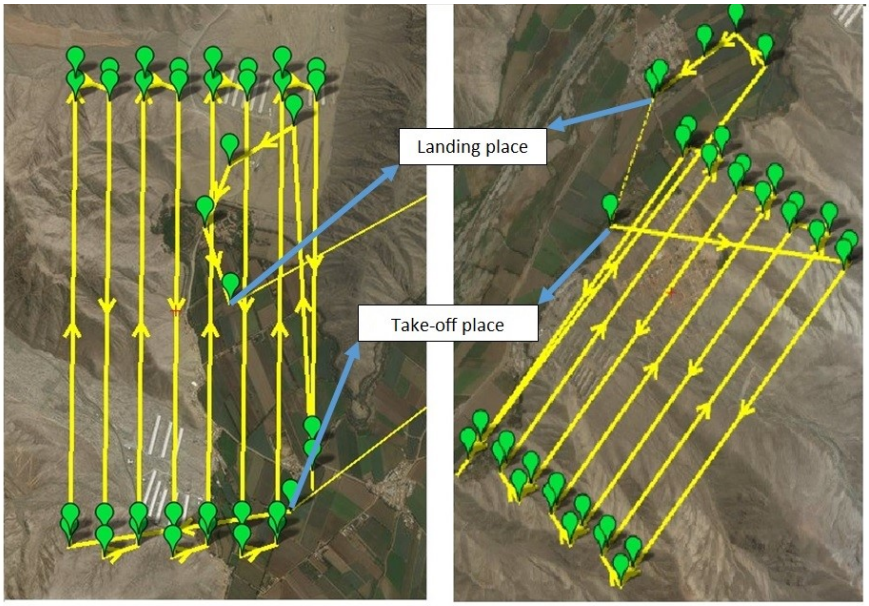

Figure 6. Flight trajectory of the two flying missions using Mission Planner software

3D Reconstruction

After performing the flights and acquiring images, a photogrammetry software was used to reconstruct the terrain that was overflown. Agisoft Photoscan software was used to process the images and generate 3D models and digital elevation models (DEM). The 3D models and DEMs of the two regions subject of this study are shown in Figures 7 and 8.

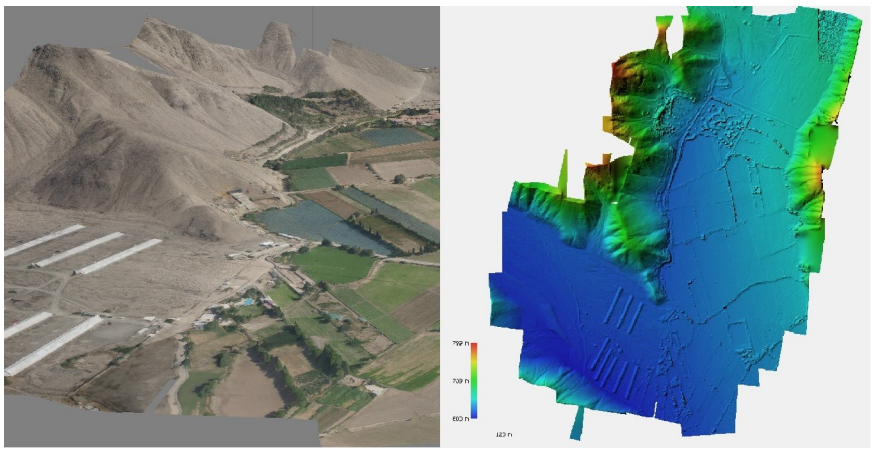

Figure 7. 3D reconstruction – Zone 1, scale 1:500

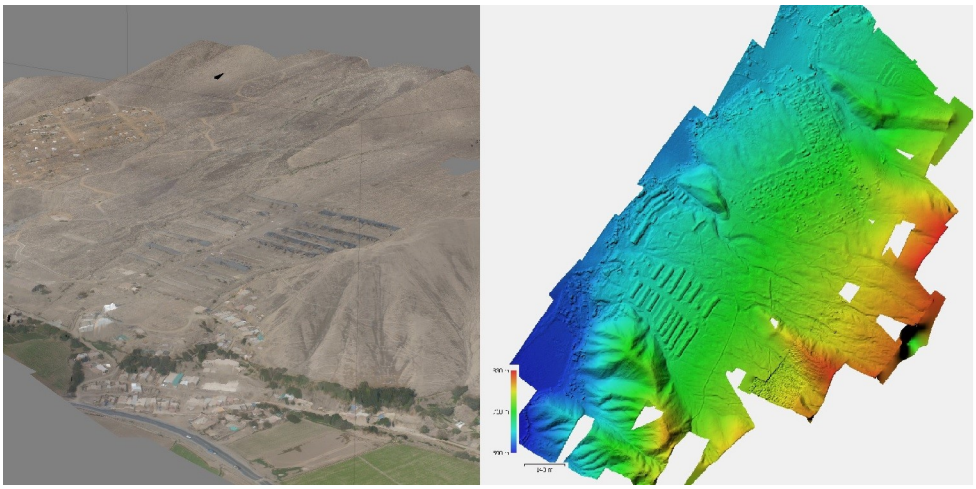

Figure 8. 3D reconstruction – Zone 2, scale 1:1000

Surface flow model

A surface flow model is needed to assess the possibility of a landslide event. It can be obtained by means of processing the Digital Elevation Models obtained from the previous procedure. The D-infinity algorithm, proposed by David G. Tarboron, was implemented using Matlab software for each DEM.

Phase Two: Multirotor Aircraft

The system features a Turbo Ace Matrix-E aircraft frame. It is described as a quadcopter UAV model made of carbon fiber deck which supports a 1000 mm wingspan and it has two main components: one frame consisting of 2 Carbon fiber Structural Beams and 4 15" T-Motor Precision Propellers.

Avionics System

The Avionics System is built around the Naza-M V2 Flight Controller from DJI, whose tasks include the control of all the actuators of the UAV, reception of sensor information for state feedback for the system control algorithm, trajectory planning, signal reception from the Ground RC Controller, among others. For this purpose, the Naza-M V2 Flight Controller uses several important components:

- GPS & Compass Functions include GPS-Lock, Home-Lock, Course-Lock & Return-to-Home.
- Transmitter & Receiver Recommendation: 2.4GHz.
- A RC Receiver, to get the RC signals from a ground controller for manual control of the UAV and to receive the command to start autonomous flight.
- An embedded IMU, for information regarding UAV attitude.
- An embedded barometer, to calculate the pressure altitude over sea level.

Propulsion System

The Propulsion System is responsible for generating the thrust required by the UAV to move forward and control the speed of the aircraft, which is important to generate enough lift during take-off operations. Its main components are 4 Dynamically Balanced Brushless Motors, one 16,000 mAh 25C 6S (22.2V) LiPo Battery and four 40A ESCs with Cooling Algorithm.

Image Acquisition System

A Sony NEX 7 based camera system is used to capture images of 24.3 megapixels. It includes a Gyrox-7+VTX gimbal for camera stability.

Terrain Inspection for Take-Off and Landing Operations

After arriving at the area of operations, the surrounding environment must be inspected to determine suitable terrain for the Take-Off and Landing Operations. A smoother land of minor extension is considered to carry out a successful landing. Take-off operations, although not as difficult as in the fixed wing case, require a place where the ground offers stable footing.

Flight Planning (Trajectory Determination)

Test flights were carried out in the town of Huatocay near Chillón River in Perú (76°59'10.9''W, 11°45'24.7''S) on March 28, 2018. In Figure 3, the flight trajectory for the flying mission over Huatocay is shown. For these flights, a relative altitude of 70 meters was chosen, so to cover the entire town.

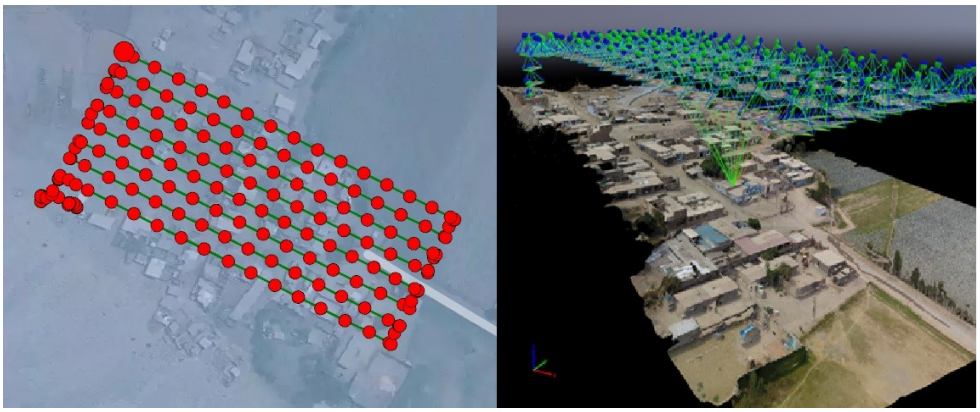

Figure 9. Flight trajectory for 3D reconstruction of Huatocay

3D Reconstruction

After performing the flight and acquiring images, photogrammetry software was used to reconstruct the terrain that was overflown. Pix4DMapper Pro software was used to process the images and generate a 3D model and a digital elevation model (DEM). The 3D model and DEM of Huatocay are shown in Figures 9 and 10.

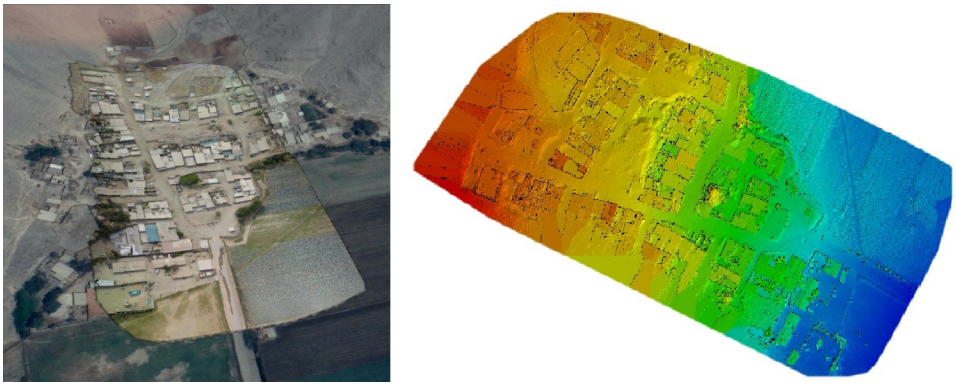

Figure 10. 3D model and DEM of Huatocay

Phase Three: Vulnerability conditions identified

Surface flow model

A surface flow model is needed to assess the possibility of a landslide event. It can be obtained by means of processing the Digital Elevation Model obtained from the previous procedure. The D-infinity algorithm, proposed by Tarboron (1997), was implemented using Matlab software for each DEM. Figure 11 shows the flow model example in red which represent potential landslide to be triggered with critical conditions such as rainfall and type of soil. This model has a close relationship with the landslide events occurred in 2017.

Figure 11. Surface flow models obtained, scale 1:500

DISCUSSION

In this work, we propose the use of Unmanned Aerial Vehicles and Digital Image Processing Software to give additional information for Disaster Risk Management purposes. The combination of these new technologies allows the user to build 3D models, digital elevation models, orthomosaics and other products that can be studied in a GIS. In comparison with traditional methods to obtain this kind of information, such us topography, the use of UAVs and photogrammetry software is a more efficient way because of time, budget and precision. Depending of the type of UAV, the mapping of certain areas can be made in less than the quarter of time spent by traditional methods. Moreover, the cost of conventional method can be three times the cost of UAV based methods (Volkmann, 2017), also using RTK points, the precision reached by the photogrammetry software is in the order of millimeters.

Albeit, the use of UAV and software to process the images possesses some important points to take in consideration. Nowadays, people need a license to pilot these vehicles in many countries, and it expresses some restrictions about the area to fly or other conditions. In addition, not all the kind of UAVs can be used to map specific areas, it requires technical information to plan the autonomous flight. Finally, when the images are acquired, it is required to use a software to build the 3D models and other products. This software is an additional expense and it is also needed to have a basic knowledge of photogrammetry to use them.

For this study, we evaluate this advantages and drawbacks related to these technologies and we are convinced that this methodology should be used because of the continuous development of UAV technology and the availability of them. The municipality of Carabayllo has recently acquired two UAV with the capabilities to map the area of study. Besides, they have been trained to use properly the UAVs, and now they are planning to acquire the license of photogrammetry software to process their images. For these reasons, we consider that this new methodology is a suitable solution to perform aerial mapping for Disaster Risk Management purposes.

CONCLUSION

The results of the information processing allowed to elaborate the susceptibility maps of the area under study, establishing potential area where material flow landslides would occur, the results found allowed to find a correspondence between the information of the affected areas due to of the Coastal Child in 2017 according to SINPAD information and the estimations obtained from the processing of the images shown in the present work.

A new version of this work should include in addition to the degree of slopes a characterization of the territory that includes the levels of risk of the area associated with the characteristics of the type of soil, configuration of the city and amount of rainfall in the study area. It is known in the literature that the landslides and their impact are the result of a more complex system that corresponds to the interaction of all these characteristics, achieving different results according to the state of the criterions, in this way it will be possible to establish at micro level the flow of landslides with more certainty. These categories can also be included considering their historical performance in a cause-effect relationship with the activation of landslides that occurred in the study area.

ACKNOWLEDGMENTS

We thank all authors from PUCP and UNI, to taking part in this first interinstitutional and interdisciplinary research collaboration. Also, we thank Penn University for the seed funding which let the meeting of different background researchers and scholars to run this first collaboration project. Finally, we remark Carabayllo's citizens and authorities participation, who supported and collaborated field work.

ABSTRACT

The Caribbean island of Dominica is at constant risk of being hit by tropical storms during the hurricane season. Therefore, Dominica and areas in similar situations need to raise their resilience to natural hazards. The potential consequences of climate change intensify this risk. After a hurricane hit, repair of damage to buildings and infrastructure can take several months. As hurricane frequency is increasing and time between hurricanes fluctuates, modeling sequences of hurricane events can help to determine different evacuation strategies. This paper introduces an agent-based model, simulating two hurricane events in one season. The prototype simulates the movement of evacuees over a road network and damage to buildings and infrastructure. Initial results show marked differences between road movements of evacuees during a second evacuation. Although shifts in the average shelter occupation are small (up to 2%) for our case study, this can indicate that adjustments to shelter capacities are necessary.

Keywords

Agent-based modelling, evacuation simulation, multi-event scenario, NetLogo, OpenStreetMap

INTRODUCTION AND BACKGROUND

Natural hazards like tropical storms and hurricanes pose a permanent risk to many regions and their population. They can cause a direct threat to life, destruction of homes and basis of life, a breakdown of the economy or the outbreak of diseases in the aftermath and more. Depending on the location, the exposure of a population towards natural hazards varies, as well as the preparedness and the resilience of a society towards a potential catastrophe (Lam et al. 2014). Small island states in the Caribbean have a high exposure to natural risks, especially to tropical cyclones and their strongest category: hurricanes. In addition to this, many countries in the Caribbean have limited resources and are vulnerable, yet not resilient to the impacts of those risks (Jetten et al. 2014).

In the Atlantic Hurricane season of 2017, 17 named storms affected Central America and the South-Eastern States of the USA (Shultz et al. 2018). Among those storms, ten developed into hurricanes. Hurricane Maria was a category five hurricane, passing directly over the island of Dominica, and affecting other islands as well. Being hit directly by the hurricane, the destructions on Dominica were disastrous. Thirty-one people died during the event, and a considerably larger number of people were severely injured (ACAPS 2018). Houses were destroyed, as was the majority of the island's infrastructure. While this event alone revealed the danger the people of Dominica are exposed to, the effects of climate change might lead to even more severe tropical cyclones and hurricanes in the future (Lam et al. 2014). As more tropical cyclones will eventually develop into hurricanes, an increase of the number of hurricanes per season can be expected too (Knutson et al. 2010).

Therefore, it is necessary to increase the preparedness and resilience of the island and its population. This is supported by an ongoing shift from an ex-post response and recovery to an ex-ante approach with a focus on minimizing the disaster risk by reduction of vulnerability, capacity building and better information and institutional strengthening. The planning and organization of shelters and evacuation routes in case of an

emergency are crucial (World Bank 2012). To optimize shelter and route planning, estimations of the population's behavior and their resulting movement in case of evacuation are needed. Due to the impacts of climate change, it is likely, that in the near future multiple high category events occur in one season, affecting the same island. Roads and bridges, previously designed to be part of an evacuation route, may be impassable and the recovery time between storms might not be sufficient to allow for reconstruction. The planning authorities and other responsible bodies need to be aware of these circumstances.

Having limited resources and capacities, the island of Dominica and its authorities need methods to be developed to help to raise resilience to catastrophes (Lam et al. 2014). Agent-based modeling offers great potential for simulations of such events and generates valuable information. The concept of agent-based modeling tries to simulate a system by representing its individual components and behaviors. In agent-based models, "individuals or agents are described as unique and autonomous entities that usually interact with each other and their environment locally" (Railsback and Grimm 2012, p. 10). Thereby it can be analyzed how the system's behavior is constituted by the characteristics and behaviors of its individual components.

There has been extensive research in the field of agent-based modeling in evacuation contexts. Chen et al. (2006) created a model for hurricane evacuation in the Florida Keys. The focus was put on the clearance time of the entire area and on how many residents would need accommodation once the route became impassable. Liu and Lim (2016) developed a simulation model for the 2011 Brisbane flood, concentrating their research on shelter assignment and routing strategy, and thereby integrating GIS-based spatial analysis. Focusing on the interactions among evacuees during an evacuation process, Zhang et al. (2009) analyzed how different behaviors of agents during the process may change the overall movement in the network. Furthermore, D'Orazio et al. (2014) designed an agent-based model approach for simulating pedestrians' evacuation in urban outdoor scenarios by analyzing videotapes of real events.

What most of the studies share is that they either focus on motorized traffic simulation, or on building or urban (public places / events) evacuation. Moreover, clearance of the affected area is often the focus of other evacuation simulations. Compared to the former-mentioned studies, this study differs as it is not possible to clear the affected area and most people evacuate via walking. Being a Caribbean island, Dominica is cut off once the hurricane hits the island. Additionally, in this study infrastructure disturbances are simulated in a multi-event scenario (two events in one season) to detect differences in shelter occupation and evacuation routes, and the resulting movement patterns, which makes the approach deviate from other comparable evacuation simulation concepts.

The main objective is to develop a system that facilitates the combined analysis of infrastructure disturbances, especially road damages, and evacuation behavior for planning purposes. It aims to do so by creating a prototype model that integrates both, infrastructure disturbances and people's behavior in evacuation events. How can agent-based modeling with an integration of a multi-event scenario based on a road network be used to improve preparedness to hurricanes in Dominica?

APPROACH, METHODS, MODEL

Model Concept and Implementation

The model's purpose is to simulate the movement of evacuees during different phases of two consecutive storm (hurricane) events and to integrate road damages done by the first storm for the following event, influencing and potentially altering the movement and shelter allocation. The phase between the events is not simulated explicitly.

The model consists of three phases per event. The phases are as follows: 1) Evacuation phase: population moving to shelters, 2) Hurricane phase: hurricane taking place, population in shelters, damages are occurring, 3) Post-hurricane phase, population returning home. The phases are repeated for the second event under different circumstances (i.e. road network affected by damages). Additionally, one phase between both blocks represents the time between two events, meaning that the population is at home, after the first event (Figure 1, Table 1). The time steps (ticks) are defined as seconds during the evacuation and the return home phase of the model run. The moment in time when the hurricane takes places, and the exact duration of a hurricane evacuation, are not simulated. Neither is the time in between two hurricanes. This is because we are simulating differences in road movement and shelter occupation rather than evacuation time.

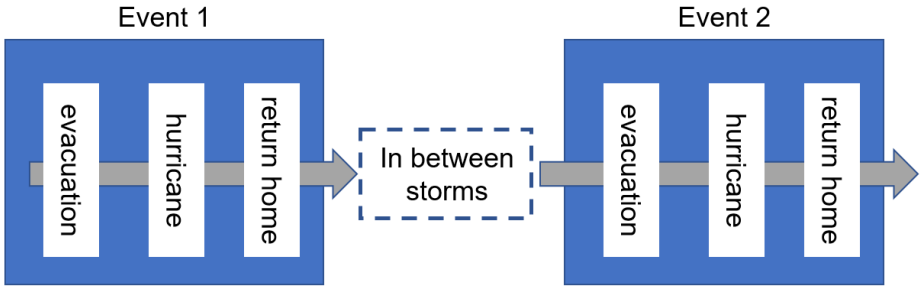

Figure 1. Schedule of the model concept and the corresponding phases per event

Table 1. Model concept phases and the corresponding actions in the simulation

Event	Phase	Concept	Actions
1	1	Evacuation phase	Households moving to shelters
	2	Hurricane phase	Households in shelters, Hurricane active, damages to roads
	3	Post-hurricane phase	Households returning home
-	4	In between events	Households at home
2	5 to 7	Repetition of 1 to 3	Repetition of 1 to 3
-	8	Post-hurricane phase	Households at home, Simulation finished

1. Evacuation phase

The evacuees are aggregated to households. At initialization, each household is assigned a building as a home. Households calculate the optimal route from their starting location to all shelters and know which shelter is the closest, based on the distance of the routes, and will always try to go the nearest shelter (Figure 2). From the home node, the distance to each shelter node is calculated, based on the optimal route and the weight value of the links (length of roads between nodes). The network extension in NetLogo 6.0.4 (Wilensky 1999) is able to find the best route using the Dijkstra algorithm, comparing different options on the network and choosing the one with the least sum of weight (distance) values (Dijkstra 1959). The distances to all shelters are compared, and the shelter node of the shelter with the least distance is defined as the destination for the household agent. The path from the home node to the destination node is now stored as an ordered list variable of the household agent, containing all links (edges). Also, all nodes along the route are stored as an ordered list. The list of nodes will be used for the movement, following node by node on the path. Once the first evacuation starts, all households start their movement at the same point of time without hesitation and without decision making of whether or when to evacuate. They move over the road network at a constant walking speed of 1.4 meters per second (Mohler et al. 2007) until reaching the destination and the list of nodes to visit is empty.

2. Hurricane phase

Once all household agents have arrived at their destination, the damage-to-nodes procedure starts, making road nodes die with a probability based on the risk zone class they are located in. The procedure uses the patches (pixels in NetLogo logic) own variable of the risk-zone-class for a probability for a node to die if it is located on the patch. On a patch with the highest value of the risk class (3), there is a risk of 10% for a node to die, 3% on a patch with a risk class of 2, and 1% on a patch with a risk class of 1. The values are an approximation based on the work with landslide and flood hazards of Jetten et al. (2014) in the CHARIM project. The CHARIM project aims to support the generation and application of landslide and flood hazard risk in the Caribbean region. Some nodes on the road network are defined as the home node for households. These can also be affected by the damage-to-node procedure. If a home node dies, it is assumed that the home of the household was destroyed. The household will then stay in the shelter.

3. Return home phase

After the hurricane phase, households will return to their home locations. The calculate-path-home procedure calculates the best way home. This does not necessarily have to be the inverse of the route the household has taken to the shelter, as the road network may have changed due to the previously mentioned damage-to-nodes procedure. If a household cannot find a path leading to their home location, which may occur if all connecting roads were destroyed, they stay at the shelter. When all household agents arrived at their home location, the steps are repeated. However, the road network will stay altered, representing the damages done by the hurricane in the second phase. The route calculation of the households in the next evacuation phase takes these changes into account.

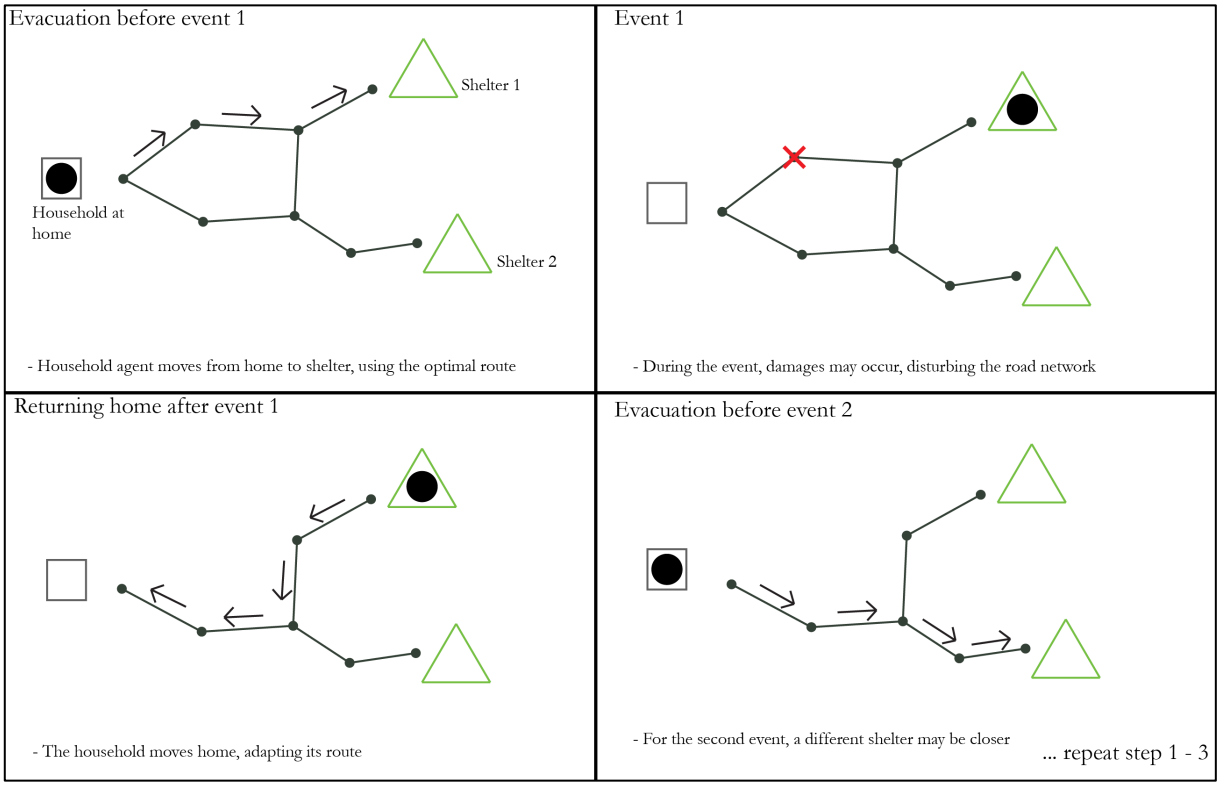

Figure 2. Logic of routing procedures based on Dijkstra algorithm. Depending on the phase, the road network can be affected and altered through damages

Study Area and Data Description

The prototype model will be tested on Roseau, the capital of Dominica. This area has a relatively dense population with a good road coverage, multiple shelters, and potential damage to infrastructure (Figure 3). The number of household agents in the model should reflect the population of the study area. Five thousand households is a realistic number, considering the population of Roseau (14.725) (Commonwealth of Dominica 2011). This is supported by the number of potential dwellings in the study area (5030), after data editing. For this study, the following data is needed: roads, buildings, the location of shelters and areas of potential risk (damage).

Roads and buildings

OpenStreetMap (OSM) data was used for retrieving data on the street network and building locations, using the OSM keys “highway” for streets and “building” for buildings. The Humanitarian OpenStreetMap Team (HOT) carried out an activation (actively pursuing the creation of map data with the help of volunteers in response to a crisis) for data improvement, reacting to the disaster caused by Hurricane Maria. It aimed to improve the buildings and road data coverage by performing multiple projects in the Caribbean, including one explicitly for Dominica (OpenStreetMap contributors 2018).

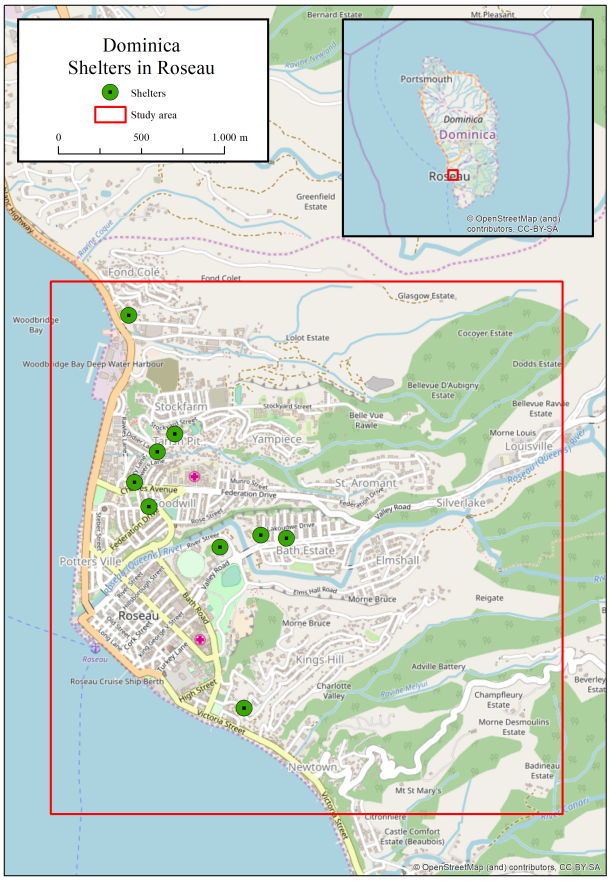

Figure 3. Study area (Roseau) and location of shelters

For the methodology of this study, it is advantageous to have a relatively high number of nodes for the road network, as the nodes are used for the placement of the agents, for defining road damages and for route calculation. Thus, long segments without nodes were edited manually, adding more nodes and splitting the segment into multiple parts.

Buildings were identified as residential (dwellings) or non-residential based on building size (area). To exclude non-residential buildings, only those larger than 20m² and smaller than 300m² were kept as potential dwellings. The selection of these values is partially arbitrary, as no more information (e.g. attributes of buildings data) is available for the study area.

Some of the buildings represent hurricane shelters. The data about locations of hurricane shelters in Dominica was downloaded from the GeoNode data-sharing platform of the Caribbean Handbook on Risk Information Management (CHARIM) project (Jetten et al. 2014). Nine shelters are defined in the respective study area of the city Roseau and surroundings.

Risk zones

For estimating the probability of road damage during a hurricane event, road damage risk zones have been created based on flood-risk and landslide susceptibility, classified within the CHARIM project. Combining both raster datasets and reclassifying the combinations, three classes of potential risk zones were defined (Table 2, Figure 4). A classification value of 1 means a relatively low chance of a road being damaged, a value of 3 a high probability.

Table 2. Risk zone definition: Reclassification of a combination of flood hazard and landslide susceptibility datasets, resulting in three classes of potential risk (1 – low chance of a road being damaged, 2 – medium, 3 – high)

		Flood hazard extent				
		None	1:50 year rainfall	1:20 year rainfall	1:10 year rainfall	1:5 year rainfall
Landslide susceptibility	Low	0	1	1	2	3
	Medium	1	2	2	2	3
	High	3	3	3	3	3

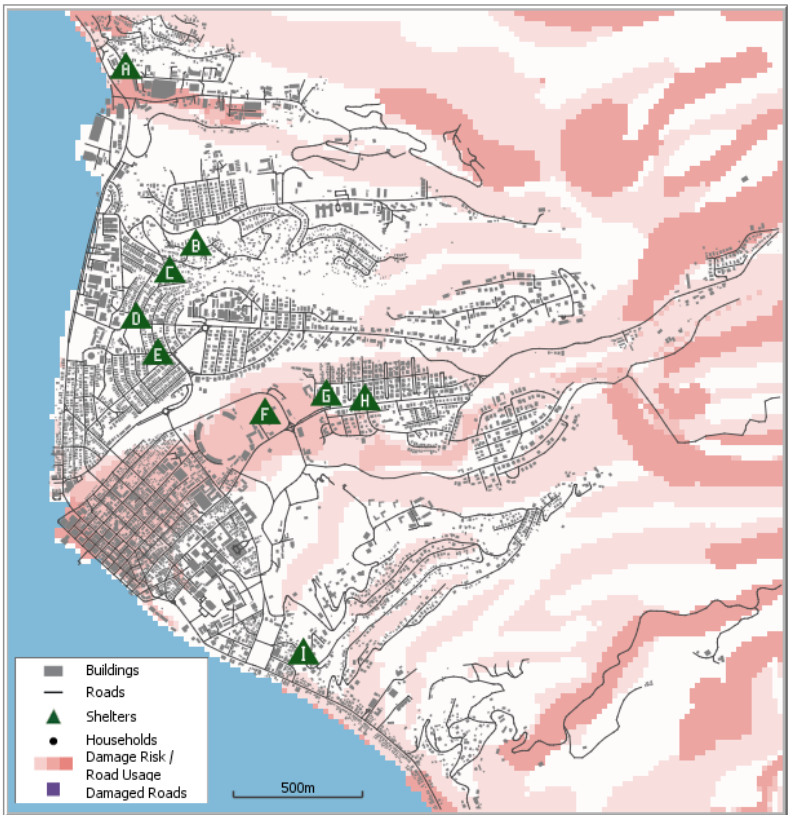

Figure 4. Overview of integrated data: Risk zones, buildings and roads

Model output and experiments

The described conceptual model was implemented in, and the described geodata was imported into the NetLogo 6.0.4 software. Experiments with multiple simulation runs were conducted. Two types of model output are defined to evaluate the model performance: the number of evacuees in each shelter during the hurricanes and the movement pattern of the evacuees during evacuations. As two consecutive events are simulated in each simulation run, we can determine the difference in shelter occupation and road network use between the two events.

A counter procedure was defined to detect differences in the movement pattern of evacuees as a result of a changed road network. Each patch has a counter variable, counting the number of households located on the patch at each time step during the evacuation phases. These counter values lead to a pattern, which can be interpreted as a relative usage of the roads. For both events, one individual counter exists and thereby allows the comparison of road usage (and route choices) in the evacuation phase.

Additionally, the number of households per shelter for each hurricane event is tracked. The comparison of shelter occupation reveals a possible over-occupation (above the available space) and changes in occupation between two events. The combined observation of relative road usage and numbers of evacuees per shelter will allow a first interpretation of the influences of road damages on movement patterns and shelter allocation.

As the procedure of road damages, i.e. nodes dying during the hurricane phase, includes a probability based on the predefined risk zones, the patterns of damages will be different for each simulation run. To assess the influence of the stochastic elements, the simulation was run 100 times with the same setup. Observing the development of the average number of road damages in the first event, the variation of the resulting values is relatively stable after 25 runs (Figure 5).

For those 25 runs, the values for road usage (counted households on a patch) for the first event without road damages and the second event including road damages are compared by computing the difference between the events for each model run. The average of those differences is calculated and visualized. Furthermore, the average number of household agents per shelter for both events is calculated.

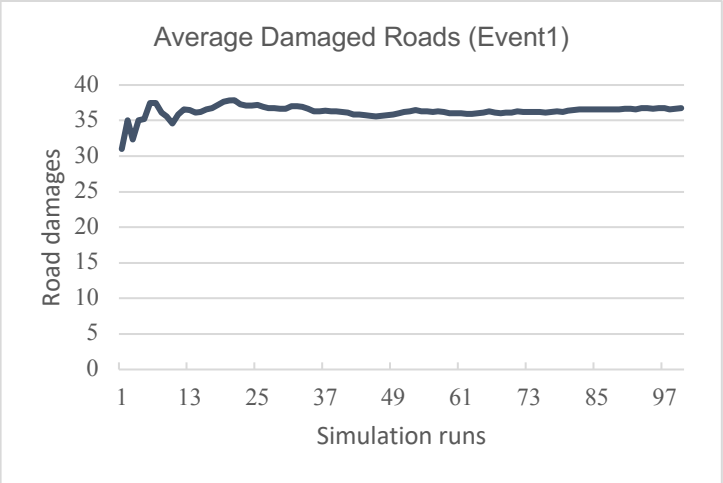

Figure 5. Average damaged roads during the first event after a number of runs

RESULTS AND DISCUSSION

In this study, it was examined how road damages caused by storm events would affect the movement of evacuees, changing their route choices and thereby influencing the shelter allocation. Results for the movement pattern (Figure 6) show that changes are mainly occurring on main roads running in an east-western direction and that the difference in road usage between the two hurricane events is considerable. This can be interpreted as an effect of the combination of the high number of households living in the area, the damage caused to these roads, and the fact that multiple shelters are located along the main roads.

The interplay of shelter allocation to shelter E, F, and I is of main interest for the interpretation of the results. On the route leading from the southwest to shelter F road damages frequently occur, making the road inaccessible in many runs. Additionally, alternative routes around shelter F are commonly damaged. This leads to an increase of road usage from the respective area on a route north towards shelter E, and south towards shelter I. Another interesting aspect is the movement from the eastern outskirt settlement, being connected by one road only to shelter H. Damages that occur here, make movement between the settlement and the shelter impossible, leaving a high number of households in need to stay at the shelter. Consequently, the road usage towards shelter H is reduced. Furthermore, roads leading to shelter I (at the coast from the southeast and from the inland from the northeast) are frequently damaged. Therefore, the adjacent roads are being used as alternative paths in many runs, explaining the substantial increase of usage.

Another interesting fact is the average number of households per shelter for both events (Table 3). Due to the road damage issues explained before, the average percentage of households seeking shelter in shelter F reduced by 2%. At the same time, the number of households in shelters E and I increased by 1.4% and 1.1%. As the eastern road to shelter H is frequently being damaged and inaccessible, a slight reduction of the average shelter allocation in shelter H can be observed (0.5%). If a household cannot find a path back home in the return home phase, it needs to stay in the shelter. As the numbers of Table 2 reveal, these numbers differ among the shelters. Especially the shelters F (115.5), H (81.4) and I (128.7) show relatively high average numbers of stuck households. These shelters are connected to some residential areas by a single road only and lack alternative routes. Therefore, they host a high average number of households, which cannot return home.

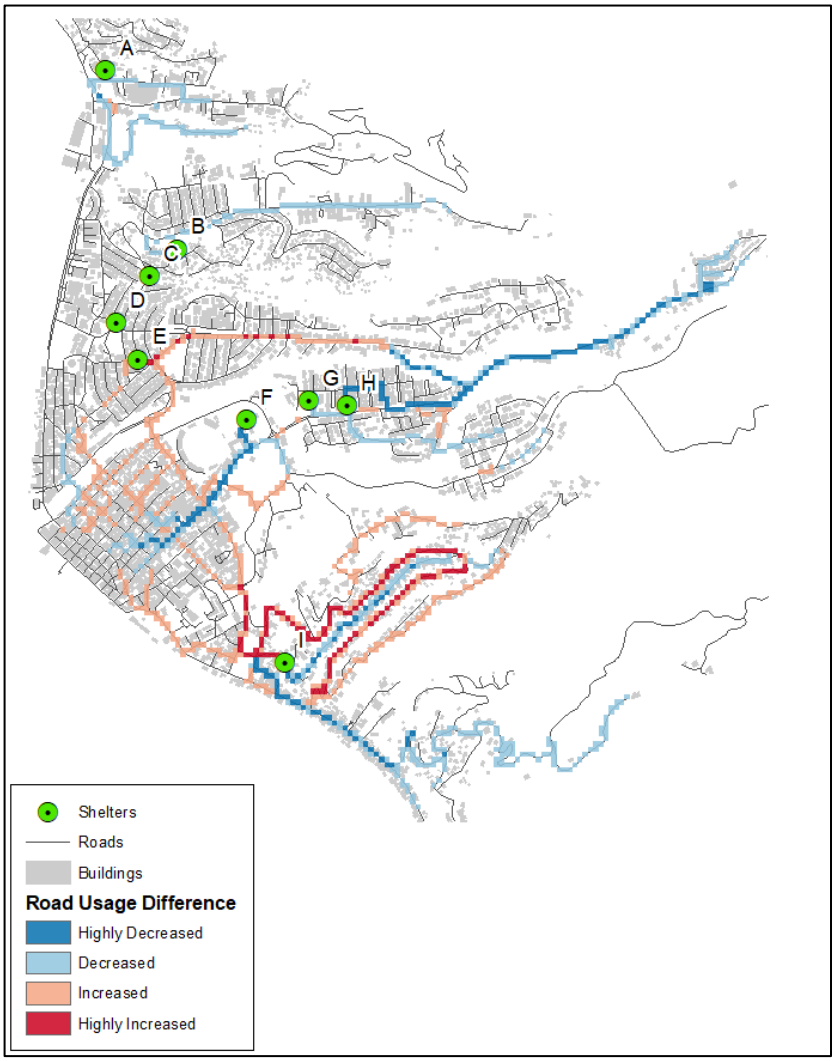

Figure 6. Average difference in road usage between event 1 and event 2 (during evacuation phases)

Table 3. Average shelter occupation per event per shelter

	Event 1		Event 2			
Shelter	**Number of households**	**Percentage of total households**	**Number of households**	**Percentage of total households**	**Tendency**	**Households staying in shelter**
A	281	5.7	277	5.6	=	51.1
B	717	14.6	717	14.6	=	10.9
C	106	2.2	110	2.2	=	4
D	222	4.5	222	4.5	=	0
E	1192	24.2	1258	25.6	↑	34.4
F	573	11.6	471	9.6	↓	115.5
G	247	5	245	5	=	14.8
H	394	8	373	7.5	↓	81.4
I	1191	24.2	1244	25.3	↑	128.7

The changed road usage and route choices for a second evacuation event, depending on the damages occurring during the first event, deliver valuable information about critical road segments and sections. If a shelter is connected to a highly populated area by a limited number of roads, and if these roads are at risk of being disturbed, the movement pattern of the evacuation changes. Using this information, planners can identify critical road segments and plan road fortifications or define alternative routes leading to the corresponding shelter. Additionally, prioritization of road reconstruction can be done. The information provided by the model might lead to the realization that the location of a specific shelter is unsuitable, as the risk of it becoming inaccessible is high.

Furthermore, the results of the model run revealed, that a disturbed road network leads to changes in the numbers of people (or households) per shelter. The model results and the derived information can be used for evaluation of shelter allocations. One effect may be that if a shelter is not accessible for a second evacuation, other shelters in the area are used by a larger number of evacuees. By using a model that takes this into account, the planner is able to prepare and avoid an unexpected over-occupation of a shelter. Also, a shelter might be cut off from the network, preventing evacuees to return home, as the roads leading back to populated places and settlements are not usable anymore. To be prepared for this, shelters, which are identified as being at risk of inaccessibility after one event, and that therefore need to house evacuees for a longer time, need to stock up their supplies or alternative shelter locations should be defined.

CONCLUSION AND FUTURE WORK

In the course of this study, a prototype agent-based model was created, combining disturbances of infrastructure and the evacuation movement of the population in the case of two consecutive hurricane events on the island of Dominica. The prototype makes use of a multi-event scenario and a network-based routing systematic. Initial runs of the simulation model revealed that damages to infrastructure have a significant influence on the movement patterns and route choices of the population, leading to changes in the road usage and shelter allocations.

Multi-event modeling can be used to find critical road segments and problematic shelter locations. This can give planners a tool that can help to take measures to improve the preparedness for hurricanes. The current prototype has some limitations, as it assumes that all people evacuate and that all evacuees select the nearest shelter as destination. This is not true, as people may decide to stay home or evaluate the safety of the shelter and select a different one based on multiple criteria. A more advanced evacuee behavior model can be integrated in the prototype to simulate the number of evacuees, and the route and shelter choices they make, using more advanced mechanisms (e.g. artificial intelligence).

The model should be tested for other areas in Dominica or other Caribbean islands and more detailed analysis can be done on the simulation results, e.g. by examining individual routes of evacuees to gain a better understanding of the evacuation behavior. The simulation phase in between the two hurricane events can be filled. During this period, road repairs can be conducted. By varying the length of the repair period, a more realistic picture can be obtained about the consequences of multiple hits. Also, it is possible to simulate more than two events in one simulation. Further tests should be conducted in this regard. The risk of road damage for the different areas can be calibrated by analyzing previous hurricane events (e.g. by using remote sensing technology). The current risk function combines two different causes: landslide and floods. These two hazards could also be separated to come to a better risk prediction.

The integration of more data, e.g. attributes of the population, building types, road surfaces etc., can lead to further details. However, the quality and availability of data should be evaluated first. As the road network, derived from OpenStreetMap, is of crucial importance for the model, specifically this data should be assessed more in future work before extending the model. Using intrinsic quality measure based on the analysis of the historic development of OpenStreetMap data could be an option (Auer et al. 2018). The model concept and its results should be validated, once the development of the model has advanced further. Sensitivity, uncertainty and robustness analysis need to be performed to test the quality of the simulation. There are several elements, which could be evaluated. By analyzing satellite or aerial images taken shortly after a hurricane occurred, the road damage function of the model could be adapted to represent a realistic damage pattern. Another option could be to compare the occupation rate of the shelters during real evacuations with the simulated occupation rate.

In general, future research need to be conducted for multi-event and routing based concepts. The implemented prototype and its applicability should be developed and assessed further, striving for a more complete and realistic model. This could finally lead to important information and insights to improve the planning of evacuation events and beyond. Further interpretation of the results, potentially with direct exchange of ideas with decision makers, should be considered. Additionally, extensive user research, such as user requirement and usability studies, also taking visualization options into account, are required to support the further development of the model concept and its implementation.

ACKNOWLEDGMENTS

The work is based on a master thesis, conducted and written at the Faculty of Geo-Information Science and Earth Observation of the University of Twente, in context of the International Erasmus Mundus Joint Master Degree (EMJMD) of Master of Science in Cartography, coordinated by the Technical University of Munich. It is supported by the Klaus Tschira Foundation (KTS), Heidelberg, and the Erasmus Mundus Master Course Scholarship. We thank the anonymous reviewers for their valuable suggestions and feedback.

Instagrammers report about the deadly wildfires of East Attica, 2018, Greece: An introductory analytic assessment for disaster management purposes

Stathis G. Arapostathis
Geographer, PhD graduate
Harokopio University
e.arapostathis@gmail.com

ABSTRACT
This article contributes to identifying the capabilities of Instagram when utilized as a source of Volunteered Geographic Information (VGI) for disaster management (DM) purposes. The geographic focus of this research is in the Mediterranean area. As case study, the fire event of East Attica 2018, Greece, was chosen. This major fire occurred on the 23rd of July 2018 and caused the death of 100 people, the injury of additional 164 while the total burnt area was about 1275,9ha. It is the deadliest in modern Greece's history and the second deadliest at a global level, within the 21st century. About 15000 related photos along with the corresponding captions and timestamps were crawled from Instagram. An initial sample of about 1100, was analyzed, by using a certain methodology divided in certain steps, the most important of which include the classification of the information to certain categories, geo-referencing and the creation of graphs and maps that visualize the processed data.

Keywords
volunteered geographic information (VGI), Instagram, social media, fires, disasters, disaster management

INTRODUCTION

There is over a decade passed since the notion of Volunteered Geographic Information (VGI) emerged from Goodchild (2007) and many scientific teams are now at the of stage researching the potentials of this phenomenon in a variety of sciences. VGI is the act of having normal citizens, without any related scientific background, produce geographic information or information with spatial extension, either intentionally or unintentionally. One of the most important applications of VGI focus on disaster management (DM). A plethora of research articles have analyzed various aspects of the potentials of VGI in disaster management, some of them are mentioned indicatively in the following paragraphs.

The work of McDougall (2011) focuses on the effectiveness of social media for providing additional insights in the flood events of Queensland floods in Australia. Those major floods affected a huge geographic area consisted of 30 cities and agricultural areas while, in terms of budget, the restoration cost was about five billion dollars. The most important conclusion of the researcher was related to the immediacy and depth of information that is provided through social media, conclusion that is also verified by Yin et al. (2012) who stated that by using this information, the relevant authorities can improve their awareness and as a result the response in emergency situations. Yin et al. (2012) also developed a system for manipulating the extracted information. Regarding fire events, previous research demonstrates some recent work about the social media network twitter and the fire event of North-East Attica that occurred in Greece during the summer of 2017 (Arapostathis and Karantzia 2019).

VGI research is not only limited on processing data of existing VGI sources but also include various participatory activities like the approach presented by Rahman et al. (2018). That approach is related to the development of a community was able to identify spots of the Dhaka city in Bangladesh, that were vulnerable to earthquakes. The community handled the development of strategies for reducing the vulnerability along with the execution of these related actions. A similar approach is presented by De Brito et al. (2018) and is related to the development of an expert community who was involved in defining the criteria that emerge a geographic area as vulnerable in the

event of a flood.

Especially regarding social media, there is a logical trend of combining various social media sources or even social media sources with satellite imagery in order to extract a more complete output (de Albuquerque et al. 2015; Morstatter et al. 2013). Another nice combination of data source is presented in the work of Smith et al. (2012) who combined social media data and data gathered from a graphics processing unit (GPU) in the case study of the Tyne and Wear floods that occurred during June and August 2012 in the United Kingdom. Those approaches are rather the most effective ways towards perfection. However, futher research is vital to be performed for each social media network exclusively, using case studies that vary geographically in order to have the most comprehensive assessment regarding the comparative potentials of each social media source when is utilized as a VGI source for DM purposes. Especially regarding geographic variations, one of the most important characteristics of user generated content is the ubiquitous and anarchic production in terms of volume, volunteers and geographic areas (Girres and Touya 2010; Haklay et al. 2010).

According to author's opinion the main open challenges, regarding the manipulation of social media datasets, are clustered in four certain categories, all transpired by the significant notion of quality. The first cluster is related to defining the appropriate classification structure for the processed information, suitable for each disaster event category according to the semantics and data properties of each VGI source. There are many articles of various respectful researchers that propose various structures either while researching certain case studies or by creating various conceptual frameworks (Albuquerque et al. 2015; Fahrer et al. 2018; Arapostathis et al. 2018; Dashti et al. 2013). However, as research in the field is constantly evolving, there should be a common definition regarding the most appropriate one.

The second cluster of challenges is related to the geo-referencing of information. Accurate and precise geo-referenced information can lead to the rapidness of the actions taken regarding response during a disaster management situation. However, this is not always feasible. The most desired outcome would be to have a precision level of few meters or even of few centimeters. Some of the DM stakeholders though, may be interested in having information displayed in other scales.

The third category of challenges is related to developing the appropriate techniques for visualizing information that makes sense to all DM participants. From the decision makers, up to simple volunteers which are trying to contribute to the way they can. Taking this into consideration, the graphs and maps used should be very simple and easily readable in few seconds despite of the educational background of each individual.

Finally, the fourth cluster of challenges is related to automation of the methodologies producing the desired output in real time. Analyzing data coming from VGI sources, such as social media, is a time-consuming process as many researchers conclude (Imran et al. 2013, Zhong et al. 2016, Grunder-Fahrer et al. 2018).

Current status of this research aspires to make a step further towards the first three categories.

CASE STUDY

The wildfires of East Attica 2018, Greece, started within the 23rd of July 2018, at 18:41 local time. Main affected areas were the areas of Mati, Marathonas, Rafina, Nea Makri, and the east side of the Penteli mountain. A hundred people died while 164 were injured. According to local witnesses, the speed of the fire was so high that burnt two young people on a scooter while they were trying to run out of the burning area. 26 people were burnt within a taverna that was located near the coastal part of Mati, while hundreds of citizens stayed into the sea for many hours. 1275 hectares were burnt in east Attica according to official measurements of the Copernicus emergency service while more than a thousand buildings were destroyed by the fire. The authorities, apart from East Attica had to deal a fire event that occurred in West Attica (region of Kineta, mountains of Geraneia) few hours before. The combination of those two fire events really struggled the antifire mechanism of the country.

This fire event, until today, is the country's deadliest since the start of modern Greece, and the world's second deadliest of the 21st century, after the Victorian fires.

DATA AND MATERIAL USED

The data were collected by using a crawler developed by Andrea Tarquini (https://github.com/h4t0n/). 15011 photographs, along with the corresponding timestamps and captions, were crawled. All of data contained at least one of the following hashtags: #athensfire, #prayforathens, #prayforgreece and #matifire. This amount of photographs is about the 38% of the total photos available in Instagram, containing those certain hashtags. The author chose not to use a certain bounding box as the news about this event were spread at a global level. The dataset consisted of 4 json datasets which included the timestamp information, the online url and the caption of each image. All images were downloaded by using a wget command in a Linux terminal.

Apart from the crawler, the author also used the Calc of LibreOffice software, for some basic edits on the dataset, R-studio for converting json files to csv and for creating scatterplots, and finally ArcGIS Pro software for creating the final maps.

METHODOLOGY

The methodology applied, was consisted on five basic steps (Figure I). The first step was related to crawling the appropriate volume of Instagram posts according to the most representative and descriptive to the fire event hashtags, while the second step was linked to the data preparation; the conversion of the files that contain the crawled information in an spreadsheet-friendly form along with the selection of the data posted within certain time periods. In the third step, the selected posts were classified into certain defined categories considering each photo and each photo's caption. In this initial investigation, 4 certain categories were defined: a. fire identification, b. disaster management info, c. consequence score values assessed from each image's caption and d. consequence score values assessed from each image. The consequence score values score board was presented in previous research (Arapostathis and Karatzia 2019) and is associated to indicating a certain numeric value that represents effectively the negative impact of each consequence as it is described in each post. The score range is defined from I to V; value I represents the simple fire event identification while value V is strictly associated to the human loss (table I). In cases of different consequence scores between the photo and the caption the highest value was selected as a default rule.

Table I: Description of the conceptual consequence score value range

CONSEQUENCE SCORE VALUES	DESCRIPTION
I	Simple fire event identification
II	Small areas consisted of burnt woodland
III	Emergency situation, large areas are burnt, property in danger
IV	Danger of human life, burnt property, extremely large areas are burnt
V	Human loss

The next step of the methodology was linked to geo-referencing. In this stage, the geo-referencing was performed by considering only the detection of geographic coordinates that exist within each photo's caption. The geo-referencing method applied, was presented in previous research for the social media network twitter (Arapostathis et al. 2018). In brief, the number of the geographic entities that are contained within the text of each caption was noted and each caption was replicated N times where N was the number of detected entities. Afterwards, the corresponding x, y coordinates were added for each caption in a way that each geographic entity of a group of replicated posts was represented once. Moreover, a geographic precision score value according to the precision level of each mentioned geolocation was indicated. Those score values range also from I to V, where I refers to the most precise geolocations (a POI, or a certain street name and number) and V is the most general, related to the administrative level of a prefecture/provincia (table II).

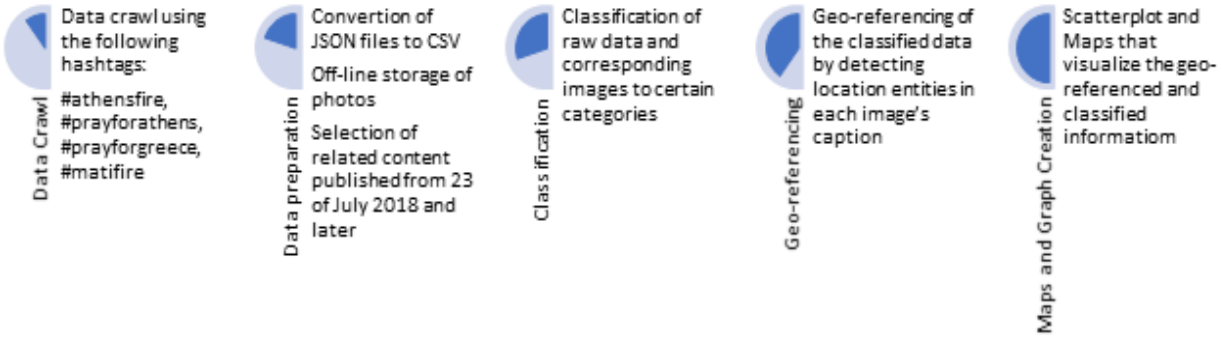
Table II: Description of the geographic precision score value range

GEOGRAPHIC PRECISION SCORE VALUES	DESCRIPTION
I	Street name and number or Specific POIS
II	Street name
III	Neighborhood or hamlet
IV	Municipality
V	Prefecture and above

Finally, the spatial distribution of all the pairs of x, y coordinates were randomized within the polygon that represents each detected geolocation. All the randomized coordinates were stored in a table which also contains the classified information. Even there is previous research related to the development of an R-script that automates

this geo-referencing technique (Arapostathis 2018) due to the initial stage of the analysis it was preferred to check a data sample, manually, checking each post in an 1 by 1 basis in order to gain experience and explore hidden potentials of Instagram, regarding the content of each post. The final step of the methodology was consisted on creating various maps and graphs that were suitable for an initial analysis of the data; In specific scatterplots were created that visualize the volume of information in certain time periods. The starting point of the time periods is the 23rd of July 2018, at 18:00 (Greek summer zone time). Moreover, three maps were generated containing information regarding a. the quantity of posts in each geographic area, b. the geo-referenced information regarding disaster management and c. the geo-referenced consequence score values, respectively. (Maps I, II, III). The total number of processed Instagram posts was 1070.

Figure *I: Methodology*



RESULTS

Figure II: Scatterplots of Instagram posts within certain time periods

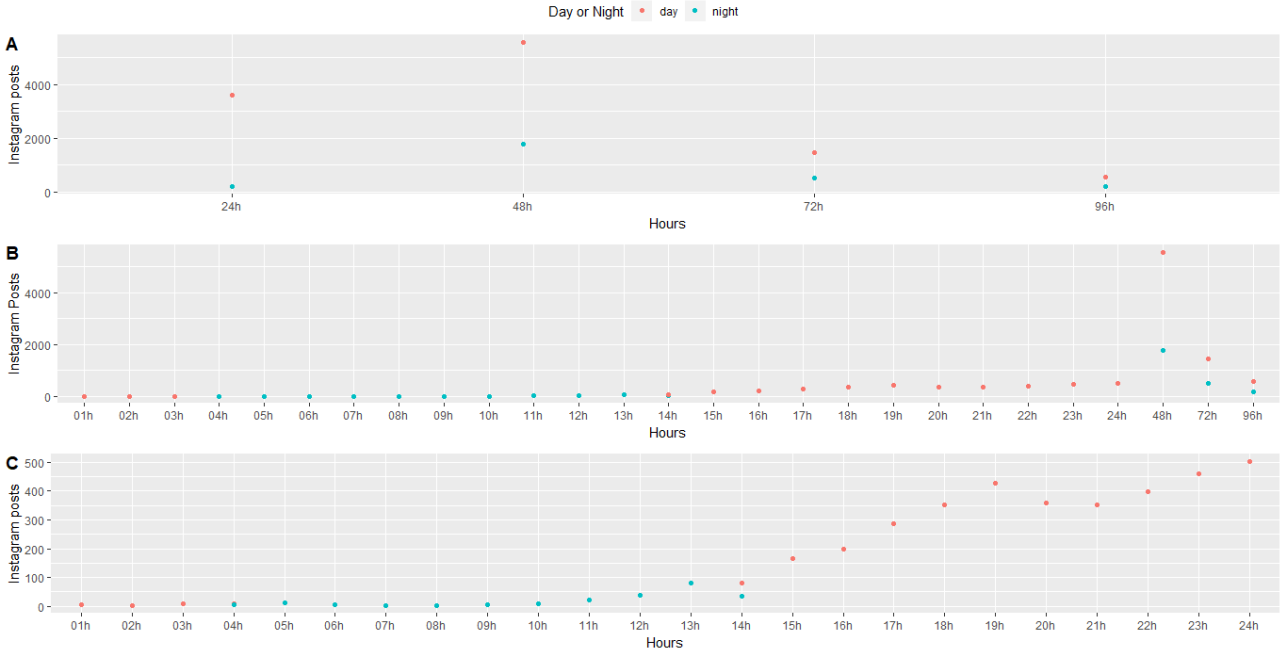


Figure II provides an interesting insight regarding the published quantity of Instagram posts through time. Axis X demonstrates the time periods values in hours (h); time starts since the occurrence of the fire event. In Axis Y the volume of instagram posts is displayed while the different colors represent the day-night condition. The most

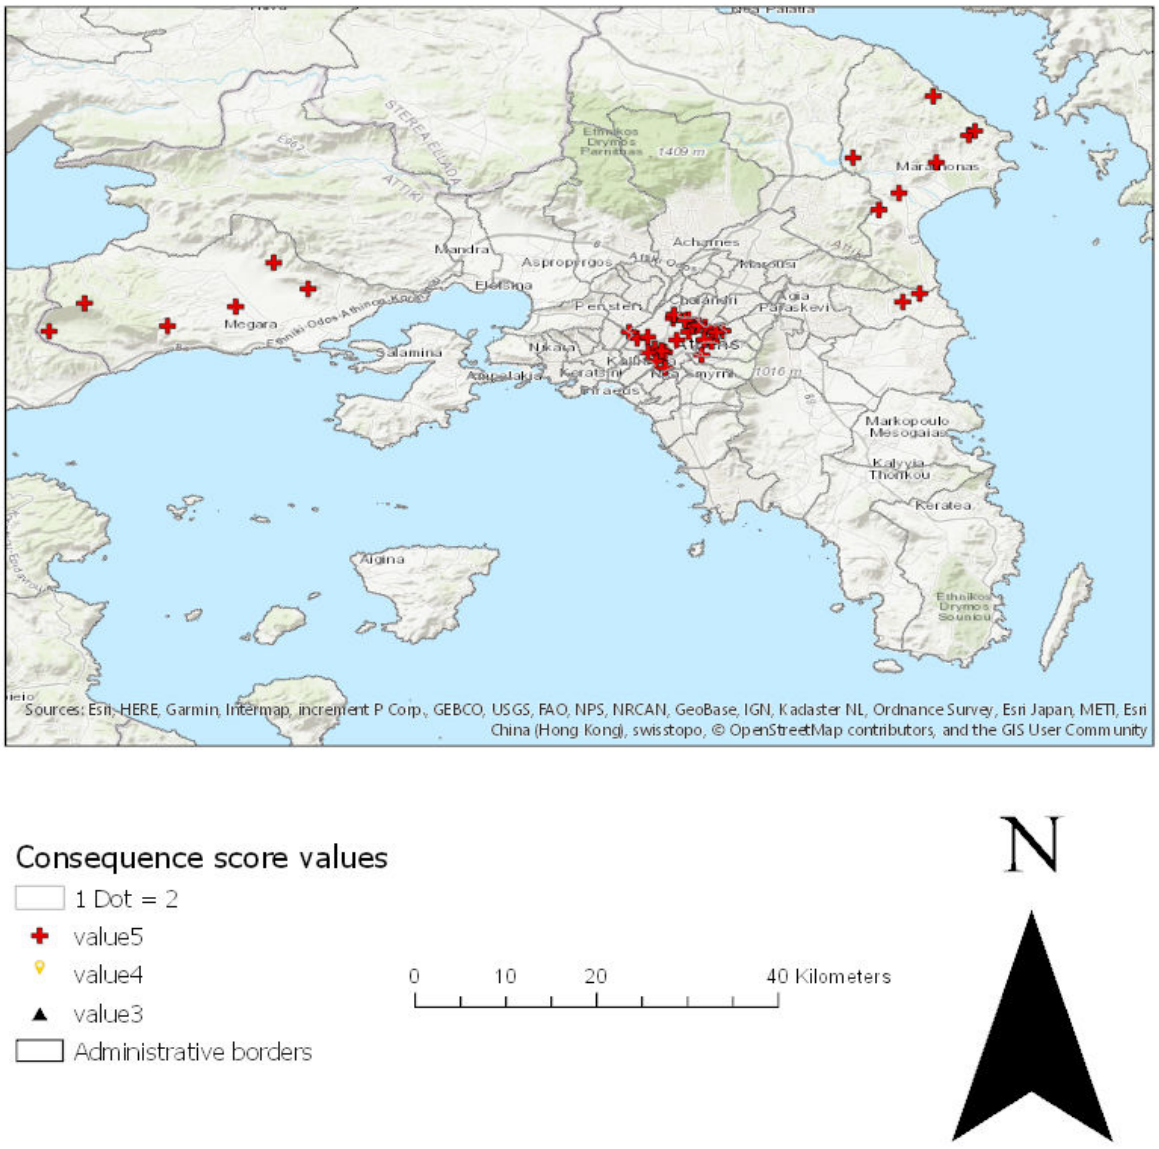
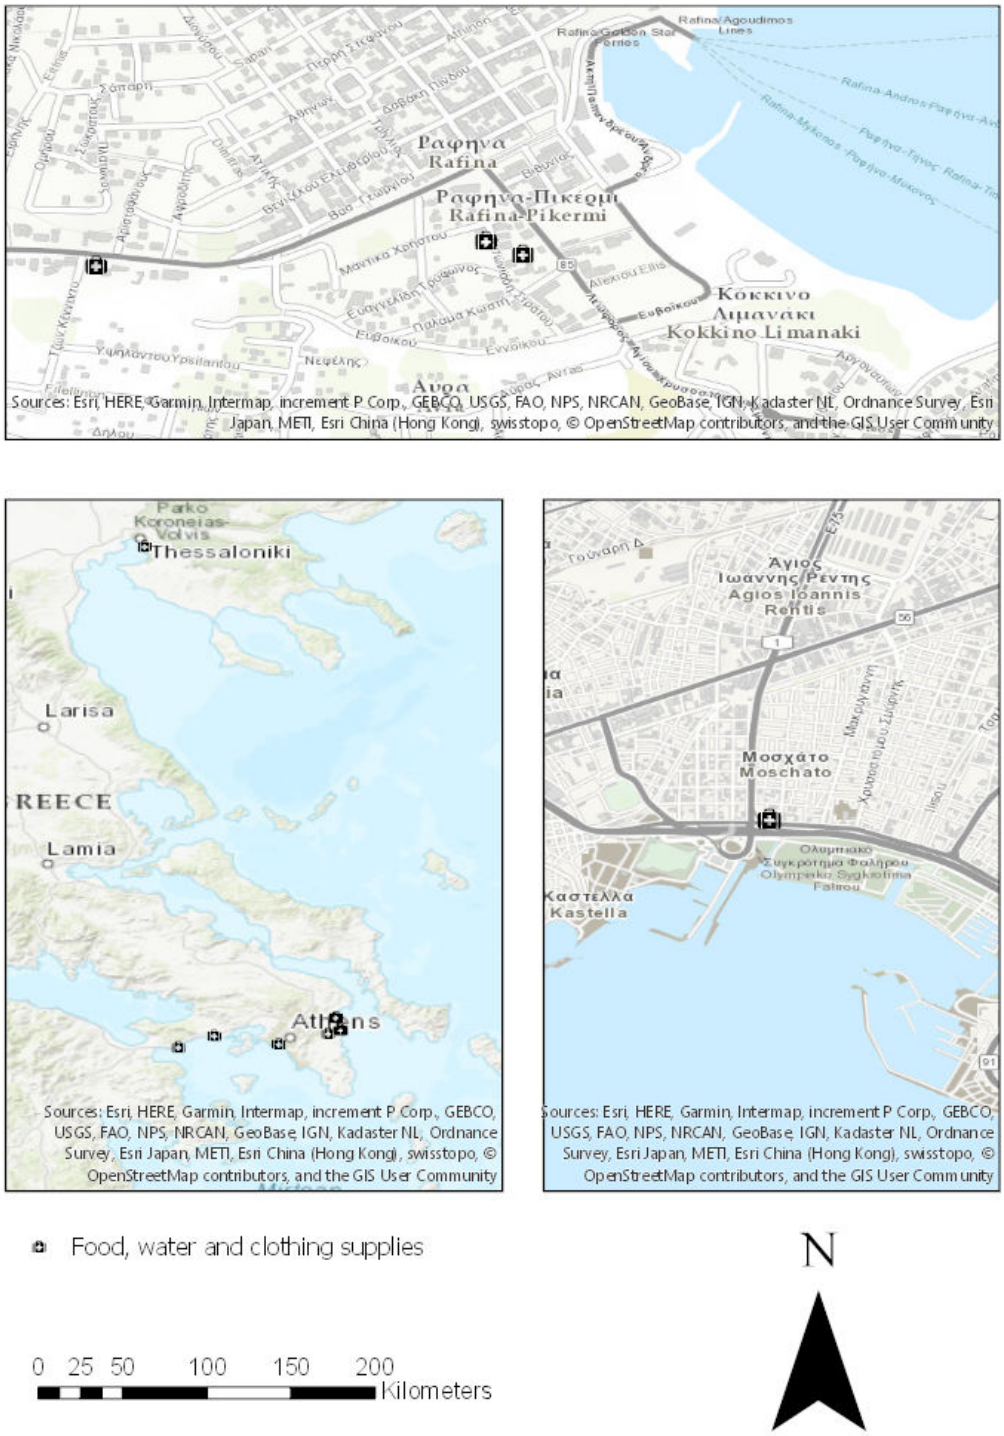
interesting part is that within the first hours, since the start of the fire event, the volume of related published posts is impressively low. The volume starts to grow significantly just after the first 13 hours while the total production is almost doubled after the first day.

Map I: Consequence Value Scores according to Instagram data (after analyzing 1100 posts)



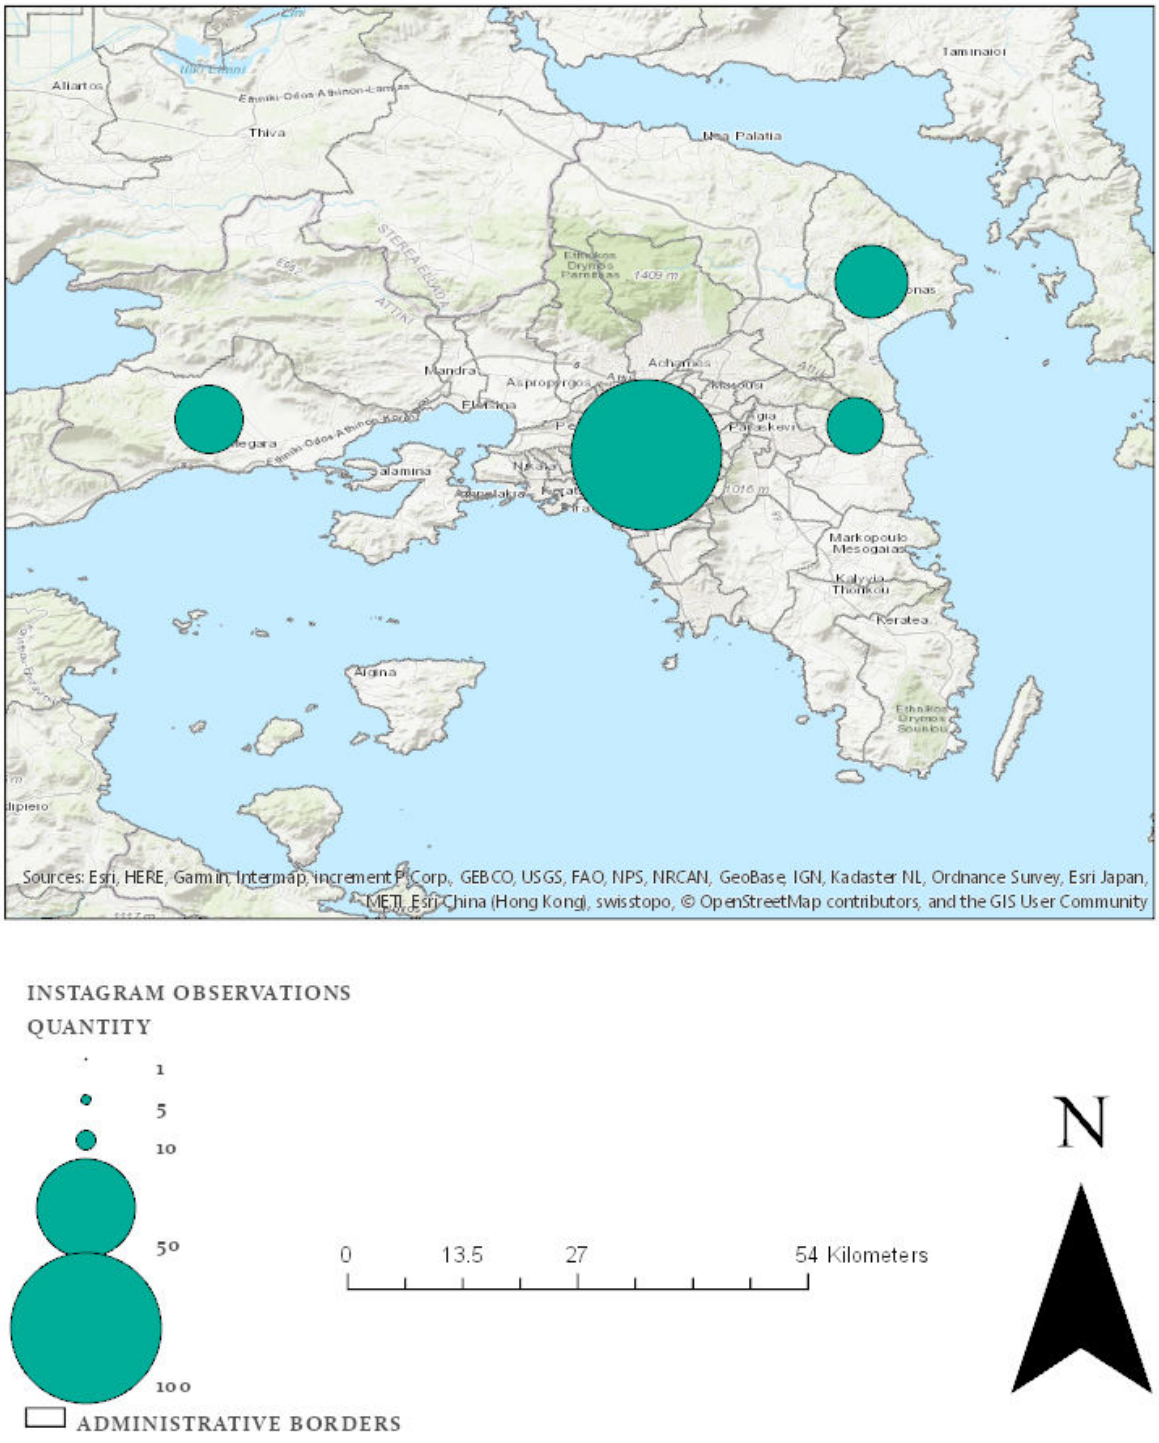
In Map I the geo-referenced consequence score values are vizualized. The outcome was a result of applying the methodology presented in previous sections. As already stated, value 5 (symbol of red cross) is linked to the human loss while each symbol represents two Instagram posts that indicate the same consequence score value. In reality, the human losses were located only at the east part of Attica. The crosses located in the municipality of Athens (central part of the map) appear due to the high values of the geographic precision that many posts received. A lot of people used the word Athens, while posting, in order to describe the whole region that is displayed in Map I (known as Tsipras syndrome). That region is the prefecture of Attica. The red crosses at the west appear due to a fire event that occurred in that area, few hours before the East Attica fire event. As a result, many Instagram posts included information for both fires along with the information that there are dead people, without clarifying the certain area in which the people died.

Map II: Disaster Management Maps: Locations for collecting resources for the fire event victims



Map II is more close to the desired final output of disaster management maps. Contains the most precise Instagram observations in terms of geography. Those spots that appear are at precision level I (POI, or street name and number) and visualize various places for collecting food and water supplies along with clothes or any other material that would be useful for the victims of the fire event.

Map III: Proportional map: Quantity of Posts in certain areas



In Map III the spatial distribution of the volume of geo-referenced posts is displayed. The map uses proportional symbols in order to visualize the quantities. The displayed symbols at the east are within the main affected areas from the fire event that was analyzed in current research, while the symbol at the west identifies a fire event that occurred in West Attica few hours before. Finally, the big circle in the center of the map is linked to the geographic precision issues (the so-called Tsipras syndrom) of the information as many Instagram posts disseminated the information that there is a fire event in the geographically general area of Athens.

DISCUSSION – CONCLUSIONS

Instagram is a powerful social media network that was surely not designed for disaster management purposes. However, major disaster events seem to concern Instagram users, who post at a high volume at least, in catastrophic events. One of the most interesting output of this research is the latency between the start of the fire event and the post of related information. This characteristic of Instagram is rather different to other social media networks, such as twitter, the dissemination of information through which, is performed almost instantly. This time lag makes Instagram rather not useful during the initial response phase of the disaster management procedures. The plethora of information though gives a nice insight regarding event-tracking purposes and for displaying some important information about disaster management procedures that are performed after the initial response. The appropriate geo-referencing of the information is still under development. Although some of the Instagram Posts may contain the x y coordinates of the spot that a photo is published, the credibility of that information is ambiguous as according to Huiji and Barbier (2011) and logical assumptions, a post could be published from another geographic place than the place that the post refers to. However, a more detailed analysis regarding that part, needs to be performed in the future in order to investigate all the potential aspects of the embedded geographic information. Moreover, the geo-referencing method used in this research extracts many coordinates. There seems to be a mess though when people are generalizing the areas in which they refer to.

One of the most important advantages of Instagram is the ability to publish a photo, as those are very helpful for classifying purposes. Although a photo has the power to instantly describe a whole situation, it is logically assumed that in disaster management situations not all photos are published. For instance, as Instagram is designed mostly for fun purposes, it is rather rare to find pictures of dead people, information that could be vital during DM procedures. That certain information though is published, in a high rhythm, within each photo's caption. Concluding, it seems that Instagram can act as a supplementary source, by giving very good insights in certain parts of the DM process. However, the final assumptions need further research.

The future steps of this introductory analysis include the processing of the total dataset, the application of SVM techniques for classifying images to the appropriate categories in almost real time, the development of more meaningful to the DM stakeholders and participants, graphs and maps. Finally, the automation of the whole steps of the methodology in a way that it could be executed at once and in real time is vital for the applicability in DM situations in live time.

ABSTRACT

The importance of community resilience has become increasingly recognized in emergency management and post-disaster community well-being. To this end, three seismic resilience planning initiatives have been conducted in the U.S. in the last decade to envision the current state of community resilience. Experts who participated in these initiatives confronted challenges that must be addressed for future planning initiatives.

We interviewed eighteen participants to learn about the community resilience planning process, its characteristics, and challenges. Conducting qualitative content analysis, we identify six main challenges to community resilience planning: complex network systems; interdependencies among built environment systems; inter-organizational collaboration; connections between the built environment and social systems; communications between built environment and social institutions' experts; and communication among decision-makers, social stakeholders, and community members. To overcome the identified challenges, we discuss the capability of human-centered simulation modeling as a combination of simulation modeling and human-centered design to facilitate community resilience planning.

Keywords

Community resilience, human-centered design, interface design, simulation modeling, recovery planning, mitigation planning, human-centered simulation modeling.

INTRODUCTION

Community disaster resilience is defined as "the ability of a community to prepare for anticipated hazard, adapt to changing conditions and withstand and recover rapidly from disruptions" (NIST 2016: V.1:1). Resilience of community is built upon a variety of community aspects that have been extensively investigated in research studies (Aldrich and Meyer 2015; Comes and de Walle 2014; Chang and Rose 2012). As disasters may cause extreme damage and long-lasting disruptions in community functioning, it is vital for community stakeholders to envision potential damages and expected recovery process beforehand. For this purpose, several community resilience planning initiatives have taken place in the U.S. in the last decade to identify community hazards, anticipate the recovery processes, establish community resilience goals and provide recommendations for decision-makers to achieve better community resilience (OSSPAC, 2013; WASSC, 2012; Poland, 2009).

Community resilience is complicated and multi-dimensional on its own. Community resilience planning, in practice, is a highly collaborative process that involves numerous community stakeholders associated with human-oriented challenges. Participants in community resilience planning include emergency managers, experts and managers of building and infrastructure systems, social stakeholders, and so on. Community resilience planning is technical and domain-oriented and requires a comprehensive understanding of the recovery process of damaged entities in the built environment and social systems. In addition to being a complex puzzle, community resilience planning is a highly user-centered process, requiring collaboration among built

environment experts with different areas of expertise, communication among experts of the built environment and social institutions, and information sharing among the planning participants, community stakeholders, governmental and elected officials, and community members. It is essential to recognize and understand the complexity of the planning process and its characteristics. As well, considering that several community resilience planning initiatives taken place in the U.S., it is beneficial to learn from these experiences to facilitate future initiatives.

In this study we investigate the process of community resilience planning and identify challenges that participants experienced in previous planning initiatives as our first research question. The next step is to determine how community resilience planning can be facilitated. Simulation modeling is widely used to model connectedness and interdependencies in network systems such as infrastructure systems (Ramachandran et al. 2015). Several research studies have successfully used simulation models to investigate community disaster recovery processes (Miles at al. 2018). However, no analytical computer-based tools like simulation models have been used in previous planning initiatives. As our second research question, we investigate if simulation models can facilitate planning initiatives, and if so, how they can address the identified challenges. Analyzing interviews conducted with experts who participated in the initiatives, we conclude that combining human-centered design with simulation modeling, referred as human-centered simulation modeling, has the potential to address observed challenges.

BACKGROUND

Community resilience is a community attribute that can be improved and adapted over time; it refers to the ability of a community to mitigate and resist against hazards and its ability to recover quickly (Bruneau et al. 2003). Several frameworks have been developed to describe the foundations of community resilience in different domains (Miles 2015; Kuling et al. 2013; Norris et al. 2008). As disasters impact various aspects of a community, community disaster resilience is also considered in diverse dimensions such as social institutions (Aldrich and Meyer 2015; Alipour et al. 2015; Semaan and Hemsley 2015), physical infrastructure (Cimellaro et al. 2011; Davis et al. 2018), economics and business (Chang and Rose 2012), and healthcare (Chandra et al. 2011; Comes and de Walle 2014). Berkes and Rose studied the characteristics of community resilience and integrated two dimensions of social–ecological systems, the psychology of development and mental health, in a framework (Berkes and Rose 2013). Chang et al. developed an approach to characterize communities' infrastructure resilience and identified key challenges including incomplete incentives and partial information (Chang et al. 2014). Berk et al. analyzed coastal state hazard mitigation plans and compared the quality of these plans (Berk et al. 2012). Labaka et al. (2014) presented a framework to identify resilience policies across technical, organizational, economic, and social dimensions (Labaka et al. 2014). Rubim and Borges (2017) conceptualized and characterized resilience in the context of complex systems (Rubim and Borges 2017). Turoff et al. developed a model for interaction among critical infrastructure systems (Turoff et al. 2016). Additionally, many research efforts have attempted to quantify community resilience and identify quantitative indicators and indices to evaluate different dimensions of community resilience (Cutter et al. 2016 and 2010; Bruneau et al. 2003).

Community resilience planning requires community decision-makers, built environment experts, and social stakeholders to collaborate to identify social goals and their dependencies (NIST 2016: V.1:1). This broad collaboration and communication among experts in different systems and non-experts makes community resilience planning more challenging due to involving human-factors in the planning process. Characteristics and challenges in emergency management have been extensively studied (Scholl and Carnes 2017; van Laere et al. 2017; Turoff et al. 2016; Gonzalez et al. 2012; Maitland et al. 2009; Dilmaghani et al. 2006). However, the existing literature does not specifically identify challenges in community resilience planning. In next section, we introduce three community seismic resilience planning taken place in the US in last decade. The initiatives are a valuable source for finding existing barriers in community resilience planning.

COMMUNITY SEISMIC RESILIENCE PLANNING IN THE U.S.

Bruneau et al. (2003) published one of the early research studies to define the concept of community seismic resilience (Bruneau et al. 2003). They defined community seismic resilience as "the ability of social units (e.g., organizations, communities) to mitigate hazards, contain the effects of disasters when they occur, and carry out recovery activities in ways that minimize social disruption and mitigate the effects of future earthquakes" (Bruneau et al. 2003). They also proposed a framework to quantify community resilience to be evaluable and measurable. This research and other studies led community experts to apply and quantify community resilience to real communities. Recognizing the importance of community resilience in the research studies, seismic

committees and urban planning associations formed and organized planning initiatives to assess resilience of their own communities.

SPUR Resilient City (2006-2009)

The first attempt at community seismic resilience planning was organized by the San Francisco Bay Area Planning and Urban Research Association (SPUR) (Poland, 2009). Experts from architecture, engineering, urban planning, and public policy planning firms were invited to work together to envision what would happen to the city after a high-magnitude earthquake. In this initiative, participants defined the concept of disaster resilience, selected a single city-wise expected earthquake scenario (10% occurrence in 50 years) as the community hazard level, established desired timeframes of recovery for buildings and infrastructure systems, estimated the anticipated resilience state for identified clusters of buildings and infrastructure systems, and provided recommendations for elected officials and community stakeholders. Comparing anticipated and desired resilience states identifies the gap between where the community is and where it should be. This concept has become more popular in similar studies. It should be noted that the current (anticipated) recovery timeframes were collaboratively estimated based on experts' judgment. This work inspired seismic committees in other states, and the procedure was followed by other community seismic resilience planning initiatives with some modifications.

Resilient Washington State (2010-2012)

In 2010, the Resilient Washington State (RWS) subcommittee of the Seismic Safety Committee under the Washington State Emergency Management Council launched a community seismic planning initiative for the state of Washington inspired by SPUR (WASSC, 2012). Since RWS held a statewide initiative, they referred to National Seismic Hazard Maps created by the U.S. Geological Survey (USGS) in 2008 to identify community hazard. RWS formed four groups consisting of critical services, utilities, transportation, and housing & economic development sectors, identified their components, and located experts from these sectors. They followed the SPUR procedure, identified community hazard, and presented desired and anticipated recovery timeframes for community entities. They also provided several recommendations for community policy makers and published their report in 2012.

Oregon Resilience Plan (2011-2013)

The Oregon Resilience Plan (ORP) was conducted as a community seismic resilience planning initiative in 2011-2013 by the Oregon Seismic Safety Policy Advisory Commission (OSSPAC) (OSSPAC, 2013). They considered a M9.0 Cascadia earthquake and tsunami as the community hazard for the state of Oregon. ORP consisted of eight task groups: Cascadia Earthquake Scenario, Business and Workforce Continuity, Coastal Communities, Critical and Essential Buildings, Transportation, Energy, Information and Communications, and Water and Wastewater. The planning process was similar to that of SPUR and RWS, but more detailed and specific to the state of Oregon. Compared to the previous initiatives, ORP perspicuously appointed long-term community goals and social needs. They established desired recovery timeframes of community entities such that business continuity in the state would not be disrupted for more than two weeks to one month. The task groups considered this goal as a criterion to identify desired recovery timeframes. As a result, the existing gaps between the anticipated state and desired state were well understood by community decision-makers and the initiative's audiences.

Community Resilience Planning Guide for Buildings and Infrastructure Systems by NIST (2016)

The National Institute of Standards and Technology (NIST) published a two-volume report, *Community Resilience Planning Guide for Buildings and Infrastructure Systems,* in 2016 examining these initiatives (NIST, 2016). This report brought community resilience planning to the forefront, with significant updates and details. Although NIST's report offered similar reasoning and conclusions as the initiatives themselves, it also provided valuable details on **how to proceed** with systematic community resilience planning. The NIST report identified community representatives who should be involved in planning. It also divided communities into the built environment dimension, including buildings and infrastructure systems, and the social dimension consisting of social institutions such as businesses, industries, and financial systems, and recommended identifying the characteristics of each dimension. More importantly, NIST suggested linking social functions with the built environment, a concept that was not explored in the existing initiatives. In this way, the relationships among numerous systems, in either the social or built environment, are well defined and the community is envisioned as it really is—an integrated whole rather than separate groups that function individually and independently. The

NIST report highlighted dependencies and cascading effects, and presented a dependency matrix among infrastructure systems, which had not been explored by the three initiatives although they had noted its significant impact.

Community resilience planning has evolved based on the lessons learned from the planning initiatives, actual events, and research studies. Similarly, the process of resilience planning has been enriched by taking into account more influential concepts, parameters and dimensions, and defining relationships among them. In summary, NIST suggested following the steps presented in Figure 1.

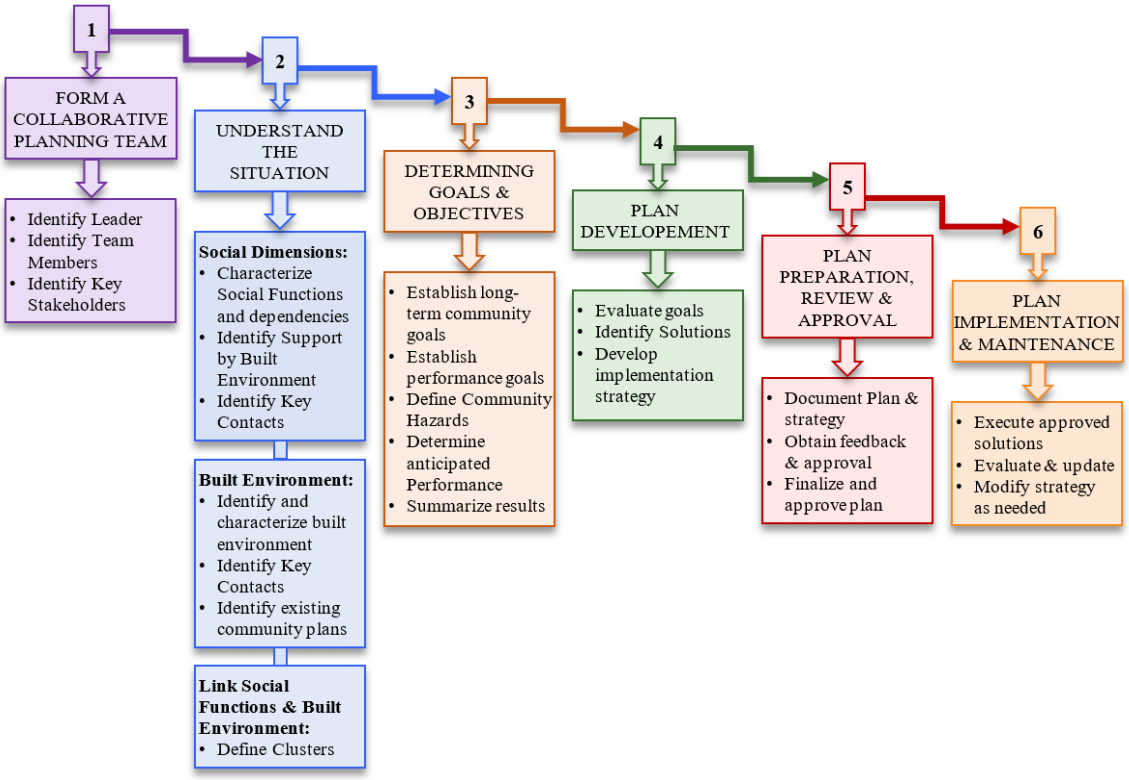

Figure 1. Six-step planning process for community resilience (NIST, 2016)

Although community resilience planning has grown quickly and NIST's report presented it as a standard and unified procedure, undertaking planning in practice comes with wide variety of surprises and challenges. In this study, we look for challenges that participants in the community resilience planning initiatives experienced. We also discuss possible ways to overcome these challenges.

METHODOLOGY

As mentioned earlier, we examine two research questions in this study. First, we aim to identify challenges appeared in the community resilience planning initiatives, and second, we want to investigate how simulation modeling can help this process from the participants' perspective. For this purpose, we reviewed the procedures and conclusions of three initiatives and conducted semi-structured interviews with the initiatives' participants to learn about the process and observed challenges. Details on the interviewees, data collection, data coding and analysis approach are provided below.

Participants and Data Collection

The first author of this study contacted several critical infrastructure agents, emergency managers, and researchers who participated in one of the initiatives via email, described the purpose of the interview, and requested a 90-minute in-person meeting to learn about their experience in the initiatives. He invited interviewees from different initiatives to recognize similarities and differences. He also interviewed a manager of critical infrastructure system who did not participate in any of the initiatives but has conducted several relevant research studies and community resilience discussion meetings with experts in infrastructure systems.

This interview was to include the perspective of an independent expert who did not participate in any of the initiatives. Overall, the first author conducted 90-minute semi-structured interviews with eighteen emergency managers, infrastructure and building experts, and researchers. Seventeen interviews were conducted in-person, and one interview was over the phone. Geographically, the interviewees were from California, Oregon, and Washington (five, seven, and six interviewees from each state, respectively). All interviews were recorded and transcribed with interviewee's permissions for further analysis except one interview where the interviewee did not grant permission to record the conversation. We relied on hand-written notes for that interview and included these notes in our qualitative content analysis. Interviews were voluntary and unpaid, and the interviewees were kind and welcoming. Interviews were conducted from May to September 2018.

Data Analysis and Qualitative Coding

Our data analysis was driven by open-coding thematic analysis. The first author applied line-by-line coding to five random interviews before establishing a codebook. Initial codes emerged from finding relationships based on the line-by-line coding. The third author, who is an experienced social scientist, university researcher, and expert in community resilience, inspected the initial codes. By establishing the initial codebook, the first and second authors coded the entire dataset. For collaborative qualitative coding, we used Code Wizard as a collaborative coding tool (Ganji et al. 2018). Code Wizard consists of programmed Microsoft Excel spreadsheets. Code Wizard is free, appropriate for small to midsize teams and academic research projects, and does not require much training, which was a significant concern for the authors. The first and second authors coded data independently and separately. Using Code Wizard, after each round of individual coding, we aggregated coded data, evaluated the Inter-Coder Reliability (ICR) coefficient, noted problematic codes, discussed the reasons for disagreement, and revised the codebook. We performed three rounds of coding to meet an acceptable ICR threshold (0.8). We coded data for two themes: (1) challenges and (2) opportunities for simulation modeling.

CHALLENGES IN COMMUNITY RESILIENCE PLANNING

Based on our qualitative content analysis, we present the main challenges in community resilience planning identified by the interviewees. We used the term **main** challenges because there were additional challenges mentioned in the interviews that we intentionally ignored. For example, a few issues occurred only in one of the initiatives and were not generalizable for other initiatives, and some other barriers taken place due to the logistics of holding meetings and time limitations.

Complex Network Systems

According to NIST, built environments that support community members and social community functions consist of infrastructure systems and buildings. Recovery of an infrastructure system to be able to provide services to consumers, regardless of its interdependencies with other systems, depends on two factors: (1) recovery of discrete damaged entities, and (2) the connections and dependencies among networked entities. Both factors should be considered in planning since ignoring either one results in a distorted and incomplete picture of the recovery process of infrastructure systems.

In the planning initiatives, participants formed task groups for infrastructure systems, and participated experts joined the groups based on their areas of expertise. Experts identified the main entities of each sector in the task group. Through technical discussions and aggregating experts' judgment, the task groups created anticipated and desired recovery timeframes for identified entities (see Figure 2). Experts typically estimated damages and recovery timeframes based on community hazard intensity, liquefaction and landslide potentials, and type, material, and age of entities.

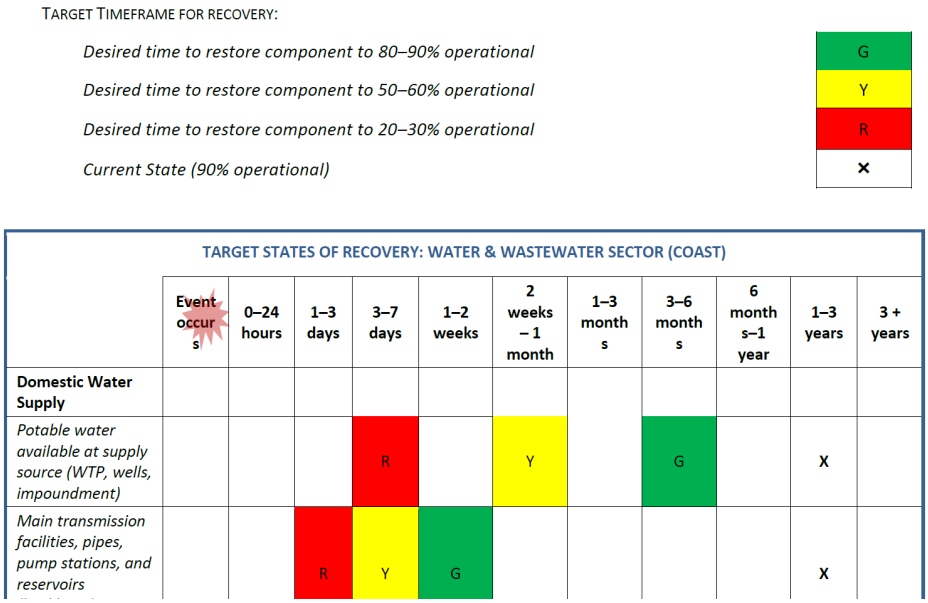

Figure 2. Desired and Anticipated Recovery Timeframe in Water & Wastewater Sector (OSSPAC, 2013)

Experienced experts provided insightful information to estimate required time for recovery of single entities. This information can be used as a basis in community resilience planning. However, overlooking the network and interconnected structure of infrastructure systems underestimates recovery timeframes from the perspective of community members who need these services regardless of the recovery of single entities. System resilience depends on the level of redundancy that exists in the system. This redundancy is gained from the network system and its structure, not just entities.

> *[Interviewee #7:] "…in water systems, there's so much dependency that exists, you've got to restore this before you restore that, before you restore that, and similarly in capacity… if you're going to restore the distribution system, you have to have sufficient supply to be able to meet that, but there's no need to build the supply capacity any faster than you can build the delivery system to be able to meet those needs."*

Due to lack of appropriate tools, and limited time and budget, the network and dependencies in infrastructure systems were not considered in the planning initiatives. In order to make anticipated recovery timeframe estimates more realistic, the network system should be taken into account in future studies.

Interdependent Network Systems and the Cascade Effect

A damage in an infrastructure system may result in disruption of serviceability of many other systems. This phenomenon, referred to **cascade effect,** is also observed in the recovery process of interdependent systems. For example, the water system relies on electricity for running pump stations and back-up generators. Therefore, serviceability of the water system depends on not only the functionality of the water system itself, but on the power system as well. Similarly, recovery of both water and power systems is contingent on access to damaged entities, which makes recovery process of water and power systems dependent on recovery of transportation system. The significant impact of interdependencies among infrastructure systems and buildings was noted in the planning initiative reports and discussed in more detail in the NIST report. However, interdependencies have not been taken into account for estimating anticipated recovery timeframes of built environment in the planning initiatives.

> *[interviewee #10:] "there are significant interdependencies. It's hard to really comprehend to what level they are important. To me, power is the big one. What can happen until power is restored? Not a whole lot...you probably can have some restorative construction happen without power, but even that's a challenge. Everything relies upon power, and how resilient is the power. What are those interdependencies, does that back everything else up in recovery?"*

Inter-Organizational Collaboration

In addition to the domain-oriented characteristics presented above, community resilience planning is challenging due to its inter-organizational nature. For example, infrastructure systems and buildings are managed by

different agencies, companies, and organizations with dissimilar procedures, priorities, and goals. Even a single infrastructure sector might be managed by multiple companies and decision-makers. Planning to make a community resilient entails all decision-makers from different organizations coming to agreement on how to proceed and what goals to pursue. Time needed for a community to recover after a disaster depends on the efficiency of experts' collaboration. For example, achieving desired recovery timeframes requires experts and managers in companies that are part of the power system (if there are multiple companies providing electric service for the community) to know how to plan for resilience to achieve these goals and how different policies might affect resilience of the entire community. Therefore, inefficient and ineffective inter-organizational collaboration is a big challenge in community resilience planning.

> *[Interviewee #2:] "In the power system, for example, there are multiple power system providers and they each have their own proprietary information, and probably many of them have done studies. [A company in infrastructure system] has studied some of their things, [another company in infrastructure system] has probably studied some of theirs, maybe they haven't studied everything, but a real challenge is getting access to that information, for starters."*

Similarly, interviewee #4 explains other challenges that emerge when decision-makers and stakeholders are from the public and private sectors and comply with different regulations:

> *[Interviewee #4:] "[infrastructure] is public and private, that's the important thing. Almost none of it is purely public, and so [...] there is proprietary information that those private sector companies hold close and have a right to hold close. And so, there are regulatory agencies, there's the utility and transportation commission, and they will honor their right to proprietary information. They try to work out planning with them, but some of it, for instance, even though you might say you want the hospital to come back first, [...] depending on the way the power outage happened, it may be that you have to fix something somewhere remote to there, because you also have to figure out how to bring the system back, and just bringing back one small branch of the system, even if it does feed the most vulnerable sector, may not do you the most good if bringing back a major substation gets you the most bang for your buck in the first twelve hours. And how they make that decision, again, is private."*

Connections between Social Institutions and Built Environment

Citizens and community members found social institutions to address their needs. NIST categorized social institutions in eight groups: (1) family/kinship; (2) the economy; (3) government; (4) health; (5) education; (6) community service organizations; (7) religious, cultural, and other organizations that support belief systems; and (8) the media. While the goal of community resilience is closely tied with the recovery of social institutions, these institutions themselves rely on functionality of the built environment (including infrastructure systems and buildings). Consequently, desired recovery timeframes for the built environment are established based on social needs. Social and built environments are connected in community resilience planning and it entails identifying "links between social functions to the supporting built environment" (NIST 2016: V.1:8). The importance of identifying these links has been gradually recognized in the community resilience planning initiatives.

The NIST report devotes an entire chapter to identifying these links. However, the three initiatives, while recognizing the importance of identifying these links, did not really consider these links to estimate anticipated or desired recovery timeframes. NIST and the planning initiatives present desired and anticipated recovery timeframes for the built environment by percentages of functionality of systems entities. For instance, the desired recovery time for functionality of 80-90% of distribution pipes is determined 1-3 days in Washington state (WASSC, 2012). The desired time to restore 50-60% of electric transmission lines in the "non-tsunami coast zone" in Oregon was determined 1-3 weeks (OSSPAC, 2013). However, it is not clear how these timelines have been assigned to support social institutions and community members where connections between the built environment and the social dimension are lacking. As another example, the ORP defines the desired recovery timeframes of infrastructure systems such that businesses, as a social entity, would not experience disruption in having infrastructure services longer than two weeks. Imagine a hypothetical scenario in which 60% of electric transmission lines have been recovered in two weeks (determined as desired recovery timeframe in ORP), but business institutions are relied on the 40% unrecovered systems. In other words, although the desired recovery timelines for the built environment may be met, it is not certain whether or not businesses would receive services from the built environment in two weeks.

> *[Interviewee #6:] "I think the other biggest shortcoming was there wasn't the opportunity to go through and say, "here is an integrated set of recommendations drawn from each of the areas that together get us the furthest down the line to resilience and … address the question of what's the appropriate sequencing and balancing of these things."*

It should be noted that connection and dependence between the social dimension and built environment is mutual. While we described how recovery of the social dimension depends on the built environment, recovery of the built environment also relies on social dimensions. For example, recovery of infrastructure systems or buildings is executed by experts, crews, engineers, and infrastructure managers. As community members, they need social institutions such as healthcare and finance/economic institutions to be able to first survive and then participate in the recovery process.

> *[Interviewee #7:] "… their experience [New Orleans Water and Sewer Board] was so revealing to me. When [Hurricane Katrina] happened, they had all of this flooding, they had all of these facilities out. More than half of their workforce did not come back to work, and so how can you restore the system and establish service to the community if you don't have the workforce necessary to be able to do anything more than basically keep the lights on? […] I can't just take just anybody and put them on a backhoe and tell them how to repair a pipe. I need trained people who are able to respond to this event and aid in the restoration and recovery of our water system. […] The other thing I want to leave you with is it goes way beyond just infrastructure. I touch on obviously the people part of it, and that's key, but the business operations side of what we do is equally important, and again, water is a wonderful example as a utility, but it's true with most every other lifeline with the exception of maybe transportation. Somebody has to pay the bill. And so, if we're out of business, we're not sending out bills, we're not collecting revenue, we're not paying out bills, and pretty soon… the good news is I can restore the water system, but I can't pay for the fuel because nobody will take my credit card. I can't pay the electric bill to run the pumps that I need, and so I don't have the ability to run a business, to be able to sustain this organization, to cut paychecks to the people that I need so desperately to be able to repair the pipes."*

Communication and Information Sharing between Experts in Built Environment and Social Institutions

Built environment experts such as managers, agents and decision-makers in infrastructure systems and social stakeholders involved in the planning must work together closely. As mentioned earlier, NIST states that decision-making for recovery planning is based on social needs and community goals. Since social dimension like social institutions depend on the built environment to be functioning, experts on the both sides must communicate to share required information. In addition to identifying physical connections and dependencies between these dimensions, collaboration and communication between stakeholders in these two groups are challenging for community resilience planning.

> *[Interviewee #13:] "So, as we move into thinking about resilience, which is about more than the structure, it's about the occupancy, it's about more than one building, it's about the organization like a community. We have to be open to working with other groups, and this is a challenge, because those other groups never heard from us, in fact they're much bigger than us. They don't want to really hear engineers, and they have almost no patience."*

One important aspect of this collaboration and communication is prioritization, which is challenging step in community resilience planning. Prioritization is inevitable due to time and resource limitations, and potential conflicts in community recovery. Communities have similarities but are completely different in terms of their built environment structures and social needs and cultural differences. Therefore, as NIST concludes, there is no global priority list or gold standard for decision-making in community recovery planning, and priorities should be determined in a community-to-community basis. It underlines the significance of needs to strengthen collaboration, communication and information sharing among decision-makers from any dimension.

> *[Interviewee #7:] "... there are competing needs for limited resources. How as a community do we prioritize those limited resources to be able to meet the needs of the recovery, to be able to get recovery balanced and do it in a way that limits loss of life and expedites the overall recovery process? This is so challenging."*

Information Sharing and Communication between Experts and Community Members

This category of challenges in community resilience planning came as a surprise in our interviews. The final audience of community resilience planning initiatives is members of the community and their elected officials. Executing the decisions made in community resilience planning is a very costly and lengthy process that requires the support of the community. Experts in community planning share information with community decision-makers, elected officials, community policy makers, and finally community members. They aim to inform community members and decision-makers about the hazards that threaten their community and warn them about potential consequences of such disasters. They also envision the community's preparedness to resist

and bounce back after the expected disaster and point out the gaps between the current and desired states of preparedness. Making a community resilient requires a budget and resources which are usually obtained from taxpayers. Resilience planning cannot successfully proceed if community members do not properly understand its importance and support long-term investments in it.

> *[Interviewee #10:] "So, [this is] all state taxpayers' money going in to support this grant program to get this money out. Some of the successes and challenges associated with getting the grant program up and running, included people who didn't understand why it was important to have safe schools... schools' job [is to] educate, not to do seismic mitigation of schools. So, there was a really big learning curve for [...] really a lot of people."*

Considering the notes above, communication with the wider community is challenging because it has its own complexities and requires specific types of skills, especially when people have incorrect perceptions about the likely post-disaster condition.

> *[Interviewee #6:] "I think it was not well understood on the part of the public... [T]hat was one of the most important things that the resilience plan did was really put some parameters on it that the public could access, and I think that a lot of the public perception in the past had either been "oh, it's not going to be that big of a deal, I don't need to worry about it" or "it's going to be the end of the world, so why should I worry about it, there's nothing I can do, everything is going to be completely destroyed." Some of the commentary that came out from Tohoku, and some of perceptions that people got from the New Yorker article kind of fueled that notion of "oh my god, it's going to be this total disaster and nobody's going to survive, there's no point in preparing." And the resilience plan, I thought, the clearest message of it was "pretty much everybody is going to survive, and you're going to get up the next morning and not going to be able to flush the toilet for three months. That's going to be your problem." That's what we have to address, is that massive disruption to everyday life that is going to make it very difficult to live here, and certainly going to make it very difficult to continue to be employed here. And so … although at the time I felt like we're just doing this, engineers are just kind of guessing in terms of the damage and they tend to guess conservative when put in those kinds of situations, I think it still ended up with the right overall message which is "this is going to be really difficult, but there are things you can do to solve, to fix it, and move ahead with it."*

FACILITATING COMMUNITY RESILIENCE PLANNING BY SIMULATION MODELS

Reviewing the reports published after the planning initiatives and based on the interviews, we noticed that other than Hazus, which was used limitedly for damage and loss estimations, no analytical computer-based tools have been used in any planning initiatives. For example, estimating anticipated recovery timeframes of damaged community entities are computationally challenging tasks in the planning initiatives. However, use of analytical computer-based tools such as simulation models was lacking in the planning process.

Simulation models are nowadays used in numerous fields such as engineering, urban planning, and supply chain management. The capability of simulation modeling to improve different phases of emergency management is widely recognized in research communities like Information Systems for Crisis Response and Management (ISCRAM). Similarly, in practice, Federal Emergency Management Agency (FEMA) emphasizes the importance of tools in emergency management, noting that "innovative models and tools" are one of three strategic needs to accomplish recovery planning (FEMA, 2012). Simulation modeling is also used in community resilience. The interviewees were asked about how simulation modeling could help them in community resilience planning. It should be noted that most of the interviewees had experience or knowledge about simulation modeling and its capability in community resilience planning. For other interviewees who had no experience, background or information in using simulation models in this field, we shortly explained how simulation modeling works and provided some examples from the literature. We analyzed their answers and categorized their responses based on the codebook that we had established to identify the challenges since (1) we could maintain the consistency of presented concepts for our audiences, and (2) we could benefit from the details provided by interviewees to understand what tasks and functionalities are needed to handle by simulation modeling in this process. The interviewees' responses reveal what limitations and challenges can be addressed by simulation modeling and where simulation models can facilitate them. In the following, we present the benefit of using simulation modeling to address each category of identified challenge.

Complex Network Systems

As discussed previously, infrastructure systems are complex networks. In such complex systems, it is extremely difficult to predict how recovery proceeds and when these systems would be able to provide services to others,

including community members, social institutions, and other dependent infrastructure systems. Simulation modeling has the capability to consider this complexity, and many research studies have used simulation modeling to simulate the post-disaster recovery process of infrastructure systems and housing as mentioned in background section. The interviewees also mentioned that simulation modeling would be helpful in community resilience planning.

> *[Interviewee #5:] "I believe if there were modeling tools available to estimate downtime, the connectedness, and the dependencies of the different lifeline sectors, … and how doing certain fixes would improve the rapidity of getting things up and running quickly, I think it would help with building resilience and mitigation projects."*

Simulation modeling also makes planning much easier if experts would like to update data. If a simulation model is already set, new updates in system entities taken place over time can be simply applied to the model to adjust outputs accordingly.

> *[Interviewee #8] "And a tool would be nice to have, something where [... it] allows you to improve the data. So, you can put in with what you know, understanding your margin is bigger, but as you get better data, that comes around [...] that can be updated and give you better results."*

> *[Interviewee #12] "we need to figure out the things that we can't work around after the disaster ... that's what the days, weeks and months are about, to identify how much time they can have to get something going again but do that kind of simulation so that you can understand what you can work around."*

Interdependencies Among Infrastructure Systems

The advantage of using simulation models to capture the complexity of system interdependencies in community resilience planning was mentioned by the interviewees more than other simulation modeling capabilities. Simulation modeling has been widely used to simulate interdependencies among critical infrastructure systems in urban planning.

> *[Interviewee #7:] "simulation modeling would really be critical to illustrate this interdependency effect … and again, I had not noodled through it, everything, when I give this talk at many different seminars, I talk about interdependencies and how everything is connected to everything."*

> *[Interviewee #14:] "If there was a way to facilitate the collaboration over the issue of interdependence, right, if there was a way to synthesize the data that reflects the way one system depends on another, and then use that to run scenarios."*

> *[Interviewee #2:] "I think, what you're talking about [possibility of using simulation modeling], in terms of being able to model those interdependencies, [is] very valuable, and then being able to communicate that, again, to the community, to our power providers, and having redundant systems, redundant load paths to bring power into the community, that's the ultimate goal."*

Inter-Organizational Collaboration

Planning for community resilience is highly collaborative. Experts need to collaborate with each other since organizations have their own plans, policies, and priorities, but their decisions impact other groups' planning. This collaboration is difficult to facilitate when several organizations are involved; this is another area where simulation modeling can be used, as it can facilitate information sharing among experts.

> *[Interviewee #11:]"So the kinds of things that I want to see [if I had simulation models] are probably more rooted to other infrastructures, you know, the buildings, roadways, bridges [...] if I had to then bring resources in, it would also give me an idea of what I might be able to work with there. [...] But if I can't get from here to there, if there's something blocking, today I can't plan on that."*

Connecting Social Institutions and Built Environment

As discussed earlier, a significant challenge in community resilience planning is connecting built environment entities and social institutions because they mutually rely on and support each other. This is extensively described by NIST due to its critical impact on planning. However, these connections and links were not identified and considered in detail in the planning initiatives due to their extreme complexity. Simulation models can be incorporated to facilitate community resilience planning in this regard. The interviewees also mentioned this and provided some details of what they expect from simulation models to help them.

[Interviewee #8:] "If you could have a model and say "what would be the outcome if we fixed up the road system first" or what would be impacted, any buildings, there would be a lot of URM [Underrepresented Minority]. You know, what would be our payback for looking, solving, retrofitting all of our URMs versus… To be able to ask some of these questions, when these things come up for planning purposes, this is where we really ought to be …"

Communication between Built Environment and Social Institutions Experts

Experts in built environment and social institutions need to communicate and share information to make sure that decision-making comprehensively considers both dimensions and their limitations. Simulation modeling can improve this communication by simulating recovery processes based on different scenarios and providing the consequences of these scenarios for experts to analyze. Since community resilience deals with many dimensions in a community, it is likely to overlook consequences that are critically important for some experts or decision-makers. Simulation modeling helps experts to quickly and inexpensively see how the recovery process changes based on their decisions.

[Interviewee #14:] "just thinking about this idea of scenario-based thinking, if there's a way to help people sort of wargame the way these things play out. "Here's what it looks like now. We wargame. We run an exercise. We get some results. We make changes. We do it again. Hopefully we're even closer. By seeing what changes, we need to make, we're getting closer." So that kind of simulation might be intriguing."

As well, simulation modeling can help prioritize decision-making. It can provide timelines, expenses, and, more importantly, social impacts of decisions made. As a result, decision might be changed if inappropriate consequences threaten community values.

[Interviewee #8:] "One of the questions that there's no really good tool for saying, for doing scenario planning. [...] you accepted that this is risk, so what do you do with all of that? So, how much does it cost you to do all of that stuff, over what amount of time? Where should I put my dollars? What should I do first? What should I do second?"

[Interviewee #2:] "So, we're just coming up with a time, but what's not in there, I always call this the five percent problem, the standard for restoration is always ninety-five percent, but who is the five percent that doesn't get the power, and that we stop caring once we're at ninety-five percent? I want to know, you know, because I did the study in [a community in the U.S.] where I found that Hispanic populations literally were restored slower than white populations."

Information Sharing and Communication between Experts and Community Members

Effective communication and information sharing between experts and non-expert community members, or non-expert elected officials, is necessary in community resilience planning. Study participants and interviewees drew attention to the benefit of simulation modeling in this regard and mentioned how it can improve this process.

[Interviewee #7:] "I think it [community resilience planning] depends on what the community's values are going to be, but it's a tremendous opportunity to have that conversation in advance [...] a tool like what you're talking about in terms of simulation allows conversation with the board or the public or the decision makers to happen in advance, so that when the event occurs you've got some guidance in terms of how to work"

[Interviewee #7:] "More importantly, in many respects, as you go through this system planning process and the investments in the infrastructure over time to build the hardened backbone and harden the facilities, your system investments are consistent with those values and the ability to make the restoration in that kind of priority sequence."

DISCUSSION AND CONCLUSION

In this study, we identified the challenges associated with the previous community resilience planning initiatives taken place in California, Washington and Oregon. For this purpose, we interviewed experts, critical infrastructure managers, and emergency management agents who participated in the initiatives. Due to the capability of simulation modeling to address the challenges mentioned in the research studies (Ganji and Miles 2018; Miles et al. 2018), we asked the interviewees to share their opinions about how simulation modeling would support the planning initiatives and presented the findings in the previous section.

As mentioned earlier, simulation modeling is widely used in community resilience, emergency management and disaster recovery. Simulation modeling has been evolved through various approaches including (1) resource-constrained modeling, (2) machine learning, (3) dynamic economic impact modeling, (4) system dynamics simulation, (5) agent-based simulation, (6) discrete-event simulation, (7) stochastic simulation, and (8) network modeling (Miles et al. 2018). Several research studies used simulation modeling in disaster recovery of various elements of communities such as water and wastewater system (Tabucchi et al. 2010), power systems (Çağnan et al. 2006) and housing recovery (Longman and Miles 2019; Burton et al. 2017; Miles and Chang 2011). It shows the capability of simulation modeling to capture complexity of these network systems mentioned as the first challenge by the interviewees. The next challenge, the interdependencies among critical infrastructure systems, is also addressed in the literature of urban planning (Turoff et al. 2016; Banuls et al. 2013; Ouyang 2014). Integrating the built environment including buildings and critical infrastructure systems and social institutions, the forth challenge, is applied in simulation modeling of disaster recovery process (Ganji and Miles 2018).

While simulation modeling can address the first, second and forth challenges, other challenges are user-oriented and human-factors are involved. Human-centered design has the potential to address the user-oriented challenges. Human-centered design considers the concerns, values, and perceptions of all stakeholders in design of simulation models in a problem-solving process (Baxter and Sommerville 2011). Ganji and Miles (2018) presented a conceptual framework of characteristics of disaster resilience and recovery planning in two main categories including domain- and user-oriented characteristics (Ganji and Miles 2018). They argued how combining human-centered design and simulation modeling is capable to overcome not only domain-oriented challenges, but also user-oriented challenges, and proposed a conceptual framework for such models. We refer this combination as *human-centered simulation modeling*.

ABSTRACT

In rapid-onset disasters the time needed for evacuation is crucial. Aside from the behaviour of the population, the road network plays a fundamental role. It serves as a medium to reach a safe area. This study analyses the entire evacuation process, from decision-making up to the arrival at an evacuation zone by combining standardised questionnaires and GIS-based simulation. Based on a case study in the Chilean community of Talcahuano, an event-based past scenario and a hypothetical future scenario is investigated, integrating the affected population in the research process. The main problem identified in past evacuations has been time delay due to congestions, which also is evident in the results of the hypothetical future scenario. A result which supports evacuation by foot. This paper argues that a combination of scientific methods is essential for analysing evacuation and to reduce the risk due to time delay, critical route and transport medium choice.

INTRODUCTION

Destroyed roads and bridges, isolated road sections, past natural disasters like the Maule Earthquake and Tsunami in 2010 (Chile) and the Great East Japan Earthquake and Tsunami in 2011 illustrate the impact of natural events on critical infrastructure (Dueñas-Osorio and Kwasinski, 2012; Elnashai et al., 2010; Kadri et al., 2014; Nobuo et al., 2011). These phenomena are not isolated events. The tendency of natural disasters and their impacts on critical infrastructure are increasing (EM-DAT, 2018; Kadri et al., 2014; Munich RE, 2018; Oh, 2010). These effects are enhanced due to progressive urban development in disaster-prone areas (Chen et al., 2012). Critical infrastructure is of fundamental significance in modern societies' unobstructed functioning of day-to-day life and if disrupted, can have severe negative consequences on security and well-being (Urlainis et al., 2014). The road network, as part of the critical infrastructure, plays a crucial role in the case of natural disasters. It ensures not only the accessibility of first responders and e.g. emergency service units, but also serves as a medium for evacuation to a safe area outside the impacted area (Chen and Qiang, 2017). Hence, the importance of the road network during the evacuation is a critical issue in disaster risk management (DRM) in order to avoid loss of human life (Bunea et al., 2016).

Evacuation is the most important strategy for saving human lives, by leaving an endangered area and reaching an evacuation zone (Charnkol and Tanaboriboon, 2006; Chen et al., 2012;Shuto, 2005). Typically, natural disasters lead to the evacuation of large population masses (Buckle, 2012). Recent disasters show that the choice of transport medium in case of evacuation is the private vehicle (Lämmel et al., 2008; León & March, 2014; Pel et al., 2012; Ramos, 2016). This often leads to capacity overload and congestion on the road network (Dow & Cutter, 2002; Litman, 2006; Ramos, 2016; Rinaldi, et al., 2001). Additionally, cascading effects, occurring during tsunamis may hinder evacuation due to the blockages of intersection by the debris of destroyed buildings or collapsed electrical towers (Elnashai et al., 2010; León and March, 2014; León et al., 2018). Human behaviour in evacuation tends to be hard to predict. Many situational factors, including official warnings and instructions, time of day and day of week, the presence of family members or behaviour of the social environment, influence the decision-making process, whether to evacuate or not, and the response to an impending hazardous event. Hence, evacuation is a complex and dynamic process and may also increase the risk for the affected people (Buckle, 2012; Charnakol and Tanaboriboon, 2006; Chen, 2012; Quarantelli, 1980; Quarantelli, 1990; Ramos, 2016).

In order to execute realistic simulations and to facilitate evacuation planning, a detailed understanding of the human behaviour during evacuation, as well as an analysis of the urban environment, especially the road network, are necessary. The conditions of the road network and comprehensive knowledge about transport medium choices, elected or hypothetically elected evacuation routes and zones and the reason for the choices, may anticipate congestion and ensure effective evacuation planning (Lämmel et al., 2008; León and March, 2014; Pel et al., 2012; Ramos, 2016).

Previous evacuation studies mostly focus on either modelling approaches (Chen and Zhan, 2008; Mas et al., 2012; Pan et al., 2007) or social science approaches (Burnside et al., 2007; Dow and Cutter, 2002; Miran et al., 2018; Nakaya, et al., 2018; Perry, 1979; Shapira et al., 2018). However, the evacuation process is highly complex due to an interaction of the human factor and its urban environment. The response of the evacuees influences congestions in the road network significantly. Therefore. the evacuation process benefits from the analysis of an interdisciplinary perspective, combining different scientific methods (Chen et al., 2012; Lindell and Prater, 2007; Naster & Birst, 2010; Quarantelli, 1985). A large number of studies in the field of social science has investigated the evacuation process during hurricane events (e.g. Dash and Gladwin, 2007; Dow and Cutter 2002; Lindell et al., 2005; Smith & Mccarty, 2009; Whitehead, et al., 2000). Hurricanes have a long forewarning time. Such an evacuation differs from the evacuation process in tsunamis, where the time for evacuation decision and response is limited (Lämmel et al., 2008; León and March, 2014).

This paper addresses these limitations, linking a social science perspective and GIS (Geographic Information System) simulation, combining both fields in a stepwise research design. Besides, emphasising the value of interdisciplinary research, this paper analyses the evacuation process in a past event and hypothetical future event. The evacuation process is analysed from the decision to evacuate up to the arrival at a safe destination in case of a tsunami. The objective of the analysis is to detect issues and challenges in evacuation and to give recommendations to improve DRM at a local level. As congestion by the use of vehicles is a major problem in evacuation (León and March, 2016; Muñoz, 2014; Ramos, 2016; Riveros, 2014), evacuation by foot is simulated.

The combination of standardised questionnaires and GIS gives insight to evacuation routes and zones used and provides alternative evacuation routes by foot.

A case study is performed, investigating the district of Las Salinas, in the coastal community of Talcahuano, Chile. The community was among the Chilean coastal cities which were hardest hit by the tsunami of the 27th of February 2010 (Martínez et al., 2011).

The paper is structured as follows. The first section gives brief insight into the research area and the impacts of the earthquake in 2010 in Chile. Section 2 explains the applied methodology. In Section 3 the results are presented, followed by the discussion in Section 4. The paper finishes with a conclusion and recommendations in Section 5.

THE RESEARCH AREA TALCAHUANO

Chile is one of the countries, most prone to earthquakes due to its geographic location at the boundaries of the South American and Nazca Plates. It has a long history of tsunamis triggered by earthquakes (Bronfman et al., 2015; INE Medio Ambiente, 2010). On the 27th of February 2010, Chile was hit by an earthquake followed by a tsunami with a magnitude of 8.8 Mw, which affected about 800 km of the shoreline (Martínez, et al., 2011; USGS, 2010). According to statements of the Chilean government, more than 12.8 million people were affected by the earthquake and the subsequent tsunami, and 521 people were killed. The two most populated areas in Chile were impacted, the metropolitan region of Santiago and the central region Bio-Bío with the conurbation of Concepción-Talcahuano (CEPAL, 2010; GEER, 2010; USGS & U.S. Department of the Interior, 2011). Approximately 51% of the regional population lives in the coastal area (Martínez, et al., 2011) .

Within the region, several bridges were damaged and collapsed as a result of the earthquake. Since these bridges are critical links in the transportation network, their being damaged affected accessibility significantly. Damage to the road network was only minor. As consequences of the earthquake and tsunami, significant damage was also apparent in Talcahuano, one of the most affected communities of the tsunami in 2010 (Elnashai et al., 2010; Fritz, et al., 2010). 18.1% of the inhabitants of the community were affected and 9,173 houses were destroyed. In total, an area of 11.04 km^2 was impacted (INE, 2018; Martínez, et al., 2011). The port and the city centre were damaged severely by the tsunami, due to its low ground elevation between 5-10 m above sea level (León and March, 2014). Figure 1 illustrates the research area and an overlapping tsunami inundation map of 2010.

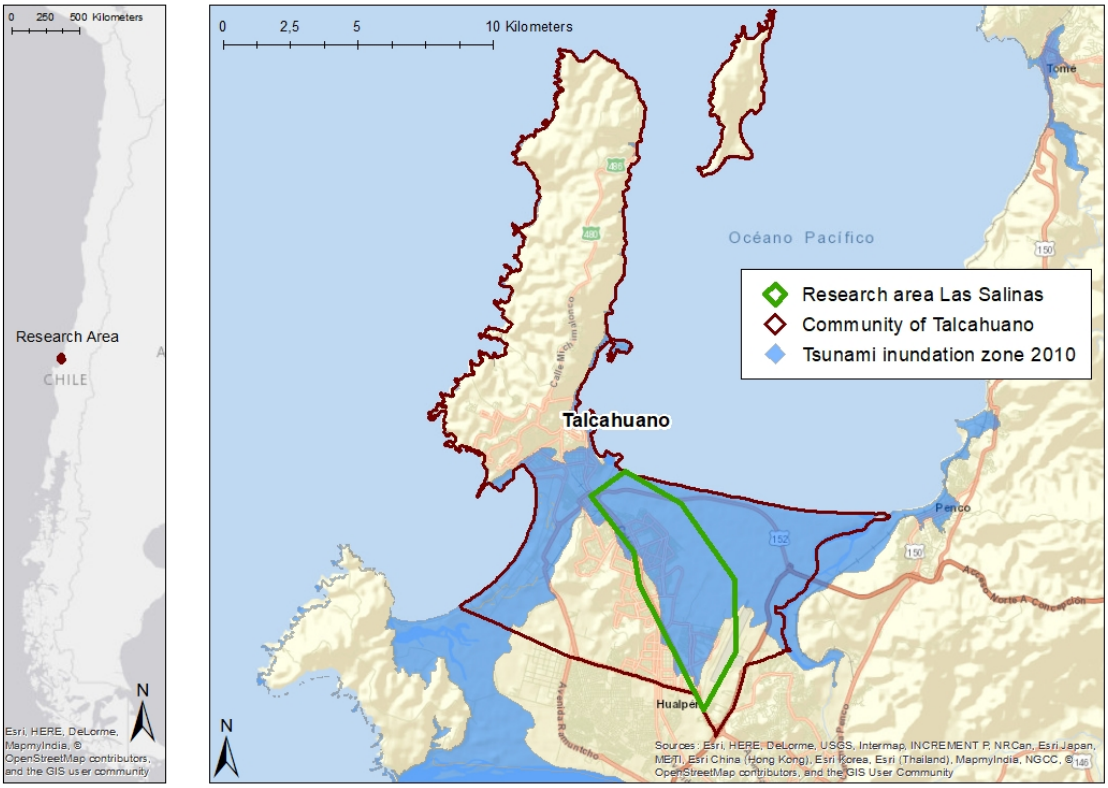

Figure 1: The Chilean territory (left), the community of Talcahuano with the research area Las Salinas and the tsunami affected area in 2010 (right).

Tsunami waves were up to 14 m high, and waves arrived between 12 to 20 minutes and 30 to 45 minutes after the earthquake, depending on the distance from the rupture zone (Vargas et al., 2010). Due to the breakdown in the communication system caused by the preceding earthquake and failures in communication between responsible institutions, no tsunami warning was released. The official institution ONEMI (Oficina Nacional de Emergencia del Ministerio del Interior y Seguridad Pública), which is responsible for the distribution of the alert, even gave a tsunami all-clear. The situation was aggravated by the centralisation of the administrative structure in Chile, which also affected the area of DRM and hindered local authorities in giving alerts. However, the majority of the coastal inhabitants left the hazard zone immediately after the earthquake (Herrmann Lunecke, 2015; León and March, 2014; Rojas et al., 2014). During that event as well as in later major earthquake and tsunami events a large part of the affected population evacuated in private vehicles. That fact led to many accidents and much congestion on the road network and impeded evacuation (León and March, 2016; Muñoz, 2014; Ramos, 2016; Riveros, 2014). The map in Figure 2 shows the official evacuation zones located 30 m above sea level and the official evacuation routes.

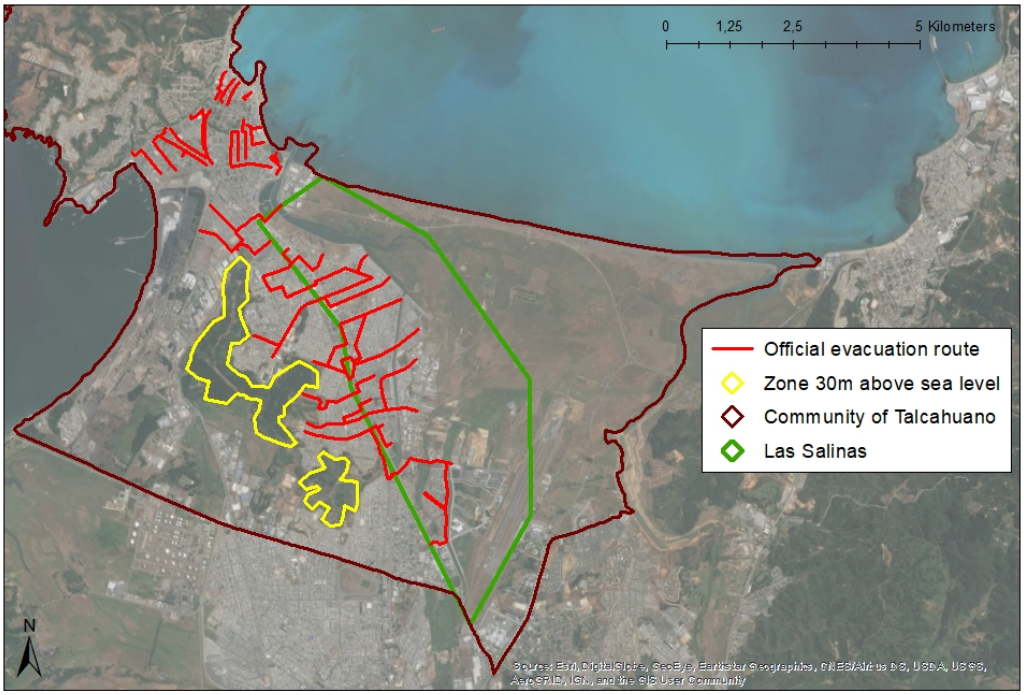

Figure 2: Official evacuation routes and zones in Talcahuano. Source: own additions based on data from Municipalidad Talcahuano (2018).

The following details are characteristics of the evacuation zones and routes of Talcahuano (see Figure 2): Evacuation zones (yellow framed area) are predominantly empty spaces and are located more or less 30 m above the sea level. An evacuation infrastructure with equipped evacuation zones is missing. The official evacuation routes and zones are marked with signs since the earthquake and tsunami of 2010. Before then, no official signposting existed (Municipalidad Talcahuano, 2018). In the following, we refer to that zone as the official evacuation zone.

METHOD

In order to analyse the evacuation process, an interdisciplinary approach was applied, combining social science and GIS simulation. We focused on the residential area of Las Salinas in the community of Talcahuano, due to the large impact there of the earthquake and tsunami event in 2010.

The research was conducted in a progressive form, the research phases were set up and linked together. Results of preceding steps were integrated in the subsequent steps. The research design can be dived in three major parts (coloured blue, green, and orange in Figure 3) with six minor phases. The first part of the social science approach represents the data collection and evaluation employing literature review, expert interviews and a standardised questionnaire. Afterwards, in the second part, a data simulation using GIS methodology was conducted. Based on the results of the preceding steps, recommendations are given.

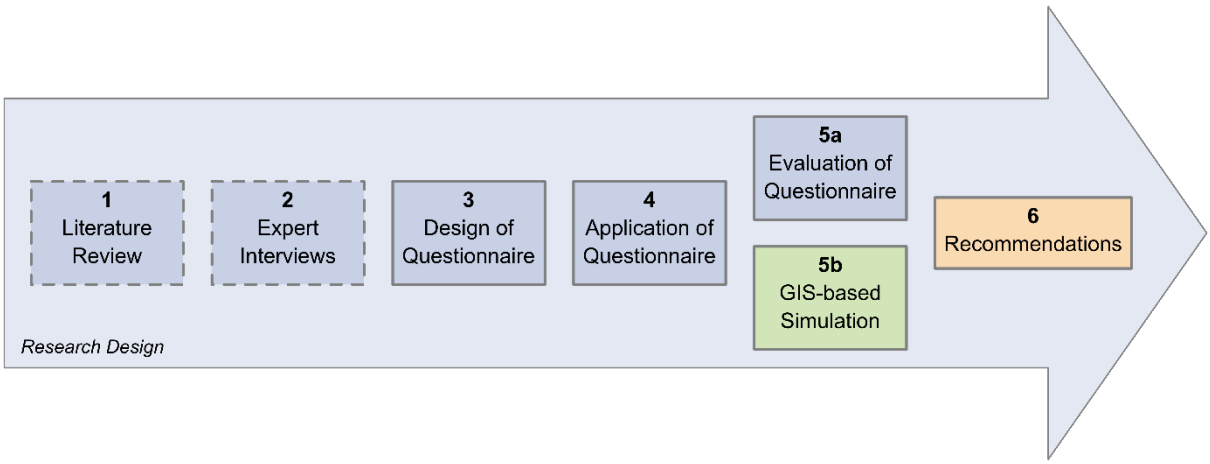

Figure 3: Overview of the research design. Steps of the social science part are highlighted in blue. The step of the GIS-based simulation is highlighted in green. Arising recommendations are highlighted in orange. Step 1 to2 in the dashed frame are not part of this paper.

Regarding the social science part of the research design, subsequent to the literature review on evacuation research, DRM, and state of the art in Chile, guided expert interviews were executed. Thereafter, Chilean experts of DRM, urban and regional planning, psychology and sociology were consulted. The results of the literature review and the expert interviews served as a basis for the design of the standardised questionnaires, which were distributed in the research area. After the application of the questionnaires, the results are statistically evaluated. The results from the marked maps, which were part of the questionnaire, were then integrated into and visualised with a GIS. In order to face the critical issues identified by means of the standardised questionnaire, further simulations were executed to perform a possible simulation by foot. On the basis of the results of both approaches, recommendation for strengthening DRM in the research area are given. In the following, the procedure of the survey, as well as the GIS simulation are explained in more detail.

The survey process

The standardised questionnaire was applied in the district Las Salinas on a household level. In total, 136 households were surveyed (N=136). The households were reached via the leaders of the *Juntas de Vecinos*, which are neighbourhood communities, uniting several times a year to discuss relevant problems and challenges within the district. The respective *Juntas de Vecinos* are spatially distributed within the district, so that the questionnaires were evenly distributed.

The questionnaire was comprised of eight parts. In the first part, socio-economic data were collected. The second part queried the experience with tsunamis and the impact on the household's property. The third and the fourth parts of the questionnaire collected data about influencing factors in the decision of evacuation and about the evacuation undertaken in the tsunami event in 2010. The fifth part requested the destination of evacuation in 2010. The sixth and the seventh parts was comprised of a combination of maps and questions. The respondents had to indicate the evacuation routes and zones they used in 2010 and respond to questions about the kind of blockages they discovered in the road network, as well as their transport medium choice. The seventh part collected data about evacuation behaviour in a possible future tsunami event, indicating possible evacuation routes and zones. The last part contained questions about the evaluation of DRM at the local and national level. The questionnaire was composed predominantly of closed questions with one or more predetermined answers possible. Respondents who did not evacuate in 2010 or had not been in the research area at the time the tsunami struck the area could mark the option "I did not evacuate".

The questionnaire, which was carried out in Spanish, was analysed with a frequency distribution using IBM SPSS Statistics 24. The results of the maps were integrated into QGIS, in order to visualise the past and future evacuation routes and zones.

GIS-based simulation of evacuation routes

For the GIS simulation, the OpenStreetMap (OSM) road network data was employed (OSM Contributers, 2018). OSM is crowd-sourced and free to use under an open license. The quality of OSM data varies between regions. A preliminary manual analysis of the road network data for the study region in Talcahuano has proven that the accuracy and completeness of the OSM data are sufficiently high.

The GIS served to evaluate and visualise the maps of the recent event-based and hypothetical future scenario of evacuation routes and zones which were marked by the respondents in the standardised questionnaire. In a further step, alternative simulations of the shortest footpaths to the nearest evacuation zones were conducted and evacuation time for walking distance to these zones was simulated for different walking speeds.

For the simulation of evacuation routes, 50 access points or roads to the evacuation zones were identified visually with the help of Google Maps satellite data. In a few cases, access points are roads that lead to the evacuation zone. In most cases, the access points to the evacuation zone are small, muddy footpaths. These points are herein called evacuation zone access points (EZAP).

The typical walking speed of pedestrians depends on multiple factors like age, disability, gender, road conditions and group size (Gates et al., 2006). In addition to these factors, the walking speed in disaster scenarios is even more unpredictable. For this simulation walking speeds were used that were observed during a simulated tsunami evacuation in Padang, Indonesia by Yosritzal et al. (2018). They observed different walking speeds for various age groups. Using their findings, three different walking speeds were applied for different age groups in this study: slow (1.35 m/s) for children under 10 years old, medium (1.4 m/s) for elderly, older than 60 years and fast (1.51 m/s) for adults between 40 and 60 years. The simulation did not consider the slope of the terrain as a factor on the walking speed.

Data on the exact location of households in Talcahuano does not exist. Thus, to obtain the starting points for the shortest path calculation to the evacuation zones, a 10 m x 10 m grid over the study region was created. The centroids of the grid cells served as starting points for the evacuation routes. Only centroids that are closer than 200 m to a road were considered for the simulation. This results in a total of approximately 180.000 starting points in the area. Then the shortest walking path via the OSM road network to the next road near an EZAP is calculated from every grid cell. For the shortest path calculation, the Dijkstra Algorithm (Dijkstra 1959) was applied. The distances from the centroid and from the EZAP to the nearest road, respectively, were added to the shortest path distance. Additionally, for every road in the network it was counted how often it is travelled. For every EZAP it was evaluated for how many starting points it is the closest.

The simulation was done using the open-source object-relational database PostgreSQL (v. 9.3) and its extension PostGIS (v. 2.3). pgRouting (v. 2.4) provides geospatial routing and other network analysis functionality. Results are illustrated with the GIS software QGIS (v. 2.18).

RESULTS

The result section is divided into two parts. According to the structure of the research design, the results of the standardised questionnaire are presented first, followed by the results of the GIS-based simulation.

Results of the survey

The results of the survey are divided into a past event and a hypothetical future scenario, and are structured in the sequence of an evacuation process, from the decision to evacuate to the arrival at the destination of evacuation. The results are based, as mentioned before, on N=136 households surveyed.

According to the results of the survey, in 2010 72.1% of the respondents evacuated, 22.8% of the interviewed person decided against evacuation or had not been in the research area at the time of the earthquake, and 5.1% did not answer the question.

The respondents were asked to indicate which factors they considered in their decision to evacuate *(multiple answers possible)*. The majority specified the intensity of the previous earthquake (58.8%) as critical for the decision to evacuate. Further factors relevant for the decision were the distance to the evacuation zone (23.5%),

availability of a car (19.1%), withdrawal of the sea (16.2%) and the evacuation of family and neighbours (14.7%). All relevant factors are illustrated in Figure 4.

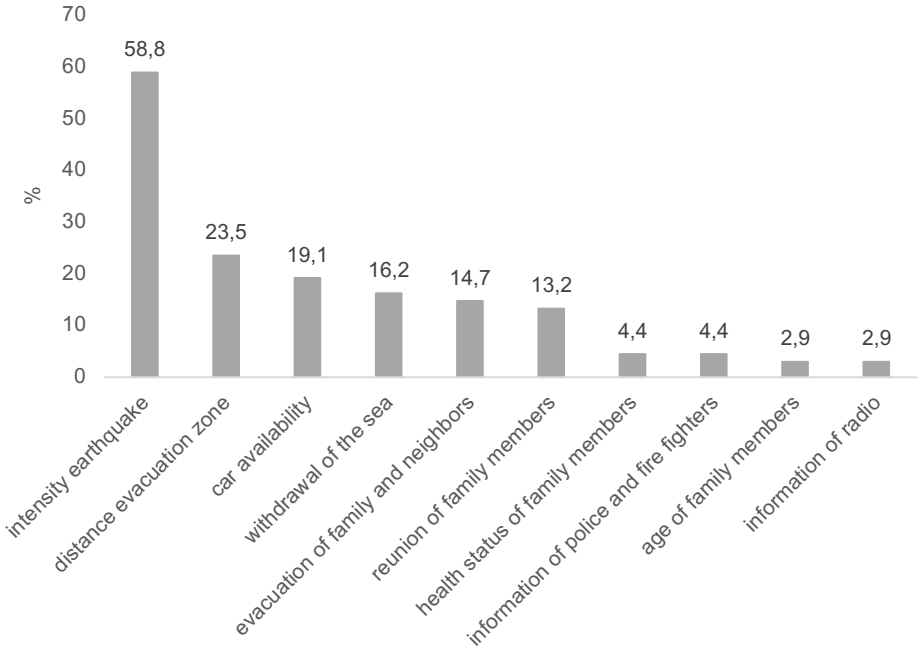

Figure 4: Factors of the decision of evacuation in 2010.

To decide whether to evacuate or not, 30.9% of the respondents indicated to have needed up to 5 minutes, 21.3% up to 10 minutes, whereas 10.3% took more than 25 minutes for their decision (Figure 5).

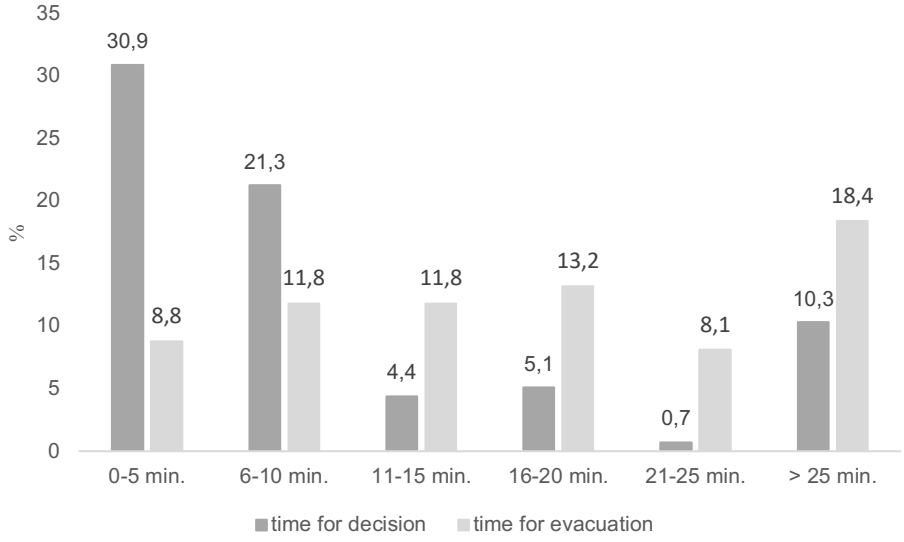

Figure 5: Time of decision-making and evacuation in the event 2010.

As a next step after making the decision to evacuate, 33.1% of the respondents collected equipment essential for survival, 27.2% tried to reunite their family and 19.9% tried to communicate with their family, and 14.7 % with their neighbours. Only 8.1% tried to get information from authorities *(multiple answers possible)*.

Finally, 59.6% evacuated with their whole family. In a hypothetical future scenario, if the family would not be together *(multiple answers possible)*, the majority (71.3%) indicated they would evacuate with present family

members. Another 27.2% indicated they would bring together all family members and 27.2% retrieve their children from kindergarten or school.

The primary transport medium for evacuation in 2010 was the private car with 52.2%, and only 17.6% indicated having evacuated by foot. The primary reason for choosing the car was speed (26.5%), followed by the presence of children and older adults (24.3%). Further, the distance to the evacuation zone (20.6%) and the possibility to overnight in the car (18.4%) were mentioned. Expected blockages and congestion (10.3%) in the road network was the fifth most common answer *(multiple answers possible)* (Figure 6).

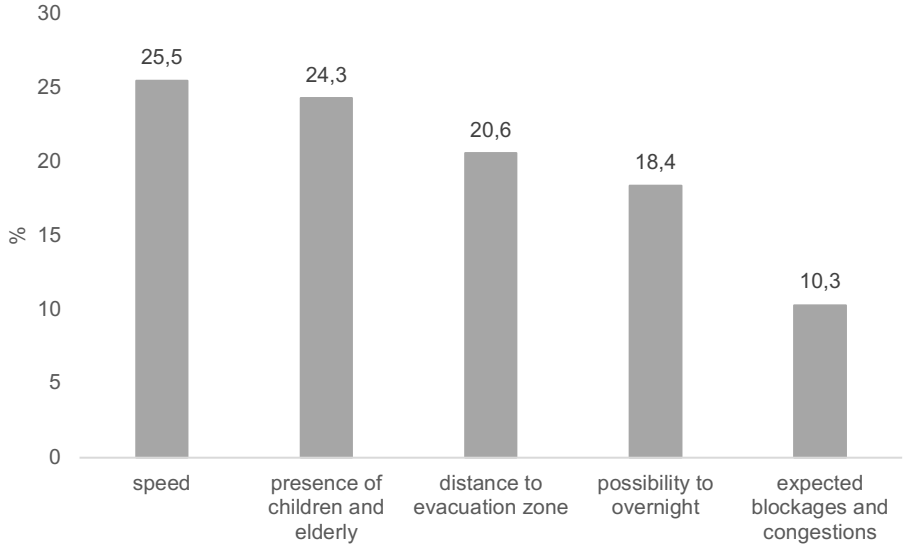

Figure 6: Reasons for the choice of transport medium.

Asking the respondents for a hypothetical future scenario, 46,3% indicated they would evacuate by car, while almost the same number (43,4%) would evacuate on foot.

Most of the evacuees (18.4%) needed more than 25 minutes to reach a safe destination, and many more needed up to 20 minutes (13.2%). Only a minority (8.8%) indicated to have needed as little as 5 minutes (Figure 5). The main reasons for the amount of time needed to evacuate were blockages (47.1%) in the road network and the distance to the evacuation zone (22.8%). The roads were mainly blocked by congestion (39.7%), persons in the street (38.3%), parked cars (21.3%) and debris (14.7%) due to the preceding earthquake *(multiple answers possible)*.

Figure 7 illustrates the evacuation routes and zones in 2010 (left) and in a hypothetical future event (right), which were indicated by the respondents on the maps. The thicker a street is highlighted the more evacuees have used it in 2010 or would use it in a hypothetical future event.

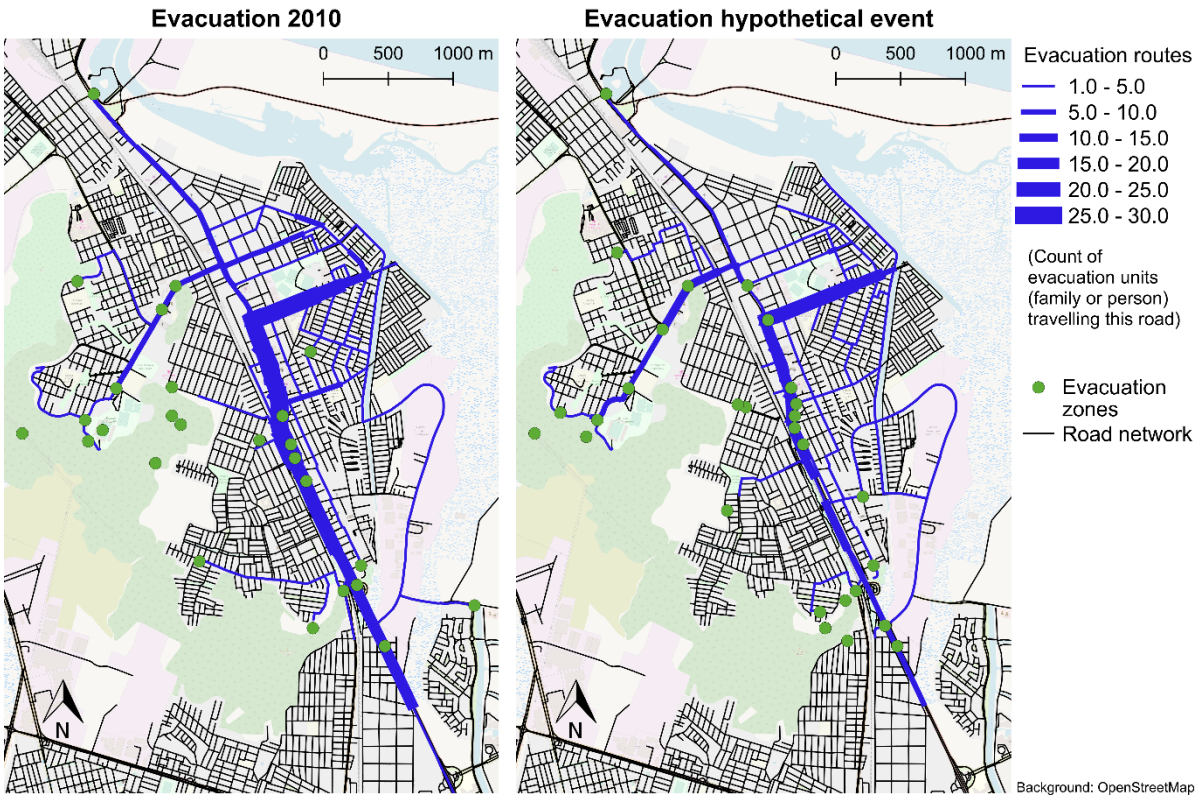

Figure 7: Evacuation routes and zones in 2010 (left), and in a hypothetical future event (right).

The majority of the evacuees indicated that they chose the route for evacuation that they are most familiar with (42.6%), or the route they consider to be the safest (17.6%), or is the shortest route to the evacuation zone (11.8%). Estimated congestion and blockages (9.6%) were not that relevant in evacuation route choice. In a hypothetical future scenario, the main reason for evacuation route choice is familiarity (58.1%). The evaluated distance to the evacuation zone (30.9%) and route security (20.6%) gain in importance for the choice, as does congestion and blockages (22.8%) *(multiple answers possible)* (Figure 8).

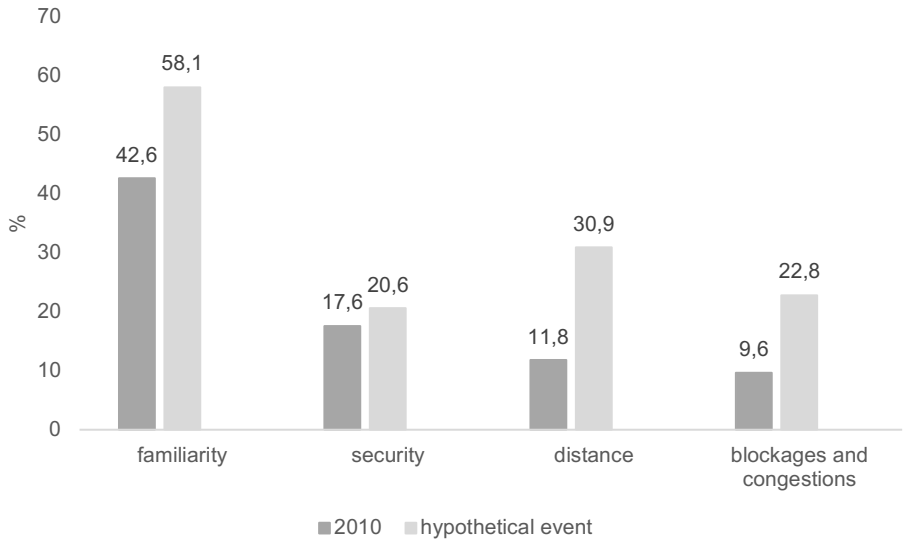

Figure 8: Reasons for the choice of the evacuation route in 2010 and in a hypothetical future event.

Regarding the destination for evacuation in 2010, most of the respondents indicated that they chose a nearby hill for evacuation (52.2%) or went to family or neighbours (8.8%). Reasons given were mainly the proximity to the house (26.5%) and accessibility (25.7%) *(multiple answers possible)*. In a hypothetical future scenario, the respondents indicated that they would go to the evacuation zones in Figure 7. Reasons are in particular the evaluation of the security of the zone (30.9%), the proximity to the house (30.1%), and evacuation zones which are recommended by authorities (22.1%). Also, accessibility (16.2%) would play a role in the choice. Recommendation by friends and family members (11%), as well as crowdedness (11%) would play a subordinate role. The facilities (shelter etc.) at the evacuation zone (2.9%) are rarely critical for the choice *(multiple answers possible)*.

Many respondents drove outside the community in 2010, so some evacuation zones are located outside the map extract in Figure 7 (left).

Results of the GIS-based simulation

The results of the walking time estimation for the three walking speeds described above are presented in Figure 9. A total area of circa 19.2 km^2 in Las Salinas was simulated. With a slow walking speed, 46.5% of the area needs an evacuation time over 15 minutes. With a medium walking speed, this decreases to 45.5% and to 43.3% with a fast walking speed. A small percentage (of 9.6% at slow speed, 7.4% at medium speed, and 4.2% at fast speed) of the area takes longer than 30 minutes (red marked area) to evacuate by foot. These results base on the assumption that the evacuees follow the shortest path to the nearest evacuation zone.

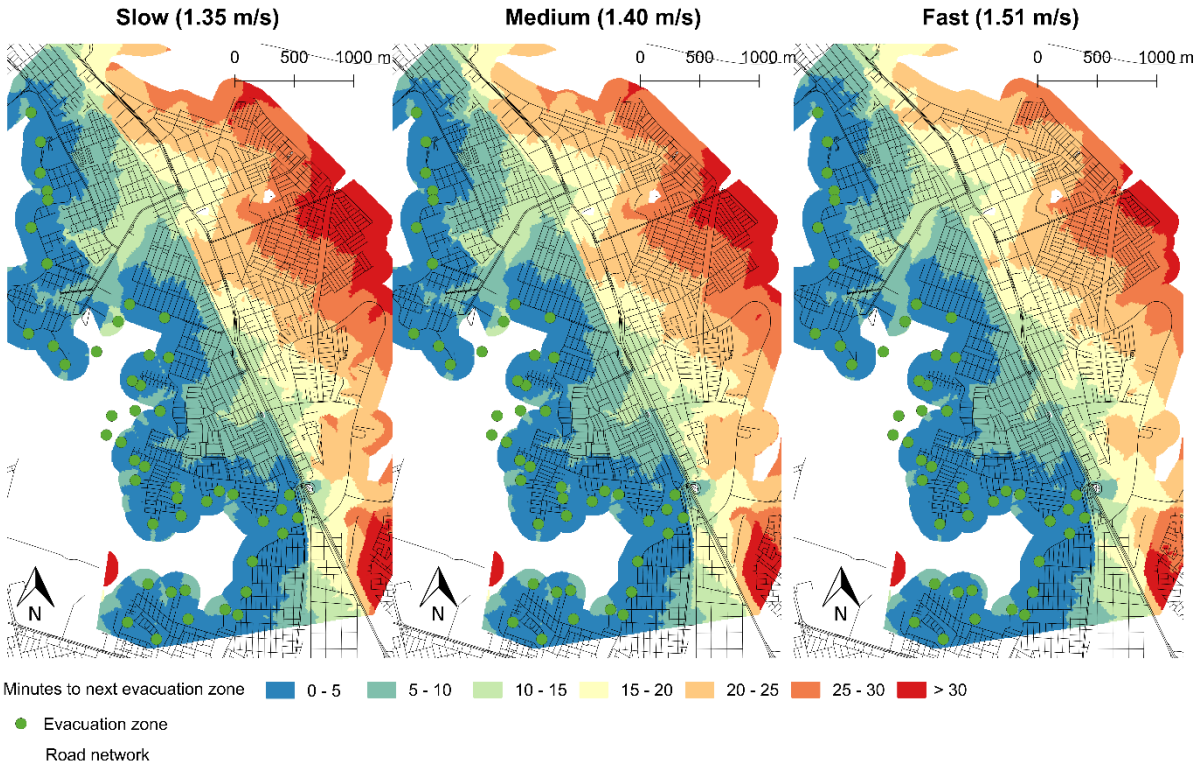

Figure 9: Evacuation times in minute for slow, medium and fast walking speed.

Figure 10 illustrates which roads and which EZAP are most used for evacuation. In total, 192.249 shortest evacuation paths were calculated. The four most often used EZAP are the nearest EZAP for 57% of the area.

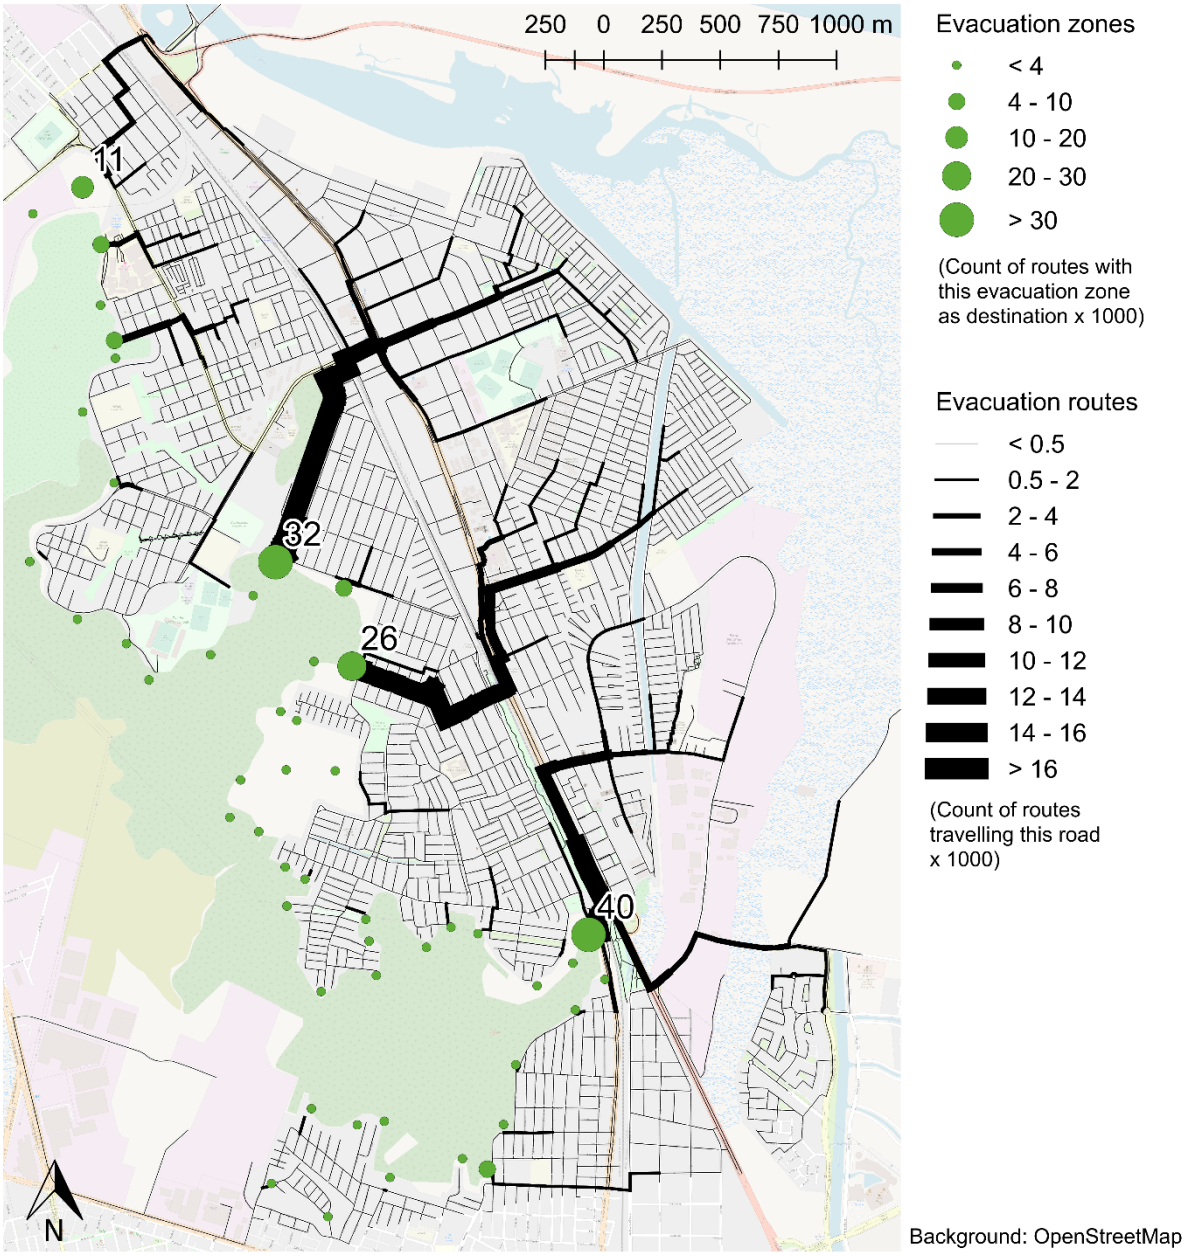

Figure 10: Most used evacuation routes and evacuation zones in Las Salinas.

Figure 10 reveals three main evacuation corridors for the inhabitants of Las Salinas.

DISCUSSION

The results of the case study reveal that irrespective of a lack of official information and the all-clear of a tsunami by responsible authorities in 2010 (Rojas et al., 2014), the majority of the respondents evacuated mostly because of the intensity of the prevenient earthquake. This behaviour may arise out of risk awareness due to past experiences.

However, despite the autonomous response of the affected population, the reported time needed for evacuation in 2010, which was a combination of the time taken for decision-making, actions for preparing the evacuation, and travel to the evacuation zone, was critical, bearing in mind that the first tsunami waves arrived 12-20 minutes after the earthquake in some coastal locations (Vargas et al., 2011). Although the majority decided within 5 minutes whether to evacuate or not, 10.3% indicated to have taken more than 25 minutes for the decision, a time period which might be critical in a hazardous event, in which time for response is limited. The delay in decision-making

may be traced back to uncertainty, due to the all-clear of tsunami by responsible authorities (Rojas et al., 2014). This delay is even longer when summing up time needed to prepare for the evacuation, including reuniting family members. Although it did not pose a problem in 2010, because the tsunami took place at night and in vacation time when most of the family members were together, the reunion of the family might become a critical issue in a hypothetical future scenario. The results revealed that the respondents would pick up their children from kindergarten or school, which both increases the time needed for evacuation and might lead to blockages of street sections due to congestion by contraflow, which might even be directed into the hazard-prone area, where many kindergartens and schools are located. Consequently, increasing traffic volume might additionally raise total evacuation time, from leaving the home until the arrival at the evacuation zone, which already took more than 25 minutes in most of the cases in 2010. Besides congestion due to car use as main transport medium, the distance to the evacuation zone posed a critical issue in evacuation time in 2010.

In order to reduce evacuation time due to congestion by car use, a GIS simulation was executed, identifying the shortest possible footpaths to the nearest evacuation zones (Figure 9). The simulation considered walking speeds of different age groups. The results demonstrate that at the east end of the research area, more than 40% of the evacuees of the area, in each speed category, would need more than 15 minutes to evacuate by foot. Consequently, the evacuees would not make it walking to the nearest evacuation zone before the first tsunami waves arrived. In 2010 the first tsunami waves arrived in some coastal locations after a few minutes. Additionally, 9.6% of the area for slow walking speed, including children under 10 years and 7.4% of the area for medium walking speed, would need more than 30 minutes to evacuate to the nearest evacuation zone. Consequently, the preference for use of the car as transport medium in evacuation in the research area becomes understandable. The indicated reasons for car use in the questionnaire, which are velocity, the presence of children and seniors and the distance to the zone, reinforce these findings. Although according to the indications the number of evacuees evacuating by foot would increase in a hypothetical scenario compared to 2010, more than half of the respondents indicate they would evacuate by car. Another reason that favours the evacuation by foot is the accessibility to the evacuation zones, since the roads are in most of the cases muddy footpaths and blocked by fences which could not be passed by car.

Comparing the evacuation route and zone choice in both scenarios (Figure 7), the main road, which crosses Talcahuano from south to north and leads outside of the community, is the primarily road chosen for evacuation. Comparing the roads chosen in the past and the hypothetical future scenario, they do not coincide with the official evacuation routes, which lead up the hills to the yellow framed evacuation zone in Figure 2, even when 22.8% indicate that the recommendation of the evacuation zone by authorities is relevant for future choice. Also, the factor of proximity to the evacuation zone gains in importance in a future scenario, however the majority would evacuate to zones outside the community according to the indications in the map. This may argue for a lack of knowledge of official evacuation routes and zones. On the other hand, knowing that the main reason for route choice is the familiarity with the route, it becomes understandable. Official evacuation routes lead just up to the hills, where no infrastructure for daily needs is located and land use is mostly dedicated as residential area. In contrast, the main road leads outside the community in direction to the next biggest city Concepción, which provides infrastructure for daily needs and workplaces. Expected congestion and blockages influenced the choice to a small degree in 2010; however, the importance of this factor in route choice gains importance in the hypothetical future scenario. Nevertheless, despite the awareness of possible congestion, the respondents indicated the same route in a hypothetical scenario.

Furthermore, as the distance of the evacuation zone was a major factor in transport medium choice, in order to detect if evacuating by foot would be an alternative, the shortest paths for walking out of the inundation zone to the nearest evacuation zone have been simulated. The simulation results show three main evacuation corridors and one minor evacuation corridor (Figure 10). Four major access points to evacuation zones are identified, which serve as a destination for 57% of the shortest evacuation routes. However, it has to be noted that these identified evacuation zones are just empty areas up the hill, which do not provide shelter and are not equipped with essential supplies like beds, food, water and medicine for evacuees. Additionally, if all households would evacuate to these areas, the capacity might be exceeded. Furthermore, the nearest paths which lead to the identified zones are particularly small muddy roads which are not paved and may not satisfy the demand in case of evacuation. Additionally, fences of private estates and the trail rail line along the main road might hinder evacuation to these zones. Examining the results of the shortest paths, those do not coincide with the results in the standardised questionnaires for the hypothetical and past scenario (Figure 7). However, they coincide with the official

evacuation routes Figure 2. Furthermore it has to be acknowledged that those evacuation zones will not be reachable for all evacuees in a short time period (see Figure 9).

CONCLUSION AND RECOMMENDATIONS

This research points out three critical issues in evacuation, identified by an analysis of a past and a hypothetical future event, integrating the affected population by means of a standardised questionnaire. These issues, namely evacuation time, distance to the evacuation zone, transport medium choice and congestions in the road network, are underpinned by the results of the GIS simulation.

The research highlights that these critical issues identified depend on one another. Given that the evacuation zones on the hills are, according to the indications in the questionnaire, too far away, the main transport medium in evacuation was and will be the car. This is fortified by the GIS analysis, which illustrates that the evacuation zones are particularly not reachable within a few minutes by foot. Familiarity was the main reason for route choice. Most of the evacuees used and will use the main road, which they use daily, resulting in congestions which increases time needed for evacuation starting from leaving the house to reaching the evacuation zone. Consequently, if the urban environment will not be adapted to the case of evacuation, e.g. build evacuation zones within the research area (see f. e. Ramos, 2016), it is questionable if in a future event, transport medium choice will change. Hence, time delay in evacuation will continue and may even be aggravated by the fact, that if a future event happens on a weekday during the day, a high percentage of the population will first pick up their children from kindergarten and school. Furthermore, the official evacuation zones on the hills, which are also identified in the GIS simulation, modelling the shortest path to the nearest evacuation zone, are not equipped with shelters and supplies like water, food, medicine and beds and are sometimes only reachable by small muddy footpaths with impediments like railroad lines or fences of private estate, which might also be a reason for not using the evacuation routes and zones heading to the hills. Even if evacuating by foot would be promoted, the nearest evacuation zones, identified in the GIS simulation, would not satisfy the capacity needed for the number of evacuees. Further, it has to be considered, that the car also provides a shelter in case of evacuation.

In order to alleviate the critical issues identified, we recommend short- and long-term measures to strengthen DRM at local level. As a short-term measure, raising awareness regarding transport medium and evacuation route and zone choice, we recommend workshops for the affected population, which would be guided by the leaders of the *Juntas de Vecinos* and local authorities responsible for DRM and urban planning. In these workshops the critical issues in evacuation, time delay, transport medium and evacuation route and zone choice should be discussed. At the end of the workshops, every household should be provided with an emergency kit and a family emergency plan, which includes strategies in evacuation. The latter should include where to meet absent family members, and which evacuation route and zone to use. The distribution of evacuation routes and zones within the *Juntas de Vecinos* should alleviate traffic flow in evacuation. These workshops should be repeated once a year, so that changes in the urban environment and human behaviour can be considered. Furthermore, the results of the workshops could be integrated in an online platform of the municipality, in order to be available for daily use to the community. The online platform should be updated by the responsible disaster managers and enriched with data of further municipality departments, such as road construction.

In order to promote evacuation by foot in the long-term, as pointed out in this research, hard measures are needed. The urban environment has to be adapted to the necessities in the case of emergency. Besides the signage of the designated evacuation routes and zones in the workshops with the *Juntas de Vecinos*, the evacuation zones have to be equipped with shelters, which would provide capacity for a certain number of evacuees and provide essential supplies. Additionally, this paper provides (see Figure 10) the nearest footpaths in the research area to the nearest evacuation zones on the hills. However, the accessibility to these zones has to be improved, removing impeding elements like fences. Furthermore, evacuation routes have to be paved and extended if necessary. Further, experts have to be aware of the scarce capacity of the nearest zones identified in this research, as they have to accommodate more than 57% of the households. Consequently, alternative routes and zones have to be provided. If evacuation by foot should be promoted, the long-term measures are indispensable. Those include as well possibilities for vertical evacuation in Las Salinas (see f. e. Ramos, 2016), given that the residents at the east end of the area would not make it walking in case of a near-field tsunami. The same is valid for families with children and seniors.

Additionally, in order to avoid counter-evacuation traffic flow, it is recommendable to relocate kindergartens and schools to evacuation zones. Furthermore, these might provide shelters in case of emergency and consequently have a multifunctional use.

This research highlights the necessity of the combination of a social science approach and GIS simulation, integrating the affected population. As the research showed, the standardised questionnaire provides insight into critical issues in a past event-based and a hypothetical future scenario. The GIS-based simulations integrate on the one hand the results of the questionnaires and provide on the other hand results of the evacuation by foot. Thus, critical issues detected by the questionnaire are faced and underpinned. The combination of the results ensures an effective evacuation planning. Disaster managers and urban planners might benefit from the results. Of course both approaches have limitations. Since the event in 2010 was seven years before the research was executed, the respondents to the questionnaire might not remember every detail of the evacuation. Additionally, the indication for the future scenario is hypothetical, so that the results contain assumptions about future choices. A limitation of the GIS simulation is that the topography of the research area, which might influence walking speed, is not considered.

Future research may consider the advantages of the application of interdisciplinary approaches, but also consider the limitations which are discussed above. The research design applied in this study can be transformed to other Chilean coastal communities, as they face similar problems and share the same social, ecological and political background. In order to apply this approach to other countries and other natural disasters, the specific context has to be considered, and the social science approach, especially the standardised questionnaire, has to be adapted to this context. It would be interesting to integrate further data collected by the standardised questionnaire, like the period of time in which the evacuation started. A (multi-)agent-based system might consider this valuable data and also consider the critical issue of contraflow, fetching the children from kindergarten and school (f.e. Mas et al., 2012).

Evacuation reduces the risk for the affected population during natural disasters, however, the evacuation might be more effective, if time delays and congestions are considered in preparation measures and strategies of DRM. Therefore, it is argued that a more detailed analysis can only be conducted if the strengths of different scientific approaches are combined, analysing human behaviour in the evacuation process as well as investigating the linkages to the road network and the urban environment, which play a crucial role in evacuation.

ACKNOWLEDGEMENT

We are grateful to Boris Sáez Arévalo, director of the department of risk management of the municipality of Talcahuano, and to his colleagues in supporting us with information, data and in the distribution of the questionnaire.

ABSTRACT

Fast and easy communication, e.g. via Twitter or Facebook, encourages self-coordination between spontaneous volunteers in disasters. Unfortunately, this is more and more challenging official disaster management. The need for the directed coordination of spontaneous volunteers triggered researchers to develop effective coordination approaches. However, evaluating and comparing such approaches as well as their exercising are lacking a standardized way to describe repeatable disaster scenarios, e.g. for simulations. Therefore, we present a novel System Entity Structure (SES) for describing disaster scenarios considering the disaster environment, communication infrastructure, disaster management, and population of spontaneous volunteers. The SES is discussed as a promising scheme for including spontaneous volunteers in disaster scenarios on a general level. Its applicability is demonstrated by a Pruned Entity Structure derived from a real disaster scenario. Based on the results, we give an outlook on our subsequent research, the XML-based Spontaneous Volunteer Coordination Scenario Definition Language (SVCSDL).

Keywords

Agent-based Simulation, Spontaneous Volunteers, Spontaneous Volunteer Coordination Scenario Definition Language (SVCSDL), System Entity Structure (SES), Disaster Scenario.

INTRODUCTION

Spontaneous volunteers, i.e. people who spontaneously help in urgent disaster situations and who are not affiliated to official civil protection organizations (Barraket *et al*., 2013; Ludwig *et al*., 2017; Zettl *et al*., 2017), play an important and active role in disaster response (Fernandez, Barbera and Dorp, 2006; Sauer *et al*., 2014; Lindner, Betke and Sackmann, 2017; Ludwig *et al*., 2017). For years, the phenomenon of spontaneous volunteers in major disaster events has moved both the media and research. Modern communication technologies, such as social media, have raised the phenomenon of spontaneous volunteers to a new level (Meissen *et al*., 2017; Reuter and Kaufhold, 2018) that makes an examination of the topic in disaster management indispensable. During the disastrous floods 2013 in Germany, the continuous presence of the disaster in social media led to massive participation of the population to cope with the disaster. While this spontaneous support of the official disaster relief forces was crucial for overcoming the disaster, it also led to various problems: due to incorrect and subjectively designed information some operating sites were overcrowded by volunteers whereas others were dramatically understaffed, and several volunteers exposed themselves to danger through unauthorized actions (Fernandez, 2007; Hofmann, Betke and Sackmann, 2014).

The enormous cooperativeness of spontaneous volunteers, as well as the lack of approaches for their coordination, have triggered a large number of new research projects (German Federal Ministry of Education and Research, 2018b). Several projects, e.g. KUBAS (Rauchecker and Schryen, 2016), AHA (German Federal Ministry of Education and Research, 2018a), REBEKA (Johanniter-Unfall-Hilfe e.V., 2018), ENSURE (Fraunhofer-Institut für Offene Kommunikationssysteme FOKUS, 2018), KOKOS (Project KOKOS, 2018) or K3 (German Federal Ministry of Education and Research, 2018c), explore the improvement of the coordination of spontaneous volunteers by using modern information and communication technologies. Recently developed concepts, demonstrators, and prototypes are confronted with the challenge of scientific evaluation to demonstrate and compare their usability and added value. This may be done in real disasters or field tests, that, however, are usually too expensive, elaborate, and partly impossible to conduct. Since field experiments are not sufficiently realistic, real disasters are too dangerous and both are hardly reproducible, computer simulation is an appropriate approach to test, evaluate, and optimize real-world scenarios and approaches with a minimal effort. Furthermore, simulations enable the disaster staff to perform exercises in using such systems at regular intervals due to the possibility to describe and define reproducible disaster scenarios. Simulating spontaneous volunteers can also facilitate the possibility of forecasting their behaviors in real disaster situations.

Regardless of how such evaluations or exercises are carried out methodically (e.g. field trials, simulations), a reusable, standardized, and ideally formalized description of disaster situations is required. Since such suitable methods do not yet exist, our research goal is to develop a model for the specification of disaster scenarios including spontaneous volunteers as an artifact that is further the basis for the subsequent development of an XML-based Spontaneous Volunteer Coordination Scenario Definition Language (SVCDSL). On the one hand, the model enables an understanding of disaster scenarios with spontaneous volunteers on a conceptual level, e.g. to develop scenarios for field trials. On the other hand, it provides the basis for developing an executable disaster scenario definition language for simulations.

The artifact development is part of a research project following the well-established Design Science Research Process methodology proposed by Peffers et al. (Peffers *et al*., 2007) and covers the third phase – "Design and Development". The whole project aims at the development of a universal spontaneous volunteer simulation application in disaster situations to evaluate and compare spontaneous volunteer coordination approaches as well as to predict the volunteers' behaviors in acute disaster situations. Agent-based simulation has therefore been identified as a proper method to simulate the behavior of spontaneous volunteers in a disaster context. Results of the first two DSRP-phases of this project are described in (Lindner *et al*., 2018; Lindner, Betke and Sackmann, 2017) where a structured literature analysis has been performed and a conceptual model of spontaneous volunteer behavior has been developed. To further enable the comparison and evaluation of spontaneous volunteer coordination approaches using agent-based simulations, it is required to identify all relevant entities as well as to establish reproducible and machine-processable scenarios. Since the development of the language artifact in this paper requires a constant exchange with experts, specialists and end-users and the results have to continuously be evaluated and improved, Action Design Research (ADR) according to Sein et al. (Sein *et al*., 2011) is utilized as a concrete method.

Based on other studies, as a first step, so-called System Entity Structures (SES) are identified and discussed as an adequate approach for our research (Section 2). Accordingly, in Section 3, relevant elements for describing disaster scenarios are identified from the literature. Following the corresponding IEEE guideline for scenario development, in Section 4 the identified elements are categorized and used for developing the aspired artifact. The applicability of the developed SES is demonstrated in Section 5 by using a concrete example of the 2013 flood disaster and transferring the SES into a so-called Pruned Entity Structure (PES). As a final step, the developed SES is discussed and an outlook for defining an open and extensible XML-based language called Spontaneous Volunteer Coordination Scenario Definition Language (SVSDL) is given.

DEVELOPING SCENARIOS WITH SYSTEM ENTITY STRUCTURES

Reproducible, reusable, and executable scenarios provide a sound foundation to evaluate coordination approaches and systems as well as to compare different ones since these scenarios enable the measurement of differences under identical circumstances. The IEEE defines scenarios on the one hand as a description of an exercise that "is part of the session database that configures the units and platforms and places them in specific locations with specific missions" (IEEE, 2011). On the other hand, scenarios are described as "[an] initial set of conditions and timeline of significant events imposed on trainees or systems" (IEEE, 2011). Although the definition and development of scenarios are defined by the IEEE on a general level, a particular method to perform scenario creation is not proposed. Instead, the selection of a proper tool or technique is seen as one explicit step of the scenario development (IEEE, 2011). To determine a suitable method for developing the aspired scenario, a literature review has been performed to identify publications that either have developed simulation scenarios in

general or that have defined scenarios for the coordination of spontaneous volunteers in particular.

For the literature review, the keywords *simulation*, *scenario*, *reproducible*, *spontaneous volunteer*, *coordination*, *scenario language*, *scenario development, agent-based simulation, disaster* and some of their combinations have been searched in various scientific databases, such as WileyOnline, ScienceDirect, SpringerLink etc. as well as in Google Scholar. We have limited our search to publications after 2000 to maintain a certain topicality. In addition, forward and backward searches have been carried out to identify further relevant publications.

The literature review revealed that the development of models for standardization and description of scenarios is addressed in various areas. For example, the Military Scenario Definition Language (MSDL) published by the Simulation Interoperability Standards Organization (SISO) has been established in the military sector (Blais, 2008; Wittman Jr., 2009). Other models exist in the transportation sector where road traffic, particularly driver behavior, was described, e.g. (Adler *et al.*, 2005; Fuchs *et al.*, 2008). Standardized scenarios are also used in health management to train nurses for emergencies (Waxman, 2010; Alinier, 2011). Furthermore, Jafer et al. have developed a language that describes standard scenarios in aviation (Jafer *et al.*, 2016). In addition, there are many contributions dealing with the development of scenarios for multi-agent systems on a general level (Murakami *et al.*, 2003; Nakajima *et al.*, 2006).

The literature review also revealed that several authors research on the question of how scenarios can be developed to better manage disasters and predict their progressions (e.g. (Sun *et al.*, 2015)). However, the proposed models are either very specific (e.g. (Su, Wang and Zhang, 2016; Simões *et al.*, 2011)) and not suitable for standardization or the scenarios rather focus on decision support for emergency forces and aid organizations (e.g. (Drury *et al.*, 2009)) and do not take spontaneous volunteers as valuable resources into consideration. In summary, our literature review revealed that there is no description of disaster scenarios especially focusing on the coordination of spontaneous volunteers yet. This fosters our effort to develop a corresponding Scenario Definition Language for describing and executing such scenarios.

However, the identified work revealed successfully applied tools and techniques for developing scenarios. In particular, the Simulation Scenario Development (SSD) as a method proposed by the IEEE has already been approved, e.g. (Jafer and Durak, 2017). Following the SSD approach, the foundation of any scenario documentation is the identification of entities, their behaviors, and events that need to be represented in the scenario(s) (IEEE, 2011). Since the behavior inevitably results from the simulation environment, we focus on the identification of events and entities. The SSD approach described by the IEEE merely provides steps that are necessary for a successful scenario definition, but, unfortunately, it does not discuss its actual application. For applying the SSD, several researchers in different domains have already successfully used so-called System Entity Structures (SES) as a methodological framework (see, e.g. (Ntaimo *et al.*, 2004; Lee and Zeigler, 2010; You, Chi and Kim, 2013; Schmidt, Durak and Pawletta, 2016; Durak *et al.*, 2017)). SES is using a data model that reflects system-engineering concepts of hierarchical decomposition and specialization (Cheon, Kim and Zeigler, 2008). SES is also based on a limited set of elements (entity, aspect, specialization, and multi-aspect) and axioms that can be introduced as a directed labeled tree (Durak *et al.*, 2017). Since this characteristics allow an automatic creation of XML schemata (Cheon, Kim and Zeigler, 2008), SES is seen as suitable to close the gap between structured scenario definitions proposed by IEEE and a machine-processable language and, thus, it is seen as an appropriate method leading to the aim of our research, namely the desired SVCSDL.

Simulation scenarios can be categorized into three types that need to be developed in the scenario development process, namely operational scenario, conceptual scenario, and executable scenario (Siegfried *et al.*, 2012; Simulation Interoperability Standards Organization, 2015). Accordingly, the operational scenario usually describes the targeted real-world scenario in a textual form providing a broad description of the desired events and elements. For our research, descriptive reports on coordinating spontaneous volunteers have been analyzed to provide basic information on how volunteers were coordinated in real disaster situations. The results of this analysis as well as the required deeper investigation on element details and interrelations are presented in Section 3 leading to the identification of entities and, consequently, to the conceptual scenario, that usually is a formal metamodel representation. As the basis for a formal description of an executable scenario in an XML-Schema that can be processed by simulation applications, all scenario-specific information is subsequently represented as a System Entity Structure (see Section 4).

ELEMENTS FOR DESCRIBING DISASTER SCENARIOS WITH SPONTANEOUS VOLUNTEERS

To develop scenarios, it is important to understand what distinguishes them. According to the IEEE guideline, scenario(s) include "types and numbers of major entities/objects that must be represented within the simulation environment" (IEEE, 2011). Consequently, the IEEE describes scenarios to have various entities being represented within the aimed at environment. As SES has already been applied to define scenarios, we adopt this

method to develop the spontaneous volunteer coordination scenario. In "Modeling & Simulation-Based Data Engineering: Introducing Pragmatics into Ontologies for Net-Centric Information Exchange" Zeigler and Hammonds explain the development of SES and all related elements. In general, SES consists of Entities, Aspects and Specializations. According to Zeigler and Hammonds "Entities represent things that exist in the real world or sometimes in an imagined world. Aspects represent ways of decomposing things into more fine-grained ones. Multi-aspects are aspects for which the components are all of one kind. Specializations represent categories or families of specific forms that a thing can assume" (Zeigler and Hammonds, 2007).

The required authoritative domain information for the scenario development (IEEE, 2011) have been identified and analyzed by literature reviews, preliminary work and expert discussions. In this section, according to the SES development by Zeigler and Hammonds, we will discuss the relevant entities for describing disaster situations and decompose them into specializations and multi-aspects and, if necessary, attach variables to the identified entities.

As basic entities that are discussed in the following in more detail, we identified **Disaster Management** and **Spontaneous Volunteers** inevitably resulting from the targeted domain and research goal. According to the IEEE guideline, the **Environment** must be taken into consideration and, thus, is a basic entity that represents a superset of the scenario components. As experiences show, communication has a significant influence on the self-coordination of spontaneous volunteers as well as on the possibilities for official disaster management to coordinate them according to the official needs. Sackmann et al. even see communication as a central design object for the coordination of supporting activities (Sackmann *et al*., 2018). Thus, as forth entity, **Communication Infrastructure** is defined as a basic entity for our scenario description as well. Furthermore, the IEEE guideline suggests modeling scenario triggers and stop conditions. As a starting point, these are defined according to the typical phases of disaster scenarios (Thieken *et al*., 2007): the scenario gets triggered by the disaster event and the beginning of the disaster response phase or its simulation. The stop of the scenario is given over to the scenario modeler since it depends on the particular goal.

Environment (Basis Entity #1)

According to the IEEE guideline, the environment is a superset of the scenario components comprising aspects, e.g. geographical regions, natural environment conditions, initial and termination conditions. This entity with its aspects defines the general behavior of entities and, consequently, the simulation of their behavior.

Inherently important for any disaster scenario and its simulation is the definition of **geographical areas**. There exist several concepts for defining areas, e.g. center point and radius (Nelson, Iii and Kravets, 2007) or polygonal pathways (Wagner and Agrawal, 2014). There might be good reasons for describing geographical regions in a very detailed manner. However, as a starting point for our scenario description, we decided to use a simple concept of overlapping circles that are defined by their center (longitude/latitude) and radius. Extending or replacing this simple concept is easy to realize without changing the general result of our research. These geographical areas are represented in our SES as a Multi-aspect as there can be several areas or locations within the environment and accordingly within the scenario. The definition of the geographical areas at the beginning of the scenarios enables the re-utilization of these regions in other entities within the SES.

Our literature review revealed **weather** to be one main aspect in the disaster context (e.g. (Geißler, 2014; Kircher, 2014)). It is not only relevant to the disaster itself but also for the willingness of volunteers to help (Geißler, 2014; Kircher, 2014). Thus, the weather was chosen to be represented within the SES. Reports and publications on past disasters proposing the weather as an influencing factor usually describe weather with attributes like "nice", "warm", "bad", "rainy" etc. (Geißler, 2014; Rauchecker and Schryen, 2018) However, since such terms are rather subjective and vague, we propose a more general type of description in terms like precipitation, rain intensity, temperature, humidity, etc. as variables in our SES. These variables can subsequently be interpreted and used to simulate the influence of weather on, e.g. the motivation of spontaneous volunteers to help. In the SES, we represent the weather as a Multi-aspect as, in combination with the geographical areas, weather can be defined locally and may be different within one scenario.

Communication Infrastructure (Basis Entity #2)

Recent disasters have shown that communication (between spontaneous volunteers themselves as well as between volunteers and official disaster management) and limited accessibility has played a crucial role in the (self-)coordination of spontaneous volunteers (Reuter and Kaufhold, 2018). Communication infrastructure and their availability in a disaster situation determine how information be disseminated and, thus, have to be described within the scenario definitions. Literature and experiences show that communication is at least determined by its technical as well as its organizational realization (see, e.g. (Asplund, Nadjm-Tehrani and Sigholm, 2009; Reuter and Kaufhold, 2018)). Thus, we defined these two dimensions as relevant aspects of our

scenario description.

From a technical perspective (**technologies**), communication infrastructure can differ with respect to communication channels and, thus, with respect to communication content. For example, SMS are limited to text-only content and require at least a GSM network, whereas mobile applications or social networks are not necessarily limited to a number of characters or text/media but require different infrastructures such as the Internet via WIFI, LTE, or HSDPA. Since the availability or access to communication technology is usually confined (e.g. not all people use all communication channels in parallel, limited capacity on the side of network provider, blackout), the description of a disaster scenario should necessarily enable the definition of capacities for specific areas. Thus, we defined communication technologies as a Multi-aspect of communication infrastructure as one scenario can have several technologies in different areas with different capacities.

From an organizational perspective (**communication types**), a first relevant characteristic of communication is the type of communication **participants**. Since self-coordination between volunteers as well as directed coordination of volunteers by official disaster management is in the focus of our research, communication participants include at least the official disaster management (**DM**) and the spontaneous volunteers (**SV**). Since both parties can be sender as well as the receiver of information, this is seen as one main aspect for describing communication infrastructure. A second main aspect is whether the **relationship** between sender and receiver is a one-to-one (**one2one**) or a one-to-many (**one2many**) relation. The possibility to describe these relations allows, together with the categorization of the communication participants, to define general possibilities for uni- or bidirectional communication. Scenarios can, thus, be limited to, e.g. the communication between spontaneous volunteers among themselves in a broadcasting manner (one2many) and, thus, influence their behavior and the kind of information that may be disseminated. However, also the technological perspective may play a role in how and which information can be disseminated, why we see technologies as a third influencing and limiting aspect in the communication type. As we assume that technologies indispensably be linked with the relationship and participants, we represent both, relationship and participants as Specializations that necessitate a selection of each. E.g. one kind of participant (e.g. SV2SV), can have one relationship (e.g. one2many), that can be realized upon a selection of technologies. This general description allows remaining open for current (and also future) communication technologies.

Disaster Management (Basis Entity #3)

Disaster management is responsible for organizing response activities during a disaster in order to minimize its impact. Disasters are tackled at so-called **operating sites** by disaster management, where official disaster relief forces work—sometimes supported by spontaneous volunteers—to mitigate disaster scales. Typically, disaster response and mitigation are conducted based on a command and control structure of different levels whereas the disaster management is on a strategical level, e.g. in the form of crisis committees. Operating sites are on a tactical or operational level. Since disaster management is usually organized from an official site (e.g., government) and usually not supported by spontaneous volunteers, the disaster management entity in our approach is focused on the description of operating sites. Operating sites are commonly the only physical contact points between spontaneous volunteers and official disaster relief forces. However, a subsequent extension of the model may include the integration of other crisis units and/or on-site emergency personnel in the future.

Following literature and official organization rules, operating sites are mainly characterized by its location resp. area (**geographicArea**), its required tasks and durations, and required resp. available resources. Depending on the scenario, there can be different operating sites, while each operating site can require different **tasks** to be fulfilled for completion (Rauchecker and Schryen, 2018). For example, common tasks in a flooding scenario may be sandbag filling, carrying sandbags, and so on at different locations along a river. However, the tasks that may be required on operating sites can differ and, thus, have to be considered within the scenario. Since our research is focused on the use of spontaneous volunteers as a valuable resource on operating sites, the coordination of operating sites is restricted to tasks that could be supported or executed by spontaneous volunteers. Therefore, we modeled the operating sites consisting of tasks and its locations as well as by defining the required number of volunteers working at a specific task for completing it effectively. Also, we identified the estimated duration of the specific task as an important variable as it influences the number of required volunteers per time unit and further has an effect on volunteers' decision to help if it is known.

Spontaneous Volunteers (Basis Entity #4)

For describing a disaster scenario, it would not be helpful to define each spontaneous volunteer and his/her decisions and behaviors individually. This would lead to a deterministic scenario and would not fulfill the requirements for using the described scenario for the evaluation of coordination systems or performing disaster

exercises. Consequently, spontaneous volunteers are described in the form of populations with probability distributions of relevant variables and entities.

To describe characteristics of individual spontaneous volunteers and their motivation to help during a disaster, the state-of-the-art is extensively discussed in (Lindner, Betke and Sackmann, 2017) providing a solid basis for describing spontaneous volunteers in disaster scenarios. Accordingly, the age, experience, concernment, etc. were exemplarily adopted into the SES as variables to describing the **general** characteristics of the population. A comprehensive list of all relevant variables is given in (Lindner, Betke and Sackmann, 2017). To assign these attributes, the required distributions can either be chosen at will or they can be derived from (demographic) data of the respective location. Since the related literature still is in an early research phase and its behavior impacting attributes have not yet fully been proven, we propose these variables to be extended in future versions. Also, the population size of potential volunteers might differ between different areas, like there are usually massive differences between rural and urban areas. To describe these location-dependent differences in disaster scenarios, we propose **geographic areas** to be an aspect of each population, particularly being an aspect of the general entity. The location-dependent modeling of populations may lead to the representation of many populations within the scenario.

In addition to these general characteristics, the description of spontaneous volunteers should be extended by their communication abilities. As mentioned, when discussing the communication infrastructure, the use of communication devices and, thus, **technologies** vary from person to person. Consequently, the availability of communication technologies is defined as an additional aspect for spontaneous volunteer populations that should be represented in disaster scenarios. For instance, the distribution of smartphone users, users of social media, etc. would be reasonable, if these infrastructures are modeled within the scenario in the communication infrastructures. Therefore, the distribution per each technology used in the scenario must be specified to affect the volunteer's behavior.

We have further identified variables and entities that are related to the **operations** spontaneous volunteers can have. One main characteristic of volunteers is their willingness and ability to perform specific tasks. Since not everybody is able to carry heavy sandbags or to take care of shocked people, this restriction has to be part of any scenario definition. The description of scenario-specific **tasks** has already been discussed in the context of disaster management, thus, to represent these tasks within the volunteer populations, we propose a distribution of all tasks within a scenario. Another behavior-impacting aspect of volunteers is external restrictions like country-specific legal requirements or regulations. Such regulations may limit the working time of spontaneous volunteers to a few hours per day. E.g., German law restricts the working time to 8 hours per day.[1] Also, physical abilities and other commitments may affect the working time. Furthermore, individual working duration preferences, i.e. for how many days a volunteer will help, have to be modeled. Thus, for describing the operation within the SES, we propose the variables "workTimeDistribution", "workDurationDistribution" as well as the aspect "tasks".

MODELING SCENARIO ELEMENTS WITH SYSTEM ENTITY STRUCTURE

The entities, (multi-)aspects, specifications, and variables defined and described in the previous section represent the static dimension of the aspired scenario description. To complete the SES according to the IEEE specification, a dynamic dimension is required, namely the time-dependent progression of simulation scenarios (IEEE, 2011). To describe the dynamics of a disaster scenario, the scenario itself, as well as the variables of the entities, have to be changeable during the scenario. The IEEE proposes time-related events that trigger a change in the parameters at the respective point in time and are accordingly interpreted by the simulation software. Since events can affect all identified SES elements, they are defined as a common characteristic at the top of the SES hierarchy. Depending on the dynamics and level of detail, a simulation scenario can consist of any number of events. We suggest the use of the actual time (time and date) for executing a disaster scenario, since time might also influence the behavior of the spontaneous volunteers (see (Lindner, Betke and Sackmann, 2017)). Consequently, we propose datetime as a variable of the event. Nevertheless, faster processing of the events in the scenarios can be facilitated by the acceleration of simulation experiments. As result, the identified and discussed mandatory elements for describing and executing disaster scenarios with taking spontaneous volunteers into consideration are depicted as an SES in Figure 1.

[1] section 3 German Hours of Work Act (ArbZG)

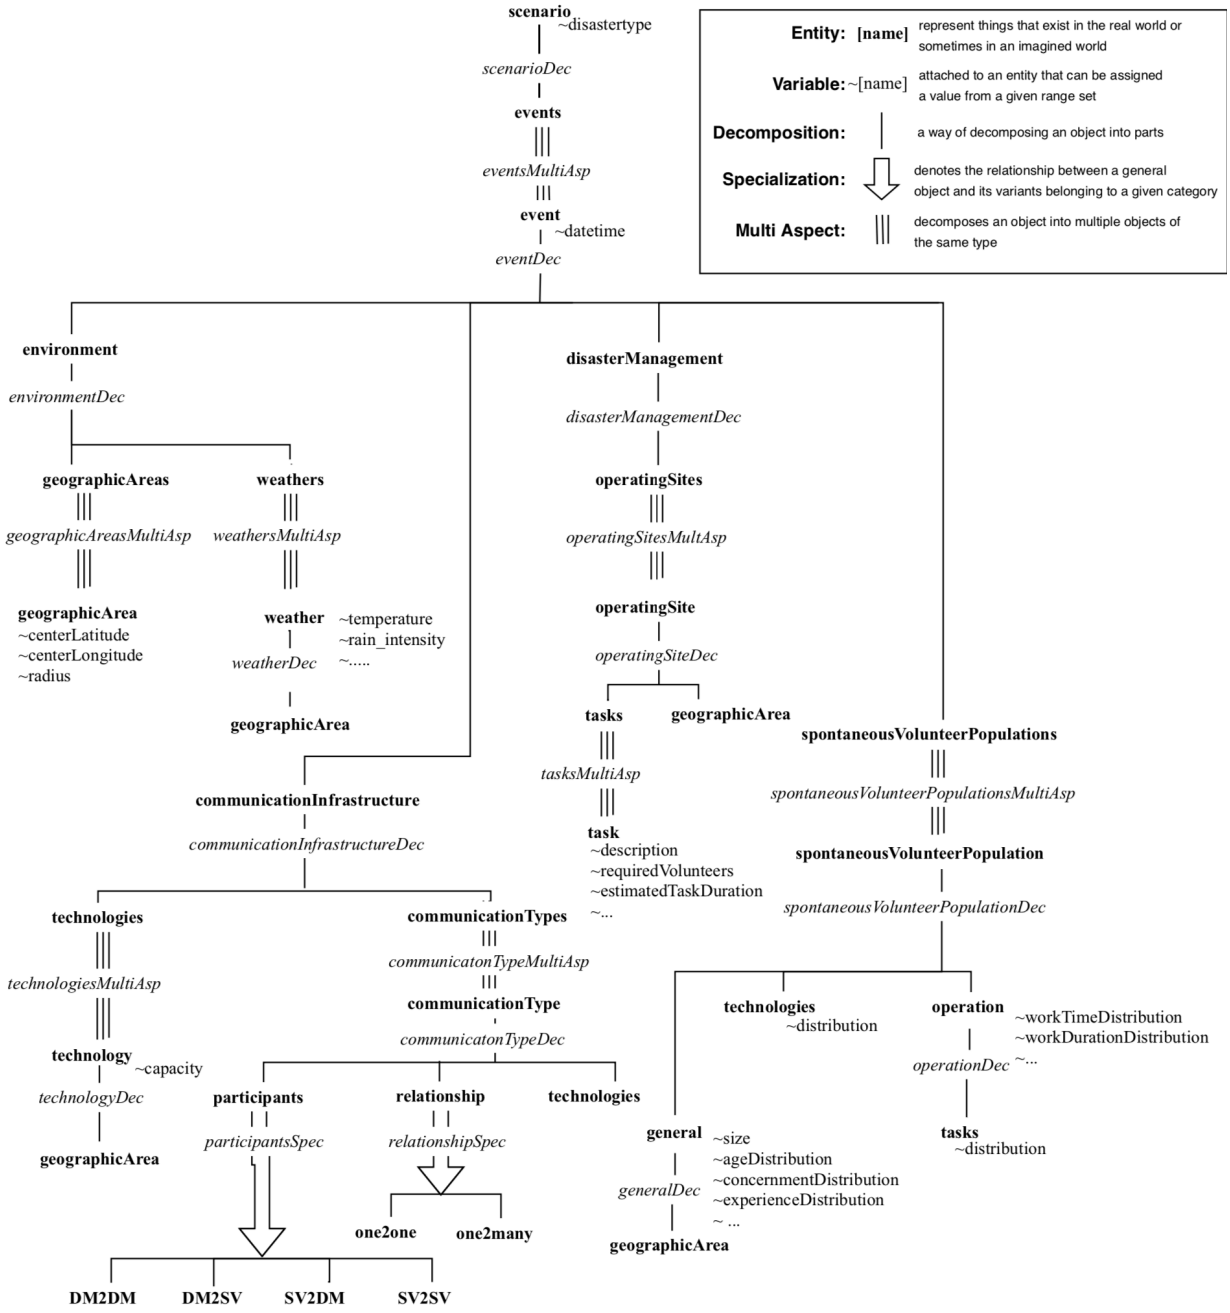

Figure 1. System Entity Structure for Disaster Scenarios

EXEMPLARY PRUNED ENTITY STRUCTURE ON 2013 FLOOD SCENARIO

To demonstrate the applicability of the proposed SES for disaster scenarios, an exemplary and simplified real-world scenario is described. Subsequently, this scenario is transformed into a so-called Pruned Entity Structure (PES) by resolving the elements of the scenario to the aspects, multi-aspects, specializations and by assigning values to the variables resulting in a selection-free tree (Durak *et al*., 2017).

The scenario has been developed in cooperation with the responsible leader of the local disaster management authority and represents an excerpt of the flood that took place in 2013 in Halle (Saale), Saxony-Anhalt, Germany. Firstly, the scenario is described in a textual form (translated from German) and secondly, it is used to derive the PES model. All scenario-relevant elements, i.e. elements that are represented in the SES, are marked bold to better understand the development of the PES.

"The **flooding** in **Halle (Saale),** became worse on the **4th of June**. Due to the impending flooding of downtown, further sand deliveries were transported to the **sandbag filling station** on the **market place** at around **2 pm**. Due to the **midsummer weather**, there were more volunteers on site than the **100 helpers actually needed**, which

challenged our personnel with additional organizational effort. Probably the central location and the proximity to the university played a role in the overcrowding market place but also the dissemination of subjective information by the local citizens via **social media** such as Facebook. In contrast, the crisis management team focused on the dissemination of information via traditional media, such as **radio**. Nevertheless, we were thankful for the numerous volunteers who helped by **filling the sandbags** at the marketplace for **more than 18 hours**."

This scenario is just a very short and basic example for pruning the SES for the disaster type: **flooding** and the datetime: **06/04/13 02:00 pm**. Since the textual scenario description is free in its structure and not complete at all, some variable assignments have to be interpreted resp. assumed. The **city** and the **market place** have been defined as geographical areas according to their center coordinates and an adequate radius. Furthermore, **midsummer-weather** has been assumed for the whole city and resolved in a temperature of 29°C and rain intensity of 0 mm/h.

As available (or relevant) communication technologies, **social media** and **radio** have been defined for the whole city. The technical capacity for both technologies is set to 100% since there haven't been reports of lacking communication availabilities during the disaster event. Since **social media** has only been used by the volunteers among themselves to communicate one-to-many, it has been interpreted as communicationType. Since official disaster management has only used **radio** for informing the volunteers, it has been defined in the same manner.

The **sandbag filling station** on the **market place** has been defined as one operating site with only one task, namely **sandbag filling**. The variables have been set to 100 volunteers needed and 18 hours estimated duration.

To define the population of volunteers, some information were not given in the textual description. E.g., we have assumed one population representing the number of inhabitants of **Halle** in 2013 according to the official statistics. The technology distributions have been chosen in line with official statistics for the percentage of people who daily use radio or social networks in Europe (European Commission, 2017).

Since we have no information on how long and how many days people have worked, we have assumed triangular distributions for workingTime (min: 2 hours, peak: 4 hours, max: 8 hours) and workingDuration (min: 1 day, peak: 3 days, max: 7 days) that seem logical to us.

Furthermore, we have assumed that only half of the population is able or willing to do heavy work. Consequently, the distribution for the task **sandbag filling** has been set to 50%. The resulting PES for the representation of the textual scenario description including all identified and interpreted information is depicted in Figure 2.

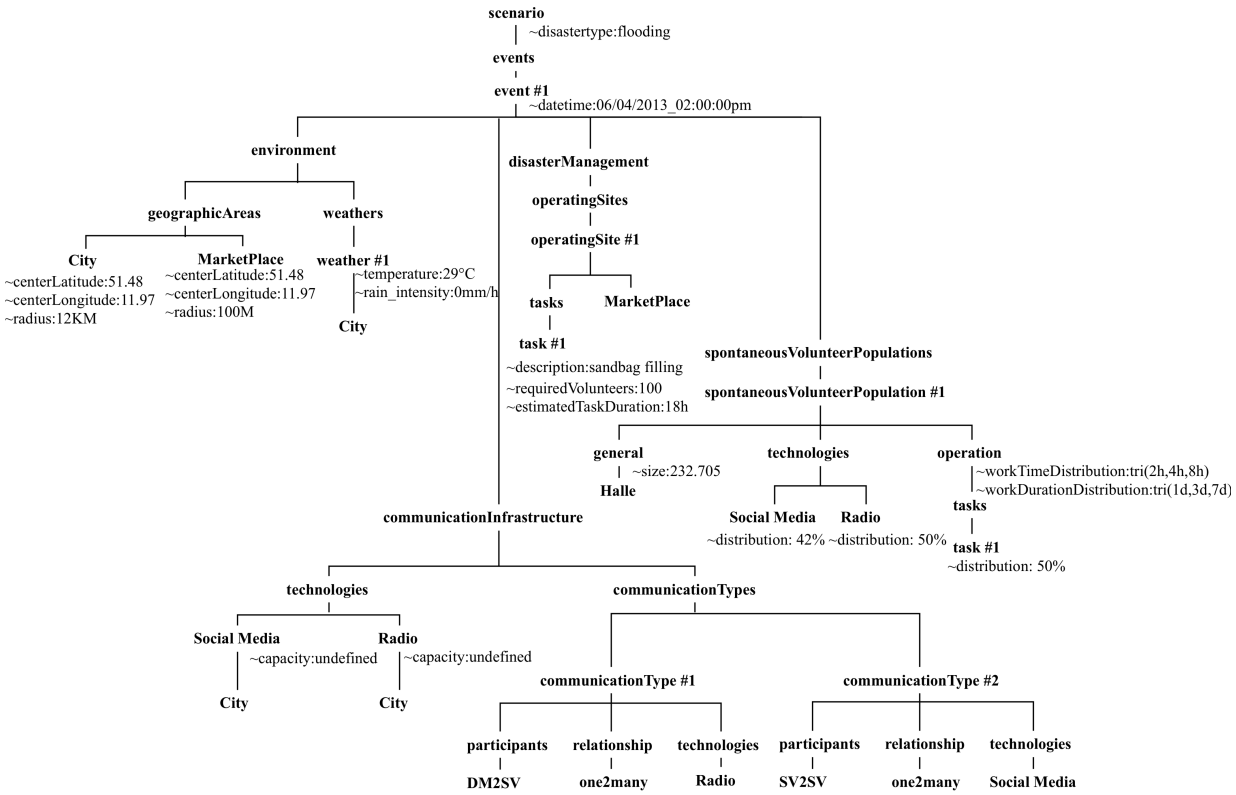

Figure 2. Pruned Entity Structure for Example Scenario

DISCUSSION AND OUTLOOK

The increasing relevance of spontaneous volunteers has led to the development of numerous research approaches aiming at their improved coordination. However, these approaches require on the one hand evaluations to test their added value and, on the other hand, a comparison to choose the approach that matches the requirements of official disaster management to transfer these approaches into practice. Computer simulations, particularly agent-based simulations, seem promising to simulate human behaviors in a disaster context and, thus, to enable evaluations and comparisons of coordination approaches. Nevertheless, agent-based simulations require reproducible disaster scenarios to compare the effects of different coordination approaches. To perform reproducible simulations in the context of spontaneous volunteer coordination, as a first step, scenarios and their related entities have to be analyzed. A second step is to provide these scenario insights as a machine-processable format to be used within the simulation.

The SES model proposed in this paper is a fundamental step for developing a Standard Scenario Definition Language for the coordination of spontaneous volunteers that can be processed within a simulation. In the presented initial version, the focus is restricted to coordination scenarios particularly for simulation experiments and, thus, only contains elements for this purpose. Following an Action Design Research approach (Sein *et al.*, 2011), the SES will be further developed and supplemented in several iteration steps in the future resulting in the SVCSDL. This is necessary, since depending on the purpose, the model may still lack information or higher level of details that may be required by other researchers. Although the SES model contains all basic entities that have been identified in our literature search and interviews addressing the coordination of spontaneous volunteers, an extensive and structured literature review (e.g. following the methodology proposed in (vom Brocke *et al.*, 2009)) is expected to bring further results. Thus, a structured literature review may supplement the proposed model and is part of our future research.

Although the SES was mainly developed for simulations, it might also be valuable for field trials in the spontaneous volunteer coordination context or even as a basis for digital volunteering scenarios as it gives insights and an understanding of what impacts and influences spontaneous volunteer scenarios. Consequently, the proposed SES model contributes to disaster research as it conceptualizes information that relate to scenarios with spontaneous volunteers.

Even though the general goal is to enable the evaluation and comparison of spontaneous volunteer coordination approaches promoted by the scenarios, we have not yet proposed and evaluated adequate measures for evaluating or comparing different coordination approaches. Since this is required for the evaluation of coordination approaches and systems, simulations, exercises, and experiments, it is one focus of our generic research project and an open research topic for the future.

Last but not least, the proposed SES model is the basis to develop an XML-based scenario language that may lead to the implementation and exchangeability of scenarios in simulation software. By defining an extensive standard language based on the SES, research on spontaneous volunteers in disaster situations, as well as the evaluation and comparison of different coordination approaches, will be supported and promoted. Thus, after completing the SES, the next step will be the language definition as a practical research question.

ABSTRACT

After a large incident on a telecommunications network, the operator typically executes an incident analysis to prevent future incidents. Research suggests that these analyses are done ad hoc, without a structured approach. In this paper, we conduct an investigation of a large incident according to the AcciMap method. We find that this method can be applied to telecommunications networks with a few small changes; we find that such a structured approach yields many more actionable recommendations than a more focused approach and we find that both the onset of an incident and the resolution phase merit their own analysis. We also find that such an analysis costs a lot of effort and we propose a more efficient approach to using this method. An unexpected outcome was that AcciMap may also be very useful for analyzing crisis organizations.

Telecommunications, AcciMap, accident analysis, incident analysis

INTRODUCTION

Telecommunications networks are part of vital and critical infrastructure that needs to be in place for society to run smoothly. Unavailability of telecommunications services can lead to unreachability of emergency services, severe traffic jams and impossibility to inform the populace. In order to make telecommunications networks more robust, we have started the LINC project with the Dutch telecom regulator. Purpose is to analyze incidents on these networks in order to learn from those incidents and share those lessons with the practitioners. These lessons may result in better risk management: impact and probability of risks may be better assessed as result of the lessons and the insights gained may result in better mitigation.

Previously, we conducted a literature review of Accident Analysis Models and Methods (Wienen *et al.* 2019). We identified three families of accident analysis methods and we also identified the methods that had seen the most scrutiny from academia. In this paper, we take the most discussed methods in academia and apply them to a real-life telecommunications incident that severely hindered the email and interactive TV services of the provider.

Please note, that in contrast to the practice in other industries, Telecommunications use the term *incident* as opposed to *accident*. In this paper, we follow this practice and hence with "incident" we mean an undesired and unplanned event that results in a loss, damage or injury.

This paper is organized as follows: first, we will share some theoretical background regarding incident analysis methods; then we pose our research questions. We will describe the research design and then the incident itself, after which we will describe the execution of the research. We then report our results, which we will then discuss and finally we will draw some conclusions, while answering our research questions.

Theoretical Background

Accident Analysis Methods can be divided into three families: sequential, epidemiological and systemic. They differ on the extent in which the socio-technical context and control loops and feedback mechanisms are addressed. As mentioned in (Wienen *et al.* 2019), the families can be described as follows. Note that we talk about incidents where in other domains the term "accident" would be used.:

Sequential incident models describe the accident as the end point of a sequence of causes.

Epidemiological models describe the incident as the product of the interaction among a set of entities and actors, some of which may be visible, and others invisible. In effect, it is a sequence of causes that are inhibited or enabled by environmental factors that also have a place in the model. This model is similar to models of how diseases develop, hence the name. A key factor in epidemiological types of analysis is the description of latent factors that contribute to the development of an unsafe act into an incident.

Systemic incident models describe the incident as the result of the interaction within a tightly coupled system and between the system and its context. Feedback loops may play an important role in these models.

We have applied both FTA (Fault Tree Analysis), the most discussed sequential method as measured in our previous research (Wienen *et al.* 2019), and AcciMap, the most discussed epidemiological method as measured in the same research. However, this paper focusses mainly on the application of AcciMap.

Research question

The telecommunications community does not have a standardized incident analysis model and method, making it hard for authorities to compare incidents and to draw lessons from those incidents. One of the goals of the LINC project is to find or create an incident analysis model and method that can be used to draw lessons from those incidents that can then be shared with the telecommunications operators. Furthermore, in reading existing incident reports, the majority of methods used was of a sequential nature – even though no real formal methods were used. This leads us to ask the following research questions:

1. Do epidemiological methods add more value to the incident analysis in Telecommunications services?
2. Is the Generic AcciMap method a viable method for analyzing Telecommunications incidents?

Research Design

In order to compare the two results, we have co-operated with two Western-European Telecommunications operators. The operators have each selected an interesting case and have provided access to sensitive information. They also provided employees who were involved with the incidents to participate in our incident analysis workshops. This article reports the results of one of the two cases: a DDOS attack.

One researcher conducted the workshops, using Branford's approach (Branford *et al.* 2009) to AcciMap, the *Generic AcciMap Approach*. The other created an FTA according to the definition in the Fault Tree Handbook (Vesely *et al.* 1981). As the incident analysis reveals sensitive information about the company involved, the details of the research have to remain confidential. The company will be called Alpha in the remainder of this article.

Short description of the Incident

According to an internal report drawn up by Alpha as part of the post mortem of the incident,

> *A distributed denial of service attack was staged against Alpha's DNS servers, using several different attacks (DNS reflection, UDP flooding, ICMP flooding). This attack caused Alpha's firewalls to collapse. As a consequence, all services behind the firewall were impacted and the customers experienced outage on DNS, mail, internet and telephony (VoIP). The attack took place in 4 waves which eventually were stopped by applying ACLs, bypassing the firewalls for DNS resolution and redirecting traffic [...] to take advantage of the [...] scrubber.*

In other words: due to an overload of requests, Alpha's firewall collapsed. This caused outage of several services for customers. To resolve the incident, the company had to redirect traffic outside their own network and to clean the traffic to their network from malicious requests.

This description implies two stages to the incident: the stage in which the incident develops and causes its harm (the *onset*) and the stage during which Alpha worked hard to resolve the incident (the *resolution*). Both stages have their own characteristics and we decided during the analysis to treat them separately, resulting in individual

AcciMaps for both stages.

EXECUTION

The execution of the analysis took place over several sessions, as indicated in the timeline below:

Table 1: timeline of the analysis

Date	Activity	Parties
16-06-2017	Preparation of 1st DDOS workshop	BCM, UT
06-07-2017	1st DDOS workshop	Alpha, UT
14-07-2017	2nd DDOS workshop	Alpha, UT
15-09-2017	Preparation of 3rd DDOS workshop	BCM, UT
03-11-2017	Formulation of recommendations onset	BCM, UT
17-11-2017	3rd DDOS workshop: Establish AcciMap of response phase	BCM, R&C, UT
24-11-2017	Formulation of recommendations response phase	BCM, UT
08-12-2017	Compare recommendations with earlier analyses	BCM, UT

Note: BCM: Business Continuity Manager – the person who is responsible for enabling the organization to continue business critical activities during the most challenging circumstances; UT: Researchers from University of Twente; R&C: representative from Risk & Compliance – the department responsible for corporate risk management and for follow up on defined risk mitigation plans.

Introduction to AcciMap

AcciMap has been thoroughly described in the literature (Branford *et al.* 2009; Salmon *et al.* 2014; Svedung and Rasmussen 2002; Underwood and Waterson 2013; Underwood and Waterson 2014). As a short introduction, AcciMap is an epidemiological incident analysis method that takes the complete socio-technical system into consideration. Part of the method is a diagram that links all causal factors to their causes, stopping only at causes for which further analysis is not useful given the incident. The Generic AcciMap Method we apply, contains three levels of causal factors: the physical / actor level, in which actions and malfunctioning equipment play a role; the organizational level, in which organizational errors and malfunctions play a role, and an external layer, subdivided into regulatory, government and society. Each causal factor is part of one layer and the causal factors that are part of the physical/actor level and the organizational level are considered in formulating recommendations for the organization suffering from the incident.

Workshops

The workshops consisted of an introduction to AcciMap including an example and subsequently performing steps 1 – 8 of the *Generic AcciMap Method.* (*See* Sidebar 1). We made a slight change to steps 2-4: we had the participants write out the causal factors on sticky notes directly and we discussed the level on which they had to be attached in the group as we put the notes on the overall AcciMap paper. The group identified 64 causal factors, and we did not finish all steps in one workshop. The factors were identified using two methods: first, we let the participants individually formulate causal factors without any other input than the introduction of AcciMap. We then presented the participants with the table with *categories of cause* as listed in Branford's article. These are listed in Sidebar 2. This helped in formulating additional causal factors.

1. (Create a blank AcciMap format on which to arrange the causes)
2. Identify the outcome(s)
3. Identify the causal factors
4. Identify the appropriate AcciMap level for each cause
5. Insert the causes
6. Insert the causal links
7. Fill in the gaps
8. Check the causal logic
9. Formulate Safety Recommendations

Sidebar 1: the 9 steps in the Generic Accimap Method

During the discussions in the first workshop, we observed that the participants not only included the causal factors leading to the incident, but also factors that impacted the resolution of the incident. We decided to make two groups of causal factors and two different AcciMaps: one for the onset of the accident and one for the resolution or response phase. We then concentrated on the onset of the accident and the completion of steps 5-8.

The onset of the accident

During the first workshops we were able to identify some of the causal links. These were recorded and modelled in a preliminary AcciMap which we completed in the second workshop. We then decided to review the final AcciMap for the onset in a smaller committee (the researchers and the representative of the company for Business Continuity). In that meeting, we also formulated the safety recommendations.

The resolution of the accident

As the workshops take quite some effort, we decided to do steps 2-9 for the response phase in a smaller committee: the two researchers and two representatives of the company: one from Risk & Compliance, and one from Business Continuity. This resulted in a second set of recommendations.

1. Financial, such as (s/a) cost cutting
2. Equipment and Design, s/a poor quality equipment
3. Defences, s/a missing alarms
4. Communication and Information, s/a inadequate knowledge
5. Auditing and Rule Enforcement, s/a missing internal auditing
6. Organizational Culture, s/a incompatible goals
7. Risk Management, s/a inadequate security
8. Manuals and Procedures, s/a missing manuals
9. Human Resources, s/a insufficient staff
10. Training, s/a inadequate exercises

Sidebar 2: Branford's Categories of Cause

Formulating the safety recommendations

We formulated safety recommendations in a manner analogous to Branford, with a few changes:

- We formulated safety recommendations per causal factor. This way, we had a structured approach to go through the different causal factors, and we made sure that we covered all three types of recommendation per causal factor.
- Branford has a heuristic to formulate recommendations: she uses the terms *Change, Control* and *Compensate* to describe different types of recommendations. *Change* means what can be rectified directly, *Control* means what can you do to control the outcome of an incident and *Compensate* means what can you do to compensate for the consequences. This heuristic we reused, but as our audience had trouble applying those terms, we chose to use the terms *Prevent, Mitigate* and *Compensate*. These terms had the same meaning in our applications, but they were more easily understood by our audience

RESULT

Table 2: Identified causal factors and recommendations per stage and AcciMap level

Stage	Number of Causal Factors			Number of Recommendations		
	External	Organizational	Physical /Actor	External	Organizational	Physical/Actor
Onset	11	17	4	0	54	6
Resolution	4	16	12	0	50	26

From previous research (Bukhsh *et al*. 2019) we found that Telecommunications operators do not use structured methods. Their analysis mostly concentrates on the physical parts of an incident, and the activities of the different actors in the incident. Applying AcciMap clearly adds more levels to the picture, as can be seen from Table 2. This was also the feedback we got from the professionals in company Alpha.

After analyzing all causal factors, we noticed that both the onset of the incident (the causal chain leading up to the incident) and the resolution of the incident (the causal chain leading up to the resolution of the incident, or back to "business as usual") were of interest to Alpha. This makes sense: from a prevention perspective, the chain of events leading to the accident is relevant to prevent a similar incident from occurring again, or at least to make the socio-technical system more robust against future attacks (as this was an incident caused by an attack, and attacks will happen). But given the fact that attacks will happen, and Telecommunications operators are always vulnerable to attacks, while hackers are resourceful, an operator will always have to plan for situations in which they could not prevent a successful attack. This means that resolution of the incident is paramount in that case: the quicker the operator is back in business, the lower the damage in terms of costs, lost revenue and damage to corporate image.

Table 3: Identified recommendations per Category of Cause and AcciMap level

Stage	Category of Cause	Organizational	Physical/Actor
Onset	Risk Management	17	
	Finance	7	
	Equipment & Design	12	6
	Defenses	5	
	Communication & Information	3	
	Auditing & Rules Enforcement	10	
Resolution	Information Sharing	6	
	Technical issues extending crisis period		6
	Crisis Management	17	4
	Staff	8	
	Training	2	
	Company Culture	5	
	Crisis Facilities & Tools	12	16

For the onset, we have grouped the recommendations according to the different categories of cause as discussed by Branford. When analyzing the recommendations for the resolution phase, these categories did not add to the understanding and we grouped the recommendations differently, as indicated in Table 3. This is not entirely unexpected: the onset can be covered by generic strategic, tactical and operational processes. All recommendations are meant to improve those processes or – if missing – define and implement them. The processes around the resolution phase are more crisis oriented: the resolution stage is one of crisis management: getting business back to normal as soon as possible in a situation in which not all information is available and the cause of the crisis is still there. In this phase, more recommendations have been formulated on the physical and actors level. This can be understood as follows: crisis facilities can be planned and prepared beforehand, but actions during the crisis (usually a situation with at least some characteristics that cannot be predicted) require a certain amount of improvisation – a feature of the actor layer.

Table 4: Comparing recommendations between investigations

Category of Cause	AcciMap	Alpha's investigation	Accountancy Firm
Risk Management	17	0	0
Finance	7	4	0
Equipment & Design	18	6	0
Defenses	5	0	0
Communication & Information	3	0	1
Auditing & Rules Enforcement	10	0	0
Information Sharing	6	0	1
Technical issues extending crisis period	6	0	1
Crisis Management	21	6	10
Staff	8	0	0
Training	2	0	2
Company Culture	5	0	0
Crisis Facilities & Tools	28	4	0
Total	136	20	15

Feedback from telecommunications operator

After applying the method to the incident, Alpha found that

- AcciMap really helps to get more insights in the context of an incident
- AcciMap is a structured method to find recommendations for the organization as a whole
- It is very time consuming
- It is not appropriate for the resolution of the incident itself, only as post mortem after the incident has been resolved
- Alpha intends to use this method in the future for the post mortem of larger incidents. We are currently preparing a second case study with Alpha, using a less-time-consuming version of AcciMap.

DISCUSSION AND CONCLUSION

Answers to the research questions

Do epidemiological methods add more value to the incident analysis in Telecommunications services?

According to Alpha, AcciMap adds more value than the ad hoc, sequential methods they used before. This is also reflected by the number of actionable recommendations when compared to the method employed by Alpha (136 vs 20). The number of recommendations from the accountancy firm is less relevant as a comparison number, as their recommendations were based on comparing Alpha's crisis organization to the firm's ideal model of a crisis organization.

Is the Generic AcciMap method a viable method for analyzing Telecommunications incidents?

According to Alpha, the method is viable for large incidents, given the investment in time and effort. For quick resolution, an epidemiological method is less apt: during the resolution phase, time is of the essence and a sequential method is more appropriate. This is also confirmed by our experience in applying FTA as part of this analysis – which took far less time. As far as we could determine from discussions with Alpha's staff, this is also in accordance with their mental model for quick incident resolution.

Other findings supporting AcciMap as a method for incident analysis in Telecommunications

The case study yielded more results than just the answers to our research question.

Difference between onset and resolution

During the analysis of the incident, we found that the experts in Alpha listed causal factors that lead to the incident as well as causal factors that prolonged the incident. To keep things manageable, we decided to create two different AcciMaps (onset and resolution) in order to give some structure to the discussion. This proved helpful and as a result, we have been able to also generate recommendations for crisis management (the brunt of the resolution phase in this case).

For Alpha, the resolution phase was as interesting as the onset to the accident. Although Alpha is keen on preventing the next incident, they do realize that incidents will happen and that quick resolution is also important.

Applicability to crisis organizations

The resolution phase is of further interest, as it is actually applying AcciMap not to an incident, but to a crisis organization: how did Alpha respond to the crisis and what lessons can be learned from that? Of the 76 recommendations for the resolution phase, at least 49 where directly related to crisis management and crisis facilities. This means that AcciMap may also be a very interesting method to analyze crisis resolution and by its extension, crisis organizations.

Difference between strict focused investigation and broad investigation

The large difference in recommendations from the AcciMap method and from the two other investigations can partially be explained by the stricter focus of the latter: both Alpha's investigation and the accountancy firm's restricted themselves (consciously or unconsciously) to only a part of the problem: Alpha's to the technical and security aspects of the incident, the accountancy firm's to the crisis management aspects. This may be an added benefit of AcciMap or indeed of any epidemiological method: it forces you to look at the incident from all angles, yielding recommendations in areas where you would beforehand not expect them, simply because you

did not consider them.

Other findings suggesting opportunities for improvement of AcciMap when applied to incident analysis in Telecommunications

Large number of actionable recommendations due to structured approach of formulating recommendations

The structured approach of formulating recommendations lead to a large number of actionable recommendations: as each causal factor was considered individually, each factor could give rise to a large number of recommendations. In our case, the average number of recommendation per causal factor in the organizational and physical/actor level was 2.5 for the resolution phase and even 2.9 for the onset. Such a large number of recommendations calls for central co-ordination of follow up and prioritization of the recommendations. We did not go into the way how to prioritize them, although several methods spring to mind (based on cost / benefit, or risk based for example).

Time consumption

As can be seen from the timetable in Table 1, the method is time consuming. It took three workshops with multiple staff, which is costly. This means that the method – in this version – is only feasible when dealing with incidents that have a severe impact on the business. This also signals an opportunity for improvement: if this effort can be reduced, the method will be easier to apply and the cost-benefit relation will improve.

Furthermore, much discussion centered around the assignment of blame: it was hard to keep the discussion away from the blame game. This may be an aspect of the organization itself, but we think we may be able to avoid these discussions by first concentrating on the physical layer of the incident – something that can be done relatively neutral and factual. After the core mechanism of the incident has been established, this small success may set a better atmosphere for the organizational discussions.

Alpha's Business Continuity Manager suggested to have a short video message from the CEO before starting an incident analysis to emphasize that the analysis should uncover *all* sources of failure with the express purpose of preventing future incidents, while also admitting that not all measures may be implemented for reasons of time or due to monetary constraints.

Lack of IT systems in the levels for AcciMap

We noticed that the AcciMap when applied to telecommunications may benefit from adding a sublevel to the physical/actor and the organizational level: Systems and Software are as important as actors and organizational aspects. We did not consider this division in this analysis, but it may be beneficial to do so in further research.

Changes to AcciMap

Changes to the model

In order to give software or digital issues a more prominent place in the AcciMap (which we feel is necessary to adequately describe phenomena in technical environments), we propose the following:

- Describe the external and the organizational layer each from the point of view of three aspects: social, physical and digital.
- Describe the outcomes in terms of operational and technical aspects
- Describe the organization in terms of its components (organizational units) and the causal factors as relating to an aspect of those components (financial, communication, information flow, et cetera).

Changes to the method

For efficiency reasons, and to get everyone on board and avoid spending too much time on avoiding blame assignment, we propose a new approach for the method. Note that it may be hard to impossible to convince the experts that non-events do not exist, or to prevent non-events from cropping up. This is why we added step 2 in the approach below. These are the proposed steps:

1. Establish the physical core mechanism of the accident including the causal flow.

2. Find mitigations. This may be in terms of failure or absence of barriers, norms and entities.
3. Find how the mitigations would have influenced the causal flow and model this.
4. Use a heuristic to find recommendations (we follow Branford in her approach to look at three aspects: prevention of an event, controlling an event and compensating for the outcome of an event).
5. Prioritize the recommendations –many methods have been described in the literature.

Future Work

We are currently applying the adapted method in a case study with another telecom operator, and will use it also in a second case study at Alpha. These studies will test the changes to model and method we propose and supply more evidence to test the claim of usefulness. Enhancing efficiency and applicability to telecommunications will in our opinion greatly improve the value of this method to operators. Greater value may lead to widespread use, giving more opportunity to learn from these incidents.

ABSTRACT

Available medical resources are the basis of efficient disaster medical relief. The medical resources assignment for disaster medical relief forces is usually fixed. However, the injury condition distribution changes in different disaster and so does the demand for the medical resources. So the assignment of medical relief forces should be more flexible and based on the injury. We analyzed the component parts and rules of disaster medical relief, defining the related concepts and rules. Then, we constructed the describing rules of injury-treatment-medical-technique-resource-assignment process. Based on these, we established the ontology of disaster medical relief system and the injury-driven medical resources assignment ontology model (MRAOM). We used the model to describe the medical relief situation after earthquake to demonstrate the model could describe complicated situations. We also used the model to describe and forecast the medical resource assignment of treating batch wounded to demonstrate the model's validity.

Keywords

Medical Resources Assignment, Disaster Medical Relief, Injury-Driven Ontology Model.

INTRODUCTION

Sudden-onset disasters could cause mass casualty incidents in short time, creating a surge in demand for emergent medical service (Reinhardt et al., 2011). Studies have shown that approximately 90% of the injuries are reported and rose in the first 7-14 days after disaster, so the disaster medical relief in the first 3 weeks are

crucial.(Zhang et al.,2012; Zhang et al.,2011; Akbari et al.,2004)

Generally, the disaster medical relief system is divided into 3 levels.(Miao and Nie,2004; Lu,2008) 1st level provides first aid which uses rapid effective methods to save life on the spot, such as basic life saving, hemostasis and wounds binding techniques. 2nd level provides advanced life saving methods which include lifesaving surgeries, severe shock correcting and other techniques aiming to decrease mortality and disability. 3rd level provides all kinds of medical services which are necessary to cure injuries and patients. 1st level is consisted of all kinds of medical rescue teams that could get to the spot as soon as possible. 2nd level is consisted of normal-function municipal hospitals nearby. 3rd level includes comprehensive healthcare organizations most of which are facilities of Department of Health Care. Studies have shown that the mortality of injuries within 1st level is the highest, while the 2nd level takes the second place. (Jiang et al.,2012) A large percentage of injury deaths occur on the field before evacuation to 2nd level medical facilities. (Cranmer,2005) This indicates that great emphasis should be placed on the 1st and 2nd level during a disaster medical relief.

Most medical institutions in the disaster area could be damaged, so the 1st level and part of 2nd level medical institutions are consisted of strengthen medical forces from the non-disaster areas, inside or outside the country, civilian or military. (Auerbach et al.,2010) Strengthen medical forces should meet the medical demand in the disaster area. The efficiency of first aid is crucial, and the basis of the efficiency is the availability of the right medical resources. Most strengthen medical forces' resources assignment is fixed. But the real needs of the resources could change according to the different injury condition distribution in the different disaster scene. So sometimes the availability of some medical resources would be low and affect the medical rescue efficiency.

This research aims to describe and forecast the medical resources assignments based on different medical relief forces and different injury condition distributions. However, emergency medical rescue is complicated, and the composition of medical forces are diversified. We choose ontology method to construct the injury-driven model to express the complicated medical rescue knowledge and help multiple-source strengthen medical forces to understand the model. Thus, organizers of disaster medical relief could have an increased awareness of the overall disaster medical rescue environment, allowing them to make better decisions more rapidly.

This article divided the process of medical resources assignment modeling into four parts: 1.The description and definition of component parts of the medical relief; 2. The definition of rule of disaster medical relief and injury medical treatment; 3. The description and definition of injury treatment profiles and medical resource assignment rules; 4. Constructing ontology model of medical relief entities and domain rules. Finally, we gave two examples to demonstrate the usage of the model.

ANALYSIS OF THE MEDICAL RESOURCES ASSIGNMENTS FOR DISASTER RELIEF

Generally, medical resources assignment is part of emergent readiness plan. The description of the emergent readiness plan needs to choose and reconstruct emergent domain knowledge. (Mendonca and Wallace,2007) As for the description of medical resources assignment, both medical and emergent domain knowledge should be chosen and reconstructed. Emergent readiness plan knowledge modeling is a interdisciplinary project and tremendous progress has been made about this modeling. Some researches proposed to construct the relationships between mission and executive condition based on an incident-mission framework. (Mors et al.,2005) Some described the structure and dynamics of the emergent organizations based on the extended sequence locus language. (Hoogendoorn et al.,2005) But most methods of illustrating the emergent readiness plan could not solve the problem of knowledge sharing.

Ontology is a knowledge description method that is easy to conceptualizing, sharing and illustrating.(Grigoris and Frank,2008) This method could clearly and accurately describe the domain concepts and their relationships. It could also describe the complex domain knowledge and its feature. So ontology could be an effective method to construct the medical resources assignment modeling.

The basic idea of describing and forecasting the medical resources assignment using an ontology model is as follow: 1. Different level of care has different treatment goals and contain different medical facilities with different medical treatment units. 2. When different injuries got to different medical facilities and went through different medical treatment units, they would accept different medical techniques to improve their condition. 3. The basis of different medical techniques is different medical resources. So the determination of medical resources assignment is based on both injury conditions and the function of medical facility.

The Component parts of the Disaster Medical Relief

Generally, most of the medical institutions in the badly damaged areas within the disaster zone are damaged. However, most injuries would occur in these areas and need medical treatments urgently. Most strengthen

medical relief force would arrive in these areas and strengthen the local medical facilities. These strengthen forces belong to 1st level or 2nd level medical care aiming to lifesaving and reducing disability. The forms of these forces are rescue teams with highly mobility or field hospitals with the placement of resuscitative surgery units as close to the first responder as possible.

According to systematical point of view, we could consider the whole level of care or one medical facility as one system. Then we could divide the system into small medical treatment units according to the medical function. Every medical function units are related to different medical techniques. Different rescue team or field hospitals could choose the placement of different medical function units with diversified medical techniques based on the goal of mission as well as the possible injury condition distribution. Carrying out different medical techniques would need different medical resources. So in different mission scenes, the same rescue team or field hospitals could have different multiple medical function units with different medical resources assignment.

Definition 1 Define the whole set of medical function units as: $B=\{b_1,b_2,\ldots,b_n\}$.

Definition 2 Define certain rescue team's or field hospital's set of medical function units as: $B_i=\{\quad\}$.

The medical function unit b_i could not be divided or it couldn't execute any medical treatment. For example, Pre-operation unit could not be divided or it couldn't finish the works before an operation.

Meanwhile, B_i is the subset of B which means $B_1,B_2,\ldots,B_n$ should satisfy the condition： B=B

Particularly, every B_i is not definitely mutual independent, which means there could be intersections between B_is. That means B1,B2,…,Bn don't have to satisfy the condition $B_i \cap_{i\neq j} B_j = \emptyset$.

Definition 3 Define the whole coverage of the medical function of the units as:

Then the coverage of the medical function of the international medical relief force, including rescue team or field hospital, is: π'

The brief structure of the international medical relief force is showed in figure 1.

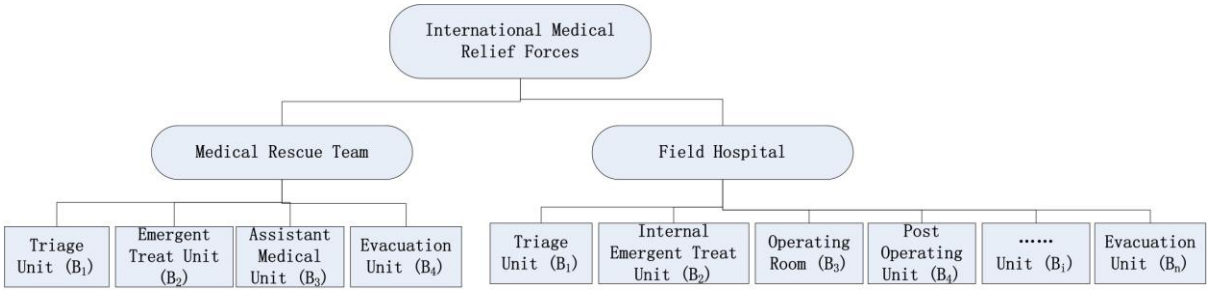

Figure 1. Brief Structure of the International Disaster Medical Relief Forces

Different function medical unit could carry out different medical techniques. Part of the relationship of function unit, medical techniques and medical resources types are showed in table 1. The medical resources which are used for the same medical techniques are combined together and signed with a specific number.

Table 1. Part of the relationship of function unit, medical techniques and medical resources types

Function Unit	Medical Technique Description	Medical Resources	Resource No.
Triage	Measure Vital Signs	Sphygmomanometer; Stethoscope	1
	Assessment &Evaluation of Patient Status	Otoscope & Opthalmaloscope	2
	Bowel Sounds Assessment	Stethoscope	3
	Circulation Check	Stethoscope	3
	Blood Gas Estimate	Analyzer Clinical Chemistry	4
	Determine Electrolyte Levels	Analyzer Clinical Chemistry	4
	.....	.....	...

Emergent Treat	Emergency Control of Hemorrhage	Bandage (Elastic or Gauze); Dressing First Aid Water-Gel; Sponge Surgical Guaze; Tape Adhesice Surgical Woven	11
	Establish Adequate Airway	Airway Nasopharyngeal / Pharyngeal	12
	Start Intravenous Infusion Site	Catheter & Needle Unit; Infusor Pressure Blood Intravenous; Intravenous inj Set; Alcohol Impregnated Cotton	13
	Insert Oro/Naso Gastric Tube	Lubricant Surgical Tube; lidocaine Hydrochloride Jelly Tube; Tube Stomach Surgical Plastic Lumen	14
	Cardiac Resuscitation	Defibrillator Monitor-Recorder; Heparin Sodium injection; Injector Tube plas Medication Needle Cart; Defibrillator Auto External	15
	Catheterization-Suprapubic	Catheterization Kit Urethral Bot-outlet Drain Bag; Lidocaine Hydrochloride Jelly Tube; Lubricant Surgical Tube	16
	.....	.....	...
Op-Room	Operation Preparation	Bag Sterilization Biohazard Disp; Detergent Enzymatic Cleaner Instrument Surgical Tube; Disinfectant Surgical Instrument Cidex	31
	Patient Preparation	Razor Surgical Preparation Disposable Plastic; Skin Preparation Kit Pre-Operative Sterile	32
	Induce/Maintain General Anesthesia	General Anesthesia Equipment Set	33
	Emergent Surgeries (hemostasis surgery, skull drilling drainage, gastric excision repair anastomosis, resection of spleen or kidney, ...)	Clamp Artery; Forceps Hemostatic; Forceps Intestinal; Forceps Tissue; Handle Surg Knife; Holder Suture Needle; Knife Sternum; Bone Surgery Corrosion Resisting; Retractor Abdominal; Retractor General Operating; Retractor Rib; Retractor Vein; Scissors General Operating Surgical; Cannula Brain Frazier	34-40
	Clean & Prepare Surgical Instrument Sets	Wash Basin; Cleaner & Lubricant Surgical Instrument Can; Detergent Enzymatic Cleaner Tube; Disinfectant Surgical Instrument Cidex; Surgical Towel Pack	41
	Assess Electrolyte Levels	Analyzer Clinical Chemistry	4
.....	.....	.....	.....

Definition 4 Define all the medical techniques as: $T=\{t_1,t_2,\ldots,t_n\}$. Then the medical techniques within a certain medical function in a certain medical facility of a certain level of care is: $Ti=\{L,F,U\backslash t_1,t_2,\ldots,t_k,\ t_k \in T\}$. L represent level of care, F represent medical facility, U represent medical function unit.

Medical resources are the basis of carrying out the medical techniques.

Definition 5 Define all the medical resources as: $R=\{r_1,r_2,\ldots,r_n\}$. Then a certain medical technique ti related medical resources are: $Ri=\{r'_1,r'_2,\ldots r'_n\}$ and $Ri \subset R$

Medical resources are mainly the equipments, instruments, medicine and medical staff. According whether to the resource could be reused or not, medical resources could divided into consumable resources and non-consumable resources.

Rules of Disaster Medical Relief

From the analysis of the component parts of the medical relief, the relationship of medical resources and medical demands are reflected by the treatment of the injuries going through the medical facilities in the different level of care. So the rules of disaster medical relief is the main ground of the medical resource

assignment. When every different injury goes through the medical facility, the injury condition gets better and certain medical resources are consumed. So generally, the rules of disaster medical relief are established in the form of "if…then". This means the injury treatment profiles are based on the injury condition. Its formalized definition is as follow：

Rule 1 Injury Treatment MITDomainRules=（InjuryCondition, TreatmentGoal）

This represent that when the injury satisfies the logical condition expression InjuryCondition, the TreatmentGoal should be achieved.

This rule expresses the relationship between injury condition and the treatment goal that the medical facility should achieve. TreatmentGoal is the most urgent medical treatment goal the medical facility should achieve based on the injury condition. It includes the chosen of care level, medical facility and medical function units in order to achieve the treatment goal. For example, for a batch of burned injuries, the treatment goal is to relieve or control the injury hazards and sustain life. Then we should choose the nearest rescue team belonging to the 1st level of care and carry out basic and advanced life supporting medical techniques.

Injury Treatment Profiles And Medical-Technique-Resource Relation Rule

The core rule of medical resources assignment is how the medical technique in the medical function units related to medical resource based on the injury condition. This part of rules include injury treatment profiles and medical-technique-resource-assignment relationship rules.

Injury Treatment Profiles

Injury treatment profile is a treatment process describing series of medical treatments which are accepted by certain injuries when they go through certain medical facility. According to different injury conditions, the profile set is consisted by different treatment process subsets. Its formalized definition is as follow.

Rule 2 Injury treatment profiles within the medical facility UstandardProfile=（goal, {treatmentProcess$_1$,…, treatmentProcess$_n$}）

Goal stands for the treatment goal which this medical facility should complete to relieve the injury hazards or improve certain physiological function. TreatmentProcess$_i$(1 n) stands for the treatment process that the medical facility should take to complete the treatment goal.

Treatment goal is a status that the injury should get after going through the medical facility. It is the basic line of injury medical treatment and its formalized definition is as follow.

Rule 3 goal=(name, params, input, output, interval)

Name stands for the medical facility's name. Params stands for the parameter description of the treatment goal. Input and output stand for the injury condition before and after going through the medical facility. Interval=[startTime, endTime] stands for the time interval that the injury goes through the medical facility which is also the interval time between the start and end point of injury treatment.

Treatment process describes a certain treatment pathway within the medical facility when the injury condition satisfy certain condition. It is constituted by a series of medical techniques with complex time relationship. Its formalized definition is as follow.

Rule 4 TreatmentProcess$_i$=(precondition$_i$, medicaltechniqueflow$_i$, timeConstraints$_i$, anotation$_i$)

Precondition$_i$ stands for the precondition of injury when accepting the treatment process. Medicaltechniqueflow$_i$ indicates series of medical techniques which are used in the treatment process. TimeConstraints$_i$ presents the time constraint set of using the medical techniques and the key point of the treatment process. Anotation$_i$ stands for other information we should take notice when using the treatment process.

The logical relationship of treatment process and its time constraint：

1. Logical relationship of treatment process.

We use flow model based on PetriNet to describe the medical techniques and the precondition of carrying them out. The process is constituted by series of medical technique and the routing structure between them. Medical technique is the basic element of the treatment process. The routing structure between them could be described

by 4 logical relationships, including sequent, parallel, choose and circulate control. This routing structure could describe the logical relationship and executing order of the medical techniques. Any treatment process could be described through reasonable organizing of the medical techniques and the four basic routing structure.

Taking the treatment process of the injury whose spine might be hurt as an example to show the modeling of treatment process. As figure 2 shows, the treatment goal is to evacuate the injury without hurting his/her spine's function. So the medical facility should determine whether or not use spinal arthodesis before evacuation. If the injury type is penetrating trauma, locating in head & neck or limbs (pre 1), then we should check the injury's neurologic function. If neurological disorder exists, which is pre1-1(t3), then we should use spinal arthodesis before evacuation (t7). If neurological disorder doesn't exist (pre1-2(t4)), then the injury could be evacuated immediately. If the injury type is blunt trauma (pre2), then we should check and evacuate the injury's consciousness. If the consciousness change get GCS<15 (pre2-1(t5)), then we should use spinal arthodesis before evacuation (t8). If the injury consciousness change get GCS≥15 (pre2-2(t6)), then we should check and evacuate whether or not the spine exists pain or softness, the neurological function has obstacles and the anatomical structure of the spine changes. If any of this three conditions exists (pre2-2-1(t9)), then we should use spinal arthodesis before evacuation (t11). If none of these conditions exists (pre2-2-2(t10)), then we should consider whether or not there exists the injury mechanism of the spine. If the injury mechanism doesn't possibly exist (pre2-2-2-1(t12)), then we could evacuate the injury without spinal arthodesis. If the injury mechanism possibly exists (pre2-2-2-2(t13)), then we should determine following conditions exist or not: 1) evidence shows that the injury take alcohol or drug; 2) other traumas; 3) couldn't normally exchange. If none of these conditions exists (pre2-2-2-2-1(t14)), then we could evacuate the injury without spinal arthodesis. If any of these conditions exists (pre2-2-2-2-2(t15)), then we should use spinal arthodesis before evacuation.

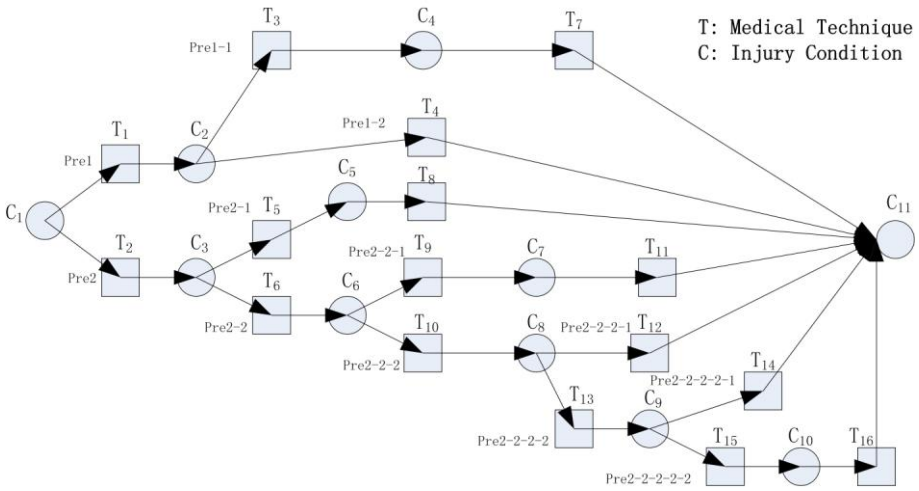

Figure 2. Brief Treatment Process Logical Relationship of The Injury With Possible Spine Wounds

2. Time Constraint

The timeliness of disaster medical relief is crucial. Injuries especially critical injuries should be treated within limited time. So there is a complex time synchronization relationship between using the medical techniques.

The time constraint include two types, one is qualitative constraint and the other is quantitative constraint. Because of the complexity of injury condition and medical treatment, even carrying out the same medical technique could hardly determine the definite time information. So we could use the qualitative constraint to describe the abstract time condition of using some medical techniques. Generally, we could describe the qualitative constraint of completing certain medical technique using "equal, before, meet, overlap, start, during, after and finish by".

Other medical techniques with definite operating time, we could use quantitative constraint to describe the start and finish time of the techniques. The formalized definition of quantitative constraint could be described as follow:

Rule 5 timeConstraint = (a≤preTimepoint-postTimepoint ≤b)

PreTimepoint and postTimepoint indicate the start time, finish time and injury treatment process reference time point.

Thus the treatment process time constraint could refer to the constraint of medical techniques.

Medical-Technique-Resource Relation Rule

When describing the rule of medical-technique-resource relationship, two points should be strengthened. One is that using a specific medical technique should be based on the medical resources within the medical facility. The other is that the use of a specific medical technique is trigged by the injury condition and should satisfy the time constraint.

We use the PDDL2.1 language based on the artificial intelligence planning to give the formalized definition of the rule as follows.

Rule 6 (Medical Technique) MTechnique= (name, params, precondition, resources, agent, effects , interval, place)

Name stands for the name of medical technique. Params represent the parameters of description. Precondition indicate the specific injury condition. Resources stands for the medical resources which are needed in carrying out the medical techniques. Agent represent the medical relief facility that implement the medical techniques. Effects indicate the treatment effects after using the medical techniques. Interval stands for the time interval that needed for medical technique implementing. Place represent the location.

Rule 7 (Medical Resources)Resources=consumResources ∪nonexpendResources

ConsumResources={cr } represent the set of consumable medical resources. nonexpendResources={nr } represent the set of nonexpendable medical resources. If and only if the medical facility has adequate medical resources, medical techniques could be carried out and could do the deed. Effects={me } stands for the medical effects.

Rule 8 (Consumable medical resources) cr=(logicalExpression, t, n)

This represent the consumable medical resources should satisfy the logical Expression after the medical technique has started t time and the amount should be n.

Rule 9 (Nonexpendable medical resources) nr=(logicalExpression, interval, n)

This represent the nonexpendable medical should satisfy the logical Expression. And during the interval time (interval=(minTime, maxTime)) of medical technique usage, the number of occupied nonexpendable medical resources is n.

Rule 10 (Treatment Effect) tre=<logicalAtom, flag, time>.

This indicate the improvement of the injury condition after t time since the applying of the medical technique. If the improvement is clear, then the sign of treatment effect is flag=true and the logical Atom is added to the injury condition. If not, the logical atom is deleted from the injury condition.

MODELLING OF THE INJURY-DRIVEN ONTOLOGY MODEL

Based on the systematic analysis, we established the medical resource assignment ontology model (MRAOM) by reusing and expanding ABC、OWL-S、SWRL ontology vocabulary & expression. The modeling include knowledge modeling of disaster medical relief system, medical relief domain rules, injury treatment profiles and medical resources assignment rules. The brief structure of MRAOM concepts and relationships is showed in figure 3. The block indicates class, the solid arrow indicates property and the dotted arrow indicates subclass.

Disaster medical relief system ontology modeling

The aim of the modeling is to describe the entity of disaster medical relief system and their relationship, as well as the characteristics of the dynamic changes of the entity during the medical relief process. We promote concepts and relationships of medical relief mission, environment elements, medical demands (injury condition distribution), entity structure, and medical resource based on the ABC ontology model.

Ontology of medical relief mission and medical demand

1. Ontology of medical relief mission

The classification of the mission ontology is according to the different types of the disaster. Different disaster correspond to different medical relief mission ontology. MRAOM uses methods to establish mission ontology as follows.
