
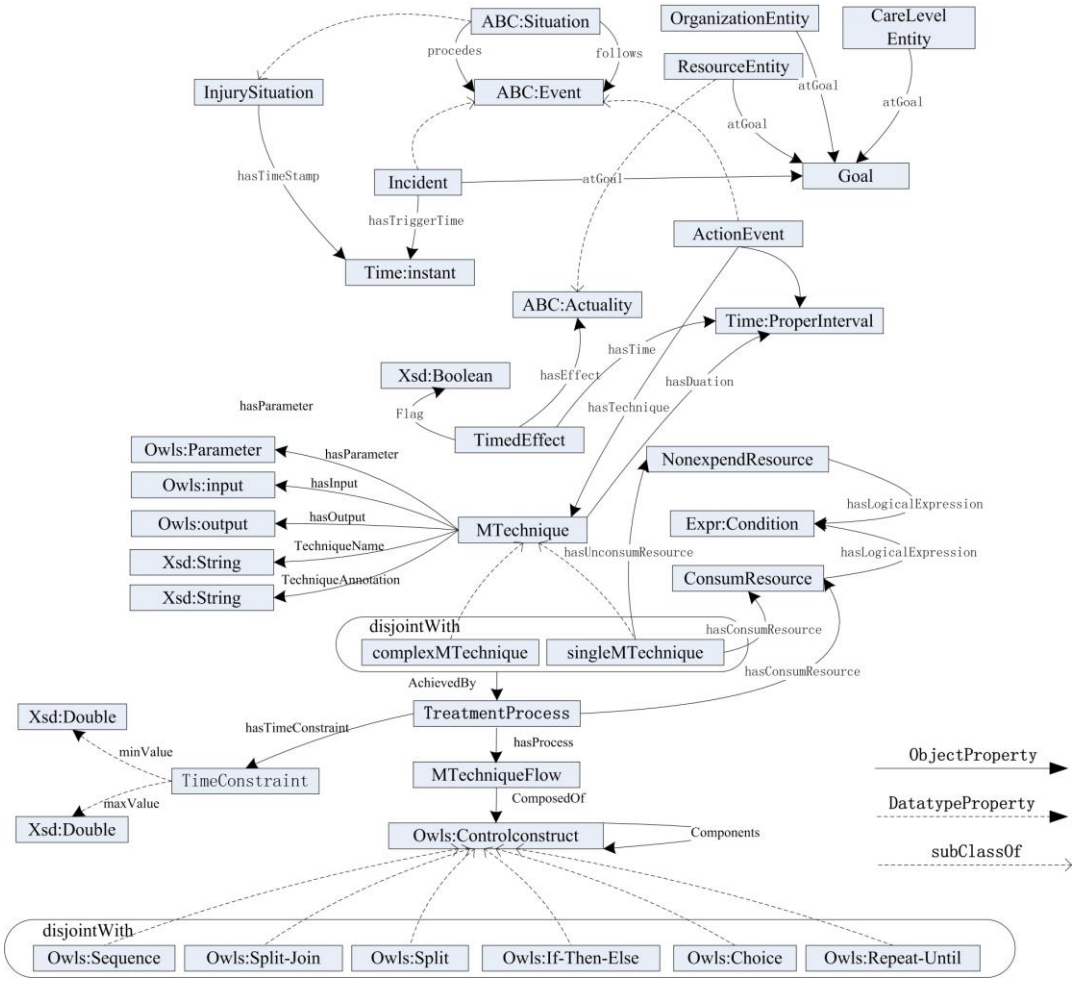

Figure 3. Brief Structure of MRAOM Concepts and Relationships

a) Establish **incident** as subclass of **ABC: event** describe the disaster. Establish properties **asTriggerTime** and **hasLocation,** with range **time: instant** and **location,** indicating the time location of the mission. Establish data attribute **type,** representing the type of disaster, such as earthquake, tsunami and soon.

b) Establish **actionevent** as subclass of **ABC: event.** Establish properties as **hasTask** and **hasInterval** with range **task** and time: properInterval, indicating the type of task and the interval time of executing the mission.

2. Ontology of medical demand

Disaster medical relief demand generally indicates the amount of injuries and the distribution of injury condition at the point of time. So it belongs to situation modeling. Establish **injurySituation** as the subclass of **ABC: situation** indicating the relief demand situation. Establish properties **hasTimeStamp** with range **time:instant.** Establish data attribute **number** and **type** to indicate the amount and condition type of the injuries.

Based on these ontology models, disaster medical relief could be modeled as a discrete event system and describe the relief process as incident series of relief mission and demands. The model could describe the dynamic action based on the changing demands.

Ontology of Medical Relief Entity

Medical relief entities include 3 classes of entity, which are care level entity, medical relief organization entity and medical resource entity. We establish the entity ontology as follows.

1. Establish **treatmentlevelEntity** as the subclass of **ABC: actuality**, indicating the level of care. It include data attribute **name** with range of **string,** indicating the name of care level. Add property **atGoal** with range **Goal**, indicating the treatment goal of the care level.

2. Establish **organizationEntity** as the subclass of **ABC：agent**, indicating the medical facility. It include data

attribute **name** with range of **string**, indicating the name of the medical facility.

3）Establish **resourceEntity** as the subclass of **ABC：actuality**, indicating the medical resources in need.

These ontology are all general concepts in the medical relief domain. In order to describe the entities more specific, we should establish particular entity concept models based on these general models.

Ontology Model of Medical Relief Domain

MRAOM use **Swrl：atom** to indicate fact. As for the problem of using SWRL ontology expressing logical atom conjunction, we use **Expr：condition** to model precondition. Thus, we could realize the ontology modeling of complex logical condition.

Establish class **domainRule** to indicate the rule of medical relief domain. It includes properties of **hasHead** and **hasCondition**, with ranges of **Swrl：atom** and **Expr：condition**, indicating the fact and precondition of the medical relief domain rule.

Ontology Model of Injury-Driven Medical Resource assignment

Medical Technique Flow modeling

Based on the ontology model Owls：process, MRAOM establishes class MTechflow, indicating the medical technique flow which is used in the injury treatment. Add data attribute TechflowName and TechflowAnnotation with range of string, indicating the name and information of the flow. Establish properties hasParameter, hasInput, hasOutput and hasResource. The first three property ranges are Owls：parameter and the 4th is properType&Number, indicating the describing parameter, input injury condition, output parameter and the medical resources that are needed to carry out the medical technique.

When establishing instance of medical technique flow, we should also establish the instance of techflowResource of resource: properType&Number as well as the instance resourceType and resourceNumber of resource: instant, indicating the type and amount of medical resources used in the flow.

The medical technique could be divided into single technique and complex technique. Single medical technique could be done by single medical function unit while complex medical technique should be completed by multiple medical function units.

1. Modeling of single medical technique

Establish class **singleTechnique** as subclass of **Technique**, indicating single medical technique. Establish properties **hasconsumResources**, **has unconsumResources**, **hasTimedEffect**, **atGoal** and **excutedBy**, with ranges of **consumResources**, **nonexpendResources**, **timedEffect**, **goal** and **organizationEntity**, indicating the consumable and non-expendable medical resources, applying effect, goal of applying and executing entity of the medical technique.

Define technique applying effect as **te=<logicalAtom, flag, time>**. MRAOM model the logical atom as **logicalAtom** based on the instant **effectLogicalAtom** of class **ABC：actuality**. In order to stamp time, we establish instant **effectTimeStamp** of **time: interval**, with properties **hasBeginning** and **hasDurationDescription.**

Establish class **TimedEffect** indicating the effect of applying the medical technique after a period of time. Add data attribute **flag**, with range of **boolean**, indicating the sign of applying effect. Add properties **hasEffect** and **hasTime**, with ranges of **ABC：actuality** and **time: interval**, indicating the applying effect logical atom and the time point of generating the applying effetct.

2. Modeling of complex medical technique

MRAOM establishes complexMTechnique as subclass of MTechnique, indicating complex medical technique which should be completed by multiple medical function unit during the injury treating. Add property achievedBy with standardized injury treatment profile. One complex medical technique model could have one or more property achievedBy, indicating multiple pathway that could complete the technique.

Medical Resource modeling

1. Consumable medical resource modeling

(Consumable medical resource) cr=(logical expression, n)

MRAOM establishes class **consumResources**, indicating consumable medical resource, including properties **haslogicalExpression** and **hasConsumStamp**. The ranges of the properties are **Expr: resources** and **number：interval**, indicating the logical expression and the number tag of the consumable medical resource, valuing **instantLogicalExpression** and **consumNumberStampInterval.**

2. Non-expendable medical resource modeling

(Non-expendable medical resource) nr=(logicalExpression, interval, n)

MRAOM uses class **Expr: Resource** to model logical expression **logicalExpression**. Establish instant **intervalLogicalExpression** of **Expr：resource**. In order to indicate the time (interval=(minValue, maxValue)) during which the medical technique occupied, establish the instant minTime of time: interval. The properties **hasBeginning** and **hasDurationDescription** are valued as **techniqueStartTimePoint** and **minValue**. Meanwhile, establish instant **maxTime** of **time: interval** with properties **hasBeginning** and **hasDurationDescription**, valuing **techniqueStartTimePoint** and **maxValue**.

Injury Treatment Profile Modeling

Injury treatment profile could connect the injury condition, medical techniques, medical resource and treatment time together. So the modeling of it is very important.

Establish class **treatmentProcess**, with properties **hasCondition**, **hasProcess** and **hasTimeConstraint**, ranging **instantCondition**, **MTechflow** and **timeConstraint**, indicating the injury condition, medical technique flow and time constraint of the injury profile. Establish data attribute **hasAnnotation**, with range of **string**, indicating the information of the profile.

The modeling of injury treatment process and time constraint are as follows.

1. Modeling of injury treatment process. According to Rule 4, injury tretment process could be described by work flow. Based on the OWL-S modeling idea, MRAOM uses the subclass of **Owls：controlConstruct**, such as Sequence、choice、split+join、iterate、condition、if-then-else、any-order、repeat-while and repeat-until, to realize the modeling of the sequent structure, chose structure, parallel structure and circulate structure of injury treatment process.

In order to describe the treatment steps of injury treatment, MRAOM establishes class **treatmentStep** as the subclass of **Owls：controlConstruct**, indicating a certain step of the injury treatment process. It includes property of **technique** with range of **MTechnique**, indicating the medical techniques used in this treatment step.

As the same as modeling complex process using OWL-S ontology model, the modeling of injury treatment process has tree structure. The root of tree is the instance of class **treatmentStep** and the root node is the instance of subclass **Owls：controlConstruct**.

2. Modeling time constraint

Use the property of **time：properInterval** to express the qualitative time constraint of applying medical techniques. As for quantitative time constraint, MRAOM establishes class **timeConstraint** according to Rule 5. Add properties **hasPreTimePoint** and **hasPostTimePoint** with range of **time：instant**. The value of it indicat the start and end time of the injury treatment. Add data attribute **minValue** and **maxValue**, indicating the minimum and maximum of the quantitative time.

Establish instance **deadlinTimeConstraint** of **timeConstraint**, indicating the time constraint of the medical technique. Its properties are **hasPreTimePoint** and **hasPostTimePoint**, valuing **time:instant** or **referenceTimePoint**, indicating the start and end point of the technique.

RESULTS & DISCUSSION

MRAOM is the model describing the knowledge system structure of international disaster medical relief

resource assignment. It could describe the major elements and rules of disaster medical relief resource assignment and realize the management and modeling of the domain knowledge. In order to display the utility and effectiveness of the model, we take earthquake medical relief as an example to show the usage of the model. The modeling tool is Protégé V4.3. Part of the model usage is as follows.

Model Usage of Describing Medical Relief Situation

The description of medical relief situation include the situation of injuries and the entities of medical relief system. The situation of injuries is described by the amount of injuries, the types of injuries and the severity degrees of injuries. The types of injuries include fracture, burn injury, crush injury, combined injury, etc. The severity degrees of injuries include minor, moderate, severe and critical. Suppose an earthquake had taken place at 7:59 on April 14th, 2010. 120 injuries were found by search team on that very day. The medical staffs at the front reported the types of injuries as fracture, crush injury and combined injury. The medical evacuating units reported that 40% of injuries were severely injured and 20% of the injuries were critical injuries. The medical relief system included two levels of care. The first level included medical rescue teams from local medical facilities and international medical team. The second level included field hospitals composed by medical forces at home and abroad. The model is used to describe the medical relief situation as showed in Figure 4.

I0 indicates the earthquake disaster. The time stamp is "2010/4/1407:59" and the location is L0. This disaster triggered medical relief situation RS0. RS0 described the medical relief situation of "2010/4/14", including the injury situation and medical relief system situation. The RS0 triggered medical relief action RA0 which indicates more emergent medical response actions to save more injuries. As showed in Figure 4, MRAOM describe the disaster medical relief system and its relief process as a discrete event system. The model could also describe the system's dynamic changes and the treatment process sequent changes.

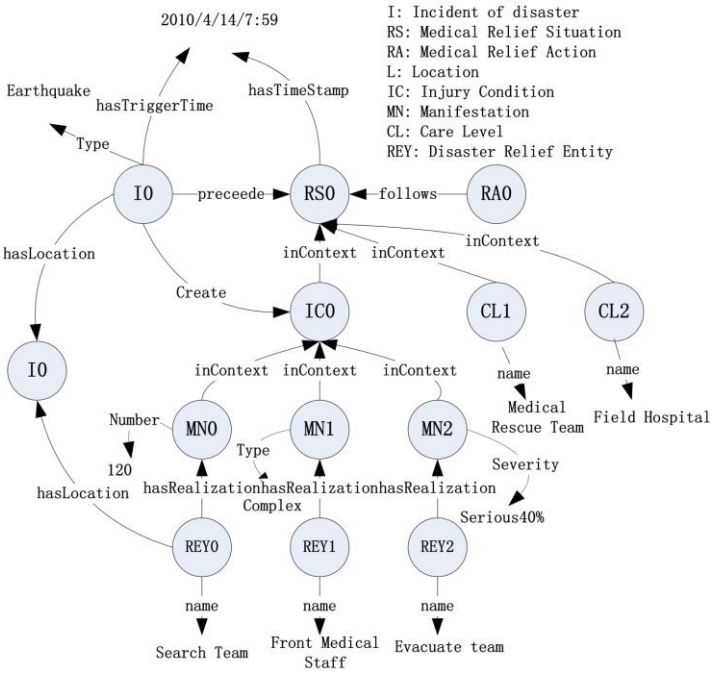

Figure 4. Brief Description of Medical Relief Situation After the Earthquake

Model Usage of Describing and Forecasting the Injury-Driven Medical Resource Assignment Process

The medical resource assignment of international disaster medical relief varies according to different injury condition, different medical relief facility and different type of disaster. Given the limited space available, only the treatment and resource assignment process of batch wounded with possible spine injury treated within the medical rescue team before evacuation was described in figure 5. The basic treatment process was described in figure 2. As showed in figure 5, the resource assignment process based on the injury treatment ontology model is tree structured. The non-root nodes are the subclass incident of class **Owls:construct** describing the structure of injury treatment process. The root nodes are incident of class medicalTreatmentStep, describing the steps of the injury medical treatment process. The combination of Medical Resource No.4, 5, 6, 8, 9, 10 is the possible

medical resource assignment of medical rescue team for treating batch wounded with possible spine injury before evacuation.

CONCLUSION

Medical resources assignment is the basis of international medical relief. This article promote an injury-driven ontology model to describe the process of injury treatment and forecast the resource assignments for different medical relief facility, different injury condition and different disaster type. This ontology model could help medical staffs with different background knowledge from different area or country have common understanding of the complex knowledge in the disaster medical relief domain. The features of this MRAOM describing and forecasting the medical resource assignments are: 1. Based on the systematic point of view, the model abstracts the entities of the medical relief into medical relief system so as to describe the complex features and dynamic activities during the injury treatment process; 2. The model could construct the complex structure and describe time-limited characteristic of the medical resources assignment.

This model describes the features of injury treatment process and medical resources assignment. However, the model is not perfect for lacking enough theoretical validation. The next step of our research would do further theoretical validation and validate the model with real cases. We would also describe the relationship between the medical relief entities and the relationship between different types of the medical resources. Based on these, we would develop a support decision-making system to help the decision makers make resources assignment for specific mission.

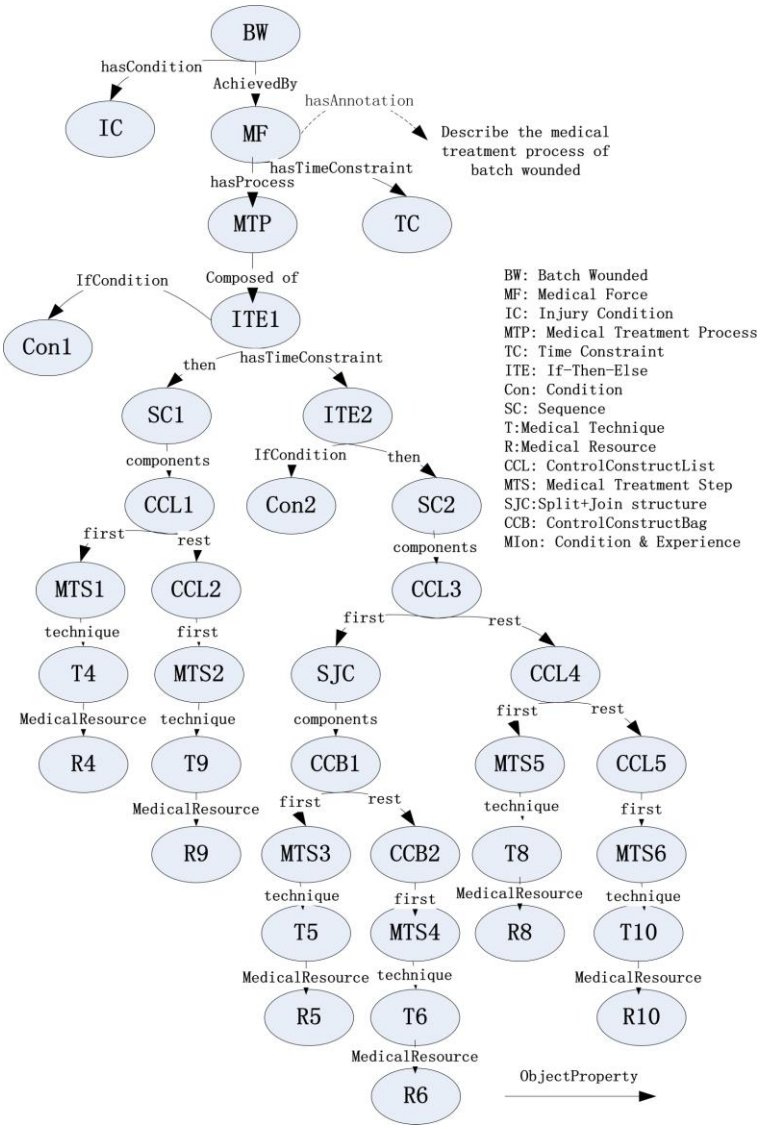

Figure 5. Part of Medical Resources Assignment Process of Batch Wounded Treatment

ABSTRACT

The aim of this work is defining fundamental principles of an Internal Security System in the presence of intentional risks in Public Administration. The relevance of this object of study has increased even more with the emergence of new terrorist groups and the proliferation of organized crime, which have been categorized as a maximum threat to Security by the government. This context has led to new regulations and legislation on Security matters at the national and international level to protect assets, people and the activity of the Administration itself. Despite the large number of regulations and relevance of this topic, there is not any study which defines in a comprehensive manner the requirements that a security system must have in the presence of intentional risks in Public Administration. The results of this work are intended to be a reference for the Public Administration, for the prevention and reaction to damage to people, property, and operation, intentionally caused by external agents, personnel themselves or users. These principles have been applied and validated through a Delphi process in the Administration of the Regional Government of Andalusia in which more than 40 security-related managers have participated.

Keywords

Delphi, Public Administration, Intentional Risks, Homeland Security, Resilience.

INTRODUCTION

The Public Administration is characterized by a great diversity of buildings and facilities for which it is difficult to identify the competencies and responsibilities in terms of security. This is due to the fact that the management scope of security is usually distributed, meeting specialty criteria in the nature of the risks and the impact area, with a very varying degree of development and formalization (Smith and Brooks, 2013; Brooks, 2012). In this way, the scope of industrial risk prevention is generally found highly regulated (ISO 31000), as well as with

legally defined powers and responsibilities. Similarly, a varying degree of legal regulation is found within the scope of information security (ISO 27000), buildings and facilities protection against fire risks, intrusions, external aggression, or against natural events (NCSE-02), such as anti-seismic protection. Likewise, in recent years, the specific legislation has increased at an international level for critical infrastructures protection (Turoff et. al 2016). Most of the specific legislation, that regulates these security areas, is of general application from both the Public Administration and any natural or legal person, according to its scope of application and the definition of responsibilities

These circumstances provide a context for the risk management and the security within the scope of the Public Administration, characterized by (1) a great diversity of the institutional areas with competences concerning issues involved in security risks, (2) a varying degree of definition and development of the organization, powers and responsibilities for security risk management, and (3) a high degree of attractiveness to intentional threats. The Public Administration, like a city inside the city, can be understood as a set of interconnected dynamic systems (Godschalk, 2003).

In spite of the relevance of security within the Public Administration, and of the millionaire budget devoted to the protection of public buildings, there is no scheme that provides an integral global vision of the risks and security management, in all the areas and level within public administrations, and for all the types of risks and impact areas. This is due to the great diversity of existing approaches in the security and resiliency scopes, from different fields (Hernantes et. al, 2017). In order to contribute an initial approximation to this field, in this article, we propose the execution of the Delphi method for the establishment of design principles, and for the definition of the Internal Security Policy within the Public Administration for the reaction and prevention against damage to people, heritage and the operation, intentionally caused by external agents, personnel or users.

The present article takes the following form: In the second section, we will analyze the different types of risks and impact areas against damage, intentionally caused by external agents, personnel or users, to people, heritage or the normal operation within the Public Administration (occupational, infrastructure, heritage, information, aggressions, external risks…). In the third section, the execution of the Delphi method for the establishment of the Internal Security System within the Public Administration will be illustrated with a real case, that of the Andalusian Regional Government, Spain. Both the validation and results of the Delphi method are presented in the fourth section.

BACKGROUND

For the characterization of the actions currently carried out in the field of security, a classification has been used in the Scope of Protection, Type of Threat and Nature of Action dimensions.

Scope of Protection

The actions currently being carried out in the field of security are aimed at the protection of certain types of protectable properties, mainly as a result of the compliance with applicable regulations and legislation.

Protection against threats to the physical security of people and assets

It is the most traditional scope of security protection, aimed at preventing losses and damages in an organization, caused by people or groups whose objective is the appropriation of property, or causing damage to facilities, assets or people (Fisher et al, 2008). This area includes means and systems for prevention, containment, surveillance, detection and action against intrusion, such as perimeter fences, surveillance cameras, access controls, presence or movement detection system and alarm and response systems (ARC). If the risk is significant, it is common for this security function to fall to a specialized area in the organization. It is also common to have authorized external security and surveillance services to perform this function since in certain cases it is required by the legal requirements in the field of private security. In this field, specific national legislation has been developed, driven in recent years by the increase in the global terrorist threat, and including legislation derived from the European directives aimed at protecting critical infrastructures.

Protection against threats to workers' health

This area includes the management of risks to worker's health derived from the conditions and nature of their job: handling of toxic substances, handling of dangerous machinery, extreme environmental conditions, physical overexertion, etc... (ISO 45000). This function usually falls to the human resources area, which may have its own prevention and occupational health service or may have an authorized external prevention system. The methodologies for the evaluation and management of occupational risks are highly developed, and the methods and recommendations praised by the National Institute for Health and Safety at Work are regularly used as a reference.

There exists extensive legislation on occupational health, which establishes precisely the responsibilities and activities of organizations in this area. In this sense, it is compulsory that the organizations have an (own or external) occupational health officer, a Prevention Plan, and prevention service. Legislation and technical standards also cover the scope of protective equipment applicable to each activity. Management standards have also been developed in this area, as well as voluntary certification schemes.

Protection against industrial threats to the personnel, population, and environment

Industrial accidents (fires, explosions, spills, toxic clouds …) have historically caused huge damage at personnel themselves in the facilities, in the environment, and in the surrounding populations. The risk management in this area is aimed at preventing the occurrence of these accidents or minimizing the damage caused (ISO 31000). There exists national legislation in this area which requires the organizations with certain characteristics to have Emergency Plans to respond to possible emergencies. These plans should define the responsibilities for the response to incidents and coordination with external intervention services (firefighters, civil protection, police officers), as well as self-protection actions (evacuation, confinement, threat containment …). The legislation also develops European directives (SEVESO) aimed at protecting the populations against the threat of major accidents. The field of industrial Security also includes the legislation and technical standards applicable to certain equipment and machinery (pressure devices, lifts, fire extinguishers …) which require its certification and periodic verification.

Protection against threats to information security

The development and widespread of the use of communication and information technologies (ICT) in recent times has led to a parallel increase in the volume and sophistication of threats for the integrity of sensitive information for individuals and organizations. Cybersecurity is the practice for the protection of the information and ICT systems against intrusions (hackers) and harmful programs (viruses and malware). It has also been developed management standards in the field of information security and voluntary certification schemes (ISO 27000; ISO 14000).

Protection against threats to essential services for the population

Essential services for the population such as drinking water supply, sanitation, transports or energy supply are subjected to increasing global threats (terrorism, geopolitical tensions…) in an increasingly independent context. In recent years, European and national legislation has been developed for the protection of critical infrastructures which provide these essential services. This legislation establishes responsibilities and mechanisms of analysis, planning, and response to mitigate the risk for these infrastructures, to protect them against threats and to respond to possible incidents which may occur. At the voluntary level, technical standards and certification schemes have been developed for global risk management and its business continuity (ISO 22301; ISO 22320).

Protection against criminal threats

In recent years, the treatment of other types of threats have been formalized such as those which affect the criminal risk of the organizations and workers (compliance) (ISO 19600). National legislation has been developed in this field, as well as international compliance management standards. It is necessary to consider that risks interact with each other so that a criminal risk for workers can become a risk for the continuity of the activity if they limit their

actions to avoid criminal risk. As it is mentioned in the table, the basic regulations may cover more than the protection area.

Type of threat

United Nations Disaster Relief Organization (UNDRO) classifies risks into those caused by natural, human or technological threats:

- Natural: risks of which triggering is not directly caused by human presence or activity, but by climatic and geological factors.
- Human: risks caused or derived from human activities and actions.
- Technological: human risks which derive from technological development and significative use and application of technologies.

On the other hand, public preparedness is considered to be important in the fight against terrorism. So, homeland security needs to give special consideration to threats of intentional origin in Public Administration. Considering the foregoing, the actions in the security area Public Administration could characterized by the criteria of responding to an accidental threat, or an intentional threat, as described in table 1.

Table 1. Types of threat

Type of threat	Description
Accidental	The technological, human and natural threat, of which occurrence is not caused by the intention of groups or individuals to cause damage to protected property.
Intentional	The technological, human and natural threat, of which occurrence is caused by the certain intention of groups or individuals to cause to damage to protected property.

Areas of protection

Security management has also developed in its approach, from its purely instrumental initial conception, in which the organizations provide reactively, ad hoc and isolated responses to emerging security needs. Currently, it is necessary a proactive and systematic approach, with a strategic intention based on the understanding of the context and necessities of stakeholder and using a formalized management system as a tool for developing such strategy. A management system is a group of elements within an organization, which are interrelated or interact to establish policies and objectives, as well as processes to achieve those objectives. Standardized Security Management System models are currently available in various protected areas (Table 2).

Table 2. Standardized Security Management Systems in Protection Area

Model	Area of protection	Type
ISO 45001 Occupational health and safety	Security and health of the workers. It substitutes OHSAS 18001 Standard	Accidental
ISO 22301 Business continuity management	Continuity of essential services	Accidental Intentional
ISO 22320 Social Security. Emergency management	Security and health of the workers Security and health of citizens	Accidental Intentional
ISO 31000 Risk management	A comprehensive model for risk management and incident response in all areas of protection	Accidental Intentional
ISO 55001 Assets management	Model for the asset life cycle management, including its conservation and maintenance	Accidental
ISO34001 Security management system	Protection against internal or external fraud. It is developing	Intentional
ISO 14001 Environmental management systems	Protection of the environmental estate	Accidental
ISO 19600 Compliance management systems	Protection of legal compliance	Accidental Intentional

CASE STUDY

In this case study, the design process of a Comprehensive Risk Management and Security System within the scope of the Regional Government of Andalusia, for comprehensive management of the different types of risks. This system is based on an institutional architecture, a governance system, and the definition of competencies and responsibilities for policy coordination, objectives, strategies and actions in terms of security amongst various government agencies, as well as amongst various operators with competences concerning any risk management area and the security of the Regional Government of Andalusia.

Context

Regional Government of Andalusia is the institution in which the self-government of the Autonomous Spanish Community of Andalusia is organized. It is integrated by the Parliament of Andalusia, the presidency of the "Junta de Andalucía" and the Governing Council. The 2019 budget amount to 34,759 million euros, and it has more than 270,000 direct employees.

Methodology

The research methodology on which this work consists of three sequential phases (Figure 1).

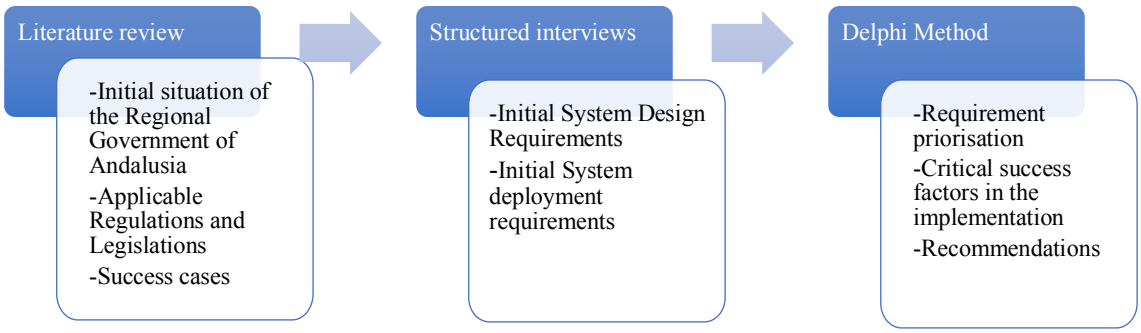

Figure 1. Methodology

The first stage is based on a review of the literature to characterize the initial situation of the security organization in the Regional Government of Andalusia, the main applicable regulations and analysis of success cases and reference of security management at national and international level. In addition, an analysis of the estate inventory has been performed, considering all Central Administrations and Agencies (excluding commercial companies) to define the scope of assets to be protected. As part of this stage, a model of approach to the Internal Security in Public Administration has been proposed, since we have not found in the literature a single approach that allows us to classify the activities at the level of security that is carried out in a Public Administration of the size of the Regional Government of Andalusia. In addition, a glossary of security terms has been compiled. This glossary is based on the main national and international standards, regulations, and legislation.

In the second stage, a series of personal interviews were carried out with 9 interlocutors with responsibilities in different areas of protection in the Regional Government of Andalusia. In these interviews, a wide variety of issues have been posed in order to characterize the current security situation in the Regional Government of Andalusia. This methodology is useful as a means of providing input for an initial approximation of design and implementation requirements of the Andalusian Regional Government's Internal Security System.

In the third stage, the conclusions obtained both from the literature and from the personalized interviews using the Delphi Method were compared. Delphi method is an analytical technique based on the judgment of a group of experts. It consists of an iterative and systematic process aimed at obtaining the opinions, and if possible consensus, of this group of experts. Its main characteristics include anonymity, controlled repetition and statistical treatment of responses. The Delphi method was developed in the Rand Corporation during the 50s (Helmer and Rescher, 1959). This technique was designed to develop a debate independent of personalities. The Delphi method is based on anonymous communication with feedback. Anonymity is required in the sense that no one knows who else is participating. Moreover, judgments are summarized and sent back to the group for further analysis in the form of sequential questionnaires. Processing data in this way help to minimize psychological effects and time demanded in comparison with another group (Linstone and Turoff, 1975; 2002). With the profound impact of the internet on organizational and community planning systems, Delphi it will foster a new age of participation through communication, coordination, and collaboration (Linstone and Turoff, 2010).

Field Work

32 experts have participated in the Delphi process, among all of them there are people responsible and key actors in the future of Internal Security System of the Andalusian Regional Government, such as Technical General Secretariat (TGS) of several Ministries, General Secretariat (GS) of Several Government Delegations, as well as Directorates-General and equivalent departments of key areas for the security field and experts in the field from other Agencies and Directorates-General of the Regional Government of Andalusia. Delphi study had a response rate of 60.37%, which means high participation in the study.

Following the Delphi Methodology, each expert was given a set of principles resulting from the provisional conclusions of the initial study. In addition, a series of open-ended questions were included in which could contribute to relevant aspects not covered in this first round of the Delphi process. In a second round, each expert was given both their response and the group's response so that they could make a comparison and make comments and assessments if they deemed it appropriate. The comments of the entire panel of experts were sent to other participants anonymously so that the rest of the group could establish the degree of agreement on further contributions from the panel of experts.

RESULTS

Design Principles

A first result of the study in the need to establish a Basic Security Management Model for the future Internal Security System for the management of risks caused by international threats of the Regional Government of Andalusia with the following components:

- Security Policy: The definition of the scope of protection, and of overall objectives, principles, and commitment in the security area.
- Government framework: Organization and responsibilities for the definition and deployment of security objects, coordination of actions for risk treatment and analysis, and for the assessment, review, and updating of the security management system.
- "Typological" Analysis of Risk: Identification of the types of threats to the protection area, and "standard methods" for the assessment of the risk associated with the impact and probability of occurrence of the threats.
- Risk treatment: Establishment of criteria and strategies for the treatment of risks, and implementation of the necessary security and protection measures to migrate the risk to an acceptable level.
- Response to incidents: Definition of responsibilities for the identification, notification, and classification of incidents, as well as for the activation and coordination of action plans to respond to the incident.
- Monitoring, Assessment, and Improvement: Monitoring of indicators, security management system audit, and incident response drills, as well as an assessment of the response to an incident that has occurred, they provide information on the effectiveness of the security management system and possible opportunities of improvement.

In a complex organization, as it is the Regional Government of Andalusia, this Base Model may require a Government Framework and deployment according to the different levels and organizational structures. Additionally, the development of the tools for the promotion of Safety Culture in the Regional Government of Andalusia has been established as a priority as a fundamental pillar of the system. Culture is an intangible force behind the measurable and observable that moves an organization to action. Due to the organizational culture has such a profound effect and the behavior of individuals, it should be understood and managed to achieve the desired objectives. The lack of Safety Culture may involve structural risks that are difficult to address. Therefore, any Security System to be promoted by the Regional Government of Andalusia must be rooted in the promotion of the Safety Culture among workers and users of the services.

Other relevant but less important aspects for the panel of experts are:

- Centralization of information: There exists a need to centralize and coordinate information and communications in a complex structure such as de Regional Government of Andalusia in the field of security.
- Resilience: A resilient organization must have the ability to ability to anticipate disruptions, adapt to events

and create lasting value. A resilient system involves the ability to absorb disturbances, respond efficiently and recover from unexpected events. In this sense, the Security System of the Regional Government of Andalusia to be resilient should have the attributes of robustness, redundancyand speed.

- Change management: The success of the implementation of the Security System in the Regional Government of Andalusia also depends on proper management of the possible resistance of a new System, making it easier for the organization itself to accept, support and effectively manage the change.

Keys of implementation

As a result of the Delphi process, the experts on the panel have provided their views on the key aspects of the implementation of each of the Internal Security System's design principles, which we summarize below:

Security Policy, Government Framework, and Management

The experts stress the need to define a Security Policy, including the Management and Government Framework, relevant areas and departments. It is outlined the need to include coordination mechanisms with other existing systems as well as with the national and international security forces. According to the panel, it is essential to consider the particularities of each of administration's activities, especially those with a higher concentration of risks.

According to the participants, the design of the Security Policy must consider all employees and positions of the Regional Government of Andalusia, considering this difference in profiles and responsibilities so that each one can apply the protection mechanisms that are relevant to them. It should also include mechanisms for monitoring, assessment and information management at all levels. The training of those responsible for Security matters is a critical aspect for the success of the implementation as well as the awareness and involvement of workers and users of the services of the Regional Government of Andalusia.

Protection area, Analysis and Risk Treatment

The result of the Delphi process indicates that the threat catalogs need to specifically address the situations of greatest risk exposure. They also count on the contribution of the knowledge of personnel at all levels of the Administration, making catalogs of threats against the administrative structure (services, sections, and negotiations), as well as against the holders of managerial posts in the Regional Government of Andalusia, according to their rank and competences.

According to the panel of experts, the Internal Security System should have communication and dissemination mechanisms that are as broad, complete and close as possible in order to make publish both the catalog of risks that an employee/site faces and the prevention and treatment mechanisms that are applicable. Technical advice on security matters should also be provided on a permanent basis to the institutions.

Responses to Incidents, monitoring, improvement:

The results of the Delphi panel show that, at the level of Incident Response, it is key the specific training of personnel (managers, coordinators, etc.), with special emphasis on those who carry out their activities in centers with high levels of risk. On the other hand, it is outlined the need to perform the Monitoring and Improvement of management indicator implementation in the field of Safety.

It would be essential to establish coordination measures by the Regional Government of Andalusia, but always considering specificities and characteristics of each area, drawing up procedures jointly between the Ministries with competence in the field of Security. In addition, the National Police Unit attached to the Autonomous Community of Andalusia should be involved in the analysis, monitoring, and improvement.

Security culture

Regarding Security Culture, the panel of experts' stresses that the training and awareness in Security are essential to avoid incidents, and also allows for a better reaction in the event of an incident.

For this, it is necessary to involve workers and users, creating Culture but without generating an atmosphere of fear. Such training should begin with that of the management staff of the Ministries and Delegations of the Government and Territorial Delegations.

In order to achieve a greater involvement and awareness by managers, public employees and users, in the opinion

of the panel of experts, it is necessary to improve horizontal and transversal communication channels in the area of security, especially with regard to new recruits who are responsible for safety or who are in charge of buildings or people subjected to relevant risks.

Other key implementations

Regarding the Centralization of Information, the panel proposes to promote the existence of a fluent information channel for those responsible for the different centers, reinforcing and guaranteeing the upward and downward channeling of information. This issue would require common information tools and standardized communication processes.

Regarding the provision of Resilience to the International Security System, the experts indicate that it would be important to guarantee the availability of means and resources in the area of Security, as well as the flexibility and adaptation of the System to the characteristics of each asset, since the risks and implications of these differ according to the context. They also propose the development of tools to analyze unforeseen situations that have caused damage, collecting the appropriate conclusions to prevent or minimize them as far as possible. Resiliency is too often measured against prior natural disasters and climate change is increasing the level of damages above past values so that by replacing what was there and damaged without increasing the resistance/survivability to larger natural disasters is a major decrease in resiliency (Turoff et al., 2018).

Finally, the experts point out that a large part of the success in the implementation of the Internal Security System lies in an adequate Management of Change, whose pillars would be the involvement of the management, awareness campaigns among public employees and users and the training of personnel.

Through adequate communication, the new International Security System should be presented as something positive and not as a new workload and responsibilities, reflecting the need for its proper development and the benefits of its implementation.

Model base

The conclusions of the panel of experts firstly highlight – with a level of agreement of 4.71 on the scale of 5, where 5 suppose "total agreement" – the need to establish a global governance framework and management of security in the face of international risks at the level of the Regional Government of Andalusia. This government framework should allow for the definition and effective and coordinated deployment of comprehensive security policies, as well as those established in each specific area of protection. As we mentioned in the methodological section, this panel of experts have key actors and responsible people in the future of Internal Security System of the Regional Government of Andalusia such as SGT of various Ministries, GS of some Government Delegations as well as Directorates-General and equivalent departments of key areas for the field of security and experts in the field from other Agencies and Directorates-General of the Regional Government of Andalusia.

A series of principles are also established for the design of an Internal Security System in the event of international threats to the Regional Government of Andalusia. A first element to be included in the design is the establishment of a Base Model for the Management of Internal Security which elements and interrelations are expressed in figure 2.

Some key properties to include in the design of the System for the correct functioning of this Base Model would be the Security Culture, the Centralization of Information, the work for Resilience and a Change Management design.

At the implementation level, key factors are considered:

- Coordination with other existing systems and at different levels of management.
- Management commitment.
- Communication with everyone involved in the system.
- Awareness-raising at all levels, including users.
- Training as a key to promoting a Culture of Security and Change Management.

In this sense, the panel of experts stress that the processes of design and implementation of the new Internal Security System must consider developments in the field, requiring the active participation of the various Ministries, Management Centers, and Entities of the Andalusian Regional Government, through the appointment of their heads or coordinators. It is essential to be able to transmit the advantages and benefit of the new System, as well as to plan the required resources for launching it and establish a well-defined roadmap for its implementation.

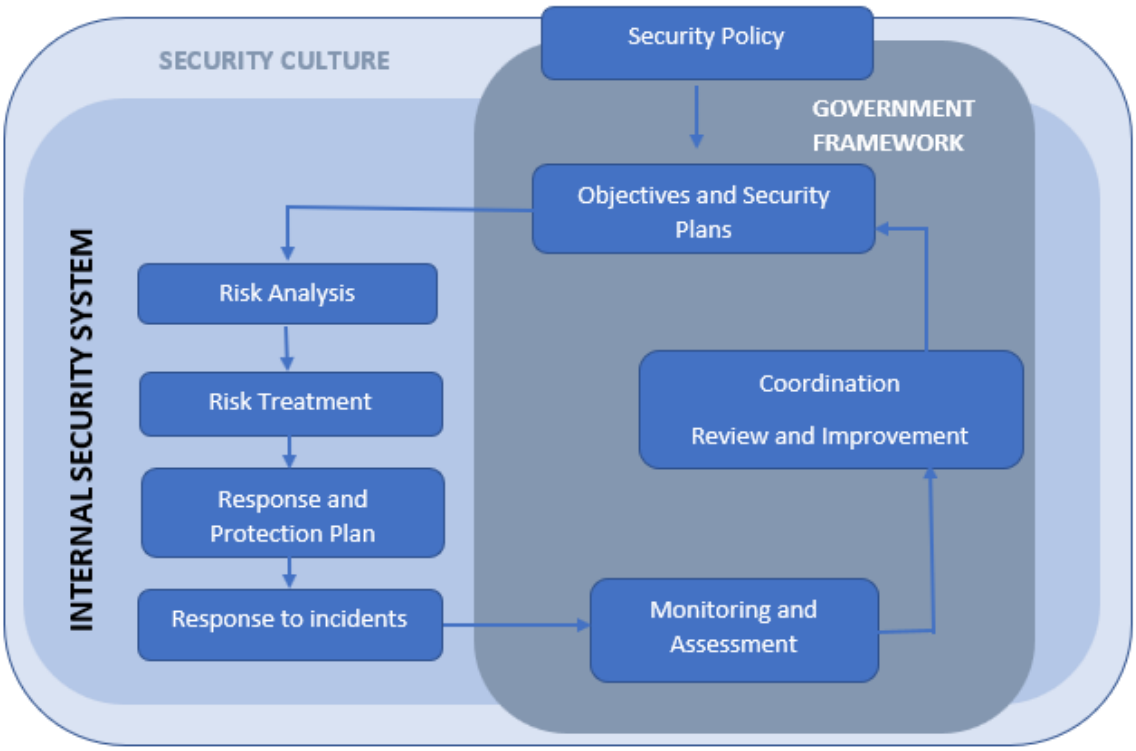

Figure 2. The relationship among elements of the Base Model for Security Management

It is also necessary the communication and the training at all levels un matters of safety, fundamentally regarding the rights and obligations derived from own and third parties' actions in the use of material elements and the use of public buildings.

CONCLUSIONS

In this article, a Delphi approach has been proposed for the establishment of design principles of a Comprehensive Risk Management and Security System in a large Public Administration. With this system, we have aimed to provide a global approach to carry out planning, prevention, protection, reaction, assessment and improvement activities, as well as the coordination amongst the various kinds of agents involved in terms of security against international threats.

One early conclusion is the transversal nature of the security within the Public Administration. This matter makes the integration and identification of a Comprehensive Risk Management and Security System with other possible high-level shortcomings within the organization with competences concerning security, respecting the identity of the rest of the systems despite defining coordination mechanisms amongst one of them, be one of the main challenges when it comes to developing a Comprehensive Risk Management and Security System

A second conclusion is the adequacy of the Delphi method to define a Comprehensive Risk Management and Security System. As it has been stated before, these systems have various kinds of ramifications and interactions with all the Public Administration structure. Due to the suitability of the Delphi method for dynamic planning in episodes of high uncertainty, this technique has shown itself to be added value in the process by the Administration for its execution. The best indication is that, based on the established principles, the regulatory support for the assurance of the governance of the Comprehensive Risk Management and Security System in a Public Administration has been developed.

ACKNOWLEDGMENTS

We want to express our gratitude to the authorities and officials of the Administration of the Junta de Andalucía who, always interested in the continuous improvement of the facilities' security, have collaborated in this research.

ABSTRACT

QuEP is a framework that guides organizations in assessing and improving their emergency plan management by following a set of principles, practices, and techniques at the different maturity levels established in the *QuEP* model. Its main objective is to be applied to real cases to discover the state of an organization's emergency plan management and recommend techniques for improvement. In this paper, we describe the first application of *QuEP* as a prior step to its implementation and possible use in official certifications for emergency plans with a guarantee of quality. So, we have applied a real case in a UPV building towards the certification of the emergency plan management.

Keywords

Emergency Plans Management, Total Quality Management, Maturity Levels, Techniques, Certification

INTRODUCTION

Organizations' efforts to instill continuous improvement is related to the ability to deliver products and services to customers with a quality mark. Organizations in different areas need to guarantee their products and services according to international quality standards. Certification gets a formal document to certifies that a product, system or person complies with guidelines established in a given standard, which has a period of validity. A certification must be objective, reliable and accepted by all interested parties.

The quality assurance approach is reinforced by a third-party certification system, where an independent, specialized and duly accredited organization certifies through an audit based on predefined quality standards; or homologate a product proving that it meets the technical. The confidence of certification by third-party is superior to the first-part certification or internal evaluation, or the second-part certification or carried out by another organization since the certifying is impartial (Camisón et al. 2007). The value of this certificate rests on the prestige or quality mark. Among the standard commonly accepted in the international scope like ISO. In fact, ISO9000 certification and Total Quality Management (TQM) practices directly affect organizational performance.

The ISO 9000 family contains some of the best-known ISO standards, which cover different aspects of quality management (D. Singhal and K. Singhal 2008). For example, ISO/IEC90003, which deals with software engineering, ISO31000 with risk management principles and guidelines, ISO14001 with similar environmental management systems-requirements, with guidance for the use of, among others (ISO 2016). Furthermore, the ISO 22320, is an international standard for Emergency Management Systems and Incident Response that allows organizations to develop and improve their response capabilities (ISO 2011).

On the other hand, as TQM implementation focuses on the criteria for a quality award, it allows some organizations to use this approach which can result in improvement based on relevant TQM models. For example, the Deming Prize (JUSE 2014), the European Quality Award (EFQM 2014), or the Malcolm Baldrige National Quality Award (Baldrige 2014), among others. A certification or Seal of Excellence shows that an organization is profitable while guaranteeing a high level of quality products or services. However, there is no certification for organizations with proper emergency plans management.

QuEP has been presented as a framework inspired by TQM to assess and improve emergency plan management in organizations (Núñez et al. 2016b). Currently, *QuEP* has a model supported by a web application, which is the *QuEP-Tool v1.0*. Applying *QuEP* to real cases is vital to determine the current state of an organization regarding its emergency plan management and what techniques it should consider for continuous improvement in its activities. Consequently, the goal is to gain skills in all the activities performed by the stakeholders before, during and after the emergency plan management. This paper describes a work in progress of how *QuEP* can be used to certify emergency plans and their subsequent maintenance as a certification by third-party.

This paper is organized as follows: Section 2 describes the emergency plan life cycle and how *QuEP* is integrated to support the certification subprocess. Section 3 describes a case study in which we assessed an organization as a pilot test for certification. Section 4 concludes the paper and outlines further work.

THE EMERGENCY PLAN LIFE CYCLE

The emergency plan follows a series of steps from the preparation, implementation and continuous maintenance, as indicated by regulations or laws such as: the "Self-protection Law" (NBA 2007) in Spain, the "Comprehensive Preparedness Guide" (CPG) 101, published by the Federal Emergency Management Agency (FEMA) (CPG101 2010) in USA, the United Kingdom's "Guidance-Emergency preparedness" (UK-gov 2013), among others.

The general process that we inferred from the regulations is shown in Figure 1, where the first step in preparing the emergency plan focuses on how the organization must follow the regulations. The second step is related to the implementation of the emergency plan, in which the organization must train staff, establish public information mechanisms, and provide resources for the application of the emergency plan. The next step is related to the certification that would allow organizations to prepare and implement better emergency plans. The last step is the maintenance and continuous improvement of the emergency plan that involves activities such as: following a continuous successive and interactive preparation process, conducting training activities, conducting emergency drills, and evaluating the emergency plan, taking into account that the emergency plan evaluation should cover a maximum period of three years.

The certifying process requires to ensure compliance with the norm through steps such as if the organization complies with the requirements defined according to local regulations, through an assessment model or approval accrediting that the organization follows certain technical specifications carried out in the different activities of the emergency plan management. Although the public administration approves regulations and laws, receives and approve the emergency plans proposed by organizations, there is a lack in the life cycle of these activities in the preparation, implantation, and maintenance of the emergency plan, which is related to the fact that there is no certification that provides adequate support for this. The weak point in this work is that in many cases organizations register their emergency plans based on current laws, but much more remains to be done, and the public administration does not provide an adequate follow-up to each step. *QuEP* supports certain activities of the emergency plan life cycle, as shown in Figure 1 by the dashed red line.

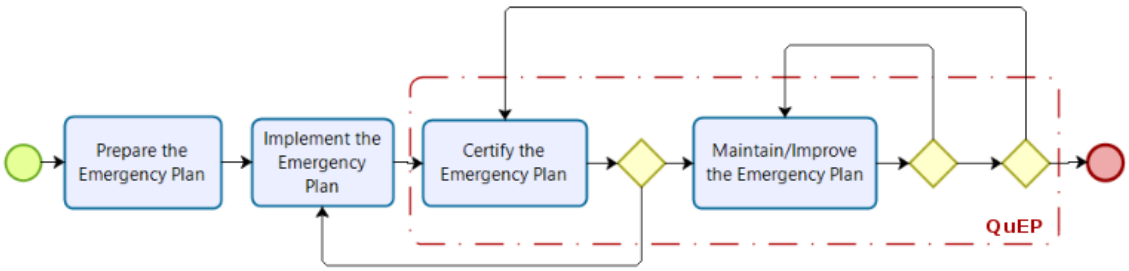

Figure 1. The Emergency Plan Life Cycle

The QuEP framework

QuEP (Quality of Emergency Plans Management) is a framework for the assessment and improvement of emergency plan management within organizations (Núñez et al. 2015). The *QuEP* framework is based on the study of quality aspects of a good emergency plan (Berke and Godschalk 2009). *QuEP* assesses the planning process and analyzes the capabilities of the participants, and all the activities carried out before, during and after the process of implementing the emergency plan. Firstly, the *QuEP* core is defined by maturity levels, which can be seen both as evaluation criteria and as a roadmap for the improvement of the different activities or practices carried out

(shown in Figure 2(a)). The *QuEP* model is then defined (shown in Figure 2(b) with a UML class diagram); this is the basis of our assessment model that is based on principles, practices and techniques (Dean and Bowen 1994). Dimensions are established that define the activities or practices that will be discussed in each of the principles and their corresponding maturity level, and finally, questionnaires formed by questions that are provided to the corresponding stakeholders by role (shown in Figure 2(b)).

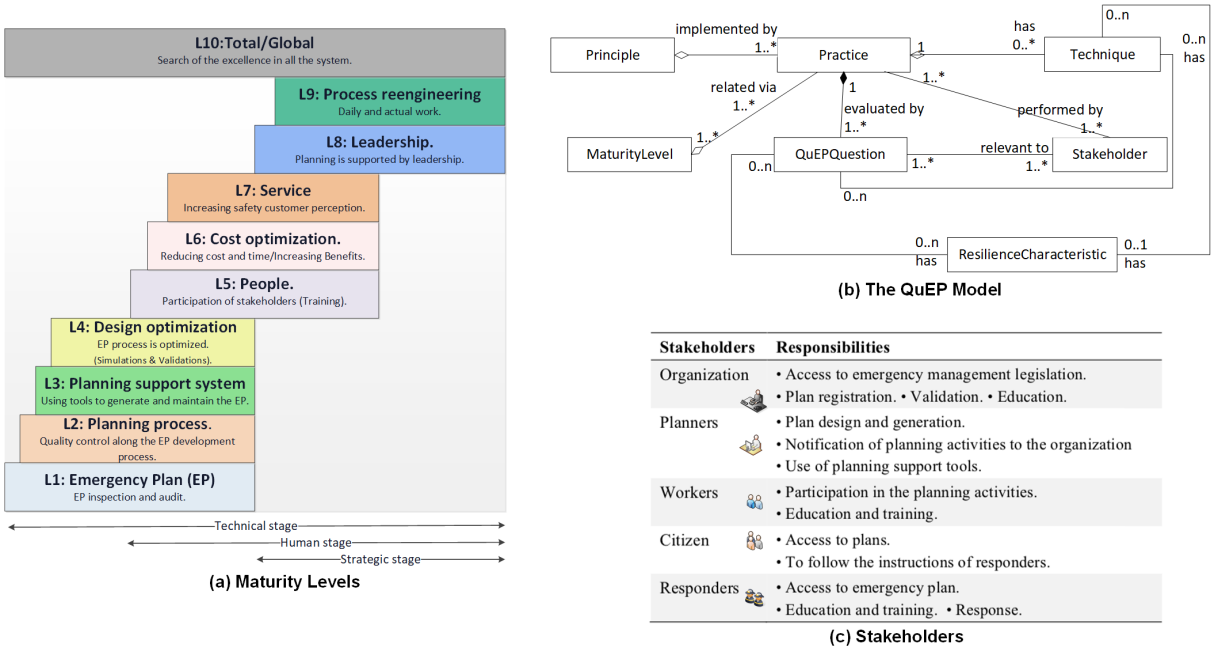

Figure 2. Maturity Levels and QuEP Model extracted from Núñez et al. 2016

Ten levels of maturity are defined in *QuEP*, from level 1 (L1: Emergency Plan) to level 10 (L10: GCT (Global/Total)). These levels are grouped into three stages: the technical stage, the human stage, and the strategic stage, following the approach proposed in Camison (Camisón 1998). Each of the levels associated with each stage is seen as the steps of a ladder that every organization committed to the search for quality improvement in the management of its emergency plan should try to climb.

QuEP principles are intended to guide the organization in the management of quality regarding emergency plans and planning processes, including the actions of all its stakeholders involved in emergency plan management activities (shown in Figure 2(c)). In *QuEP*, nine principles have been identified, including *Risk-Driven (A)*, *Implementation (B)*, *Participation (C)*, *Monitoring (D)*, *Cooperation (E)*, *Safety People (F)*, *Leadership and Policies (G)*, *Results of objectives (H)*, and *IT & Innovation (I)*. The practices are activities that facilitate the application of the principles of the QuEP framework and lead to the organization complying with them in the emergency plan management. The principles are implemented through practices that are carried out by all stakeholders in the organization. In *QuEP*, twenty-seven practices have been identified grouped by principle. For instance, practices such as *emergency drills*, *resource improvement and maintenance*, *process improvement*, and *process for updated emergency plan* concern to *Monitoring (D)* principle. The techniques provide the organization with the knowledge of what should be done to apply the best practices in the emergency plan management. A set of guidelines and recommendations associated with each of the practices was identified to identify the techniques, obtained from different guidelines, regulations or laws available in some countries. The resilience characteristics can be associated with questions and techniques as complementary practices and the coordination of multiple stakeholders working towards more resilient organizations.

Assessment of the *QuEP* framework by experts in planning and risk management is essential to validate its viability for evaluating emergency plan management (Núñez et al. 2016b). The results obtained from the *QuEP* questionnaires given to the stakeholders of an organization facilitate and automate the assessment of an organization and generate the appropriate improvement reports to identify the best practices through the support tool *QuEP-tool* (Núñez et al. 2016a). Results are presented to know the minimum requirements of an emergency plan management at each maturity level as acceptable or tolerable. Currently, the limit or threshold value μ=0,5 have defined from beforehand. Also, QuEP considers if a question has more weight than others. It means, there are questions more relevant.

Before certifying the emergency plan management first step is to perform tests in real organizations. A pilot assessment is essential to ensure that the *QuEP* model is adequate, viable and competitive in organizations under public administration regulations.

CERTIFICATION PROCESS

Our proposal for certification in organizations with *QuEP* follows a process, where the first step is the *preparation* that includes the selection of the organization and the stakeholders involved. Next step is related to the *QuEP application* in the assessed organization. The last step is the *reports presentation* to the organization related to its management of the emergency plan and the aspects that must be considered to achieve continuous improvement in its current and future activities.

Preparation

For the pilot assessment, we have selected as organization the 1F-UPV building at the UPV, and 25 *stakeholders* have participated based on roles defined in *QuEP*. In this context, we contacted the person responsible person for the emergency plan in building 1F, who participated in the organization role (Org.). A person responsible for planning and accident prevention in the UPV played the planner role (Pla.). Fifteen other people were selected for worker roles (Wrk.), of which seven were Master students, two professors, and six Ph.D. candidates in Computer Science. Eight people who had accessed the 1F building at least once participated in citizen roles (Cit.). The assessment of the responder role (Rsp.) was omitted, since no emergency drills had been held in the 1F-UPV building since 2011.

QuEP application

We have developed *QuEP-Tool v1.0* to carry out the application of *QuEP* in the 1F-UPV building. This tool support to apply *QuEP* and later get the results. In order to assess an organization *QuEP* uses questionnaires[1] according to principles and their associated practices, and a set of questions defined to assess the degree of compliance with each *QuEP* practice. Different techniques have defined to help the organization improve its practices and, as a consequence, to increase their maturity level.

To the 1F-UPV building assessment, only two of the nine principles have been assessed: the *Risk-Driven (A)* principle and the *Monitoring (D)* principle. The first step was to make visible the information and guides about the 1F-UPV building assessment through *QuEP* portal[2] protected by a password. The stakeholders who participated in this assessment were given a user password via email. The next step was to make the assessment, between April 23 and June 1, 2018. The research team then analyzed the results.

Reports presentation

The maturity levels obtained for the 1F-UPV building are shown in Figure 3. The organization reached a global maturity percentage of 54.8%, which we consider as tolerable although capable of improvement. For the certification of the emergency plan management, the tolerance should be considered at each level, defined in advance through a limit or threshold value. If we assume that it is 50%, this organization would be certified, but with a list of improvements to be made. The advantage of QuEP is that it also breaks down the results into levels, which allows a much more detailed analysis.

100% results were obtained at levels 3 and 6, since the answers to the questions for the organization holder and planner roles obtained the highest value. At level 7 most *stakeholders* responded that they did not know if the organization announced the programming of the emergency drills or if an analysis and report had been carried out after an emergency drill. Something similar happened at level 9, the vast majority were not aware of whether for example, the organization prepared periodic reports of emergencies (emergency drills, and incidents, among others) or if security inspections had to be registered.

Analysis by groups

The results divided into four groups for analysis. The first group (GRP-1, 17 *stakeholders*), consists of the results obtained from the planner (Pla.), organization holder (Org.) and workers (Wrk.), without considering the citizens (Cit.). The second group (GRP-2, 5 *stakeholders*) was made up of the results of the planner (Pla.), organization holder (Org.) and the workers (Wrk.) with experience in emergency plan management (two professors and one

[1] https://quep.webs.upv.es/quep-questionnaires/
[2] 1F-UPV building: https://quep.webs.upv.es/es/evaluacion- del- edificio- 1f/

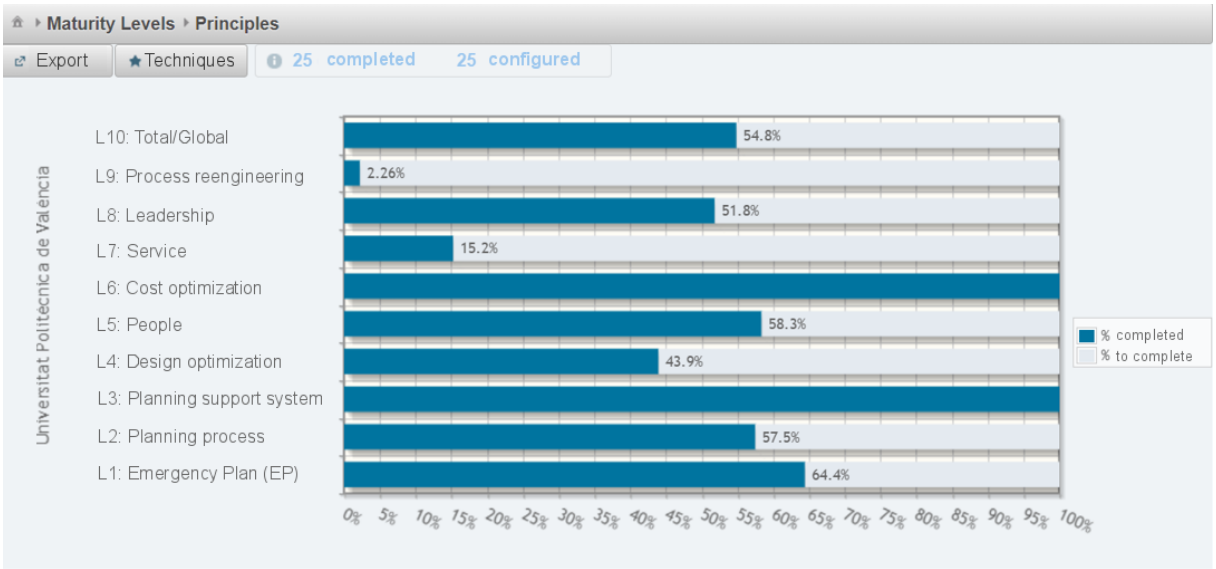

Figure 3. Results of the 1F-UPV building by *maturity levels*

Ph.D. student). The third group (GRP-3, 2 *stakeholders*) consisted of the results of the planner (Pla.) and the organization (Org.). The fourth group (GRP-4, 1 *stakeholders*) consisted only of the results of the planner (Pla.).

The results by stakeholder groups are shown in Table 1. The maturity percentage obtained at level 10 was 54.8% and in GRP-1 was 54.7%, which dropped by 1% because some citizens had more training in academic institutions than some Ph.D. students, who lacked information. In the following groups, we can see that the percentage increases as the groups are made up of participants who are aware of the management of emergency plans. In fact, the planner has the most information of the whole process of drawing up, implementing and maintenance of the emergency plan.

Table 1. Results by group

	All (25)	*GRP-1 (17)*	*GRP-2 (5)*	*GRP-3 (2)*	*GRP-4 (1)*
Global/Total (Level 10)	54.8%	54.7%	61.8%	66.8%	74.6%
Risk Driven Principle (A)	72%	71.1%	76.6%	77%	87.2%
Monitoring Principle (D)	43.2%	44%	49.5%	50.6%	67.3%

Although the score obtained from the planner results (GRP-4) is 74.6% excellent, we were interested in the planning process to disseminate the necessary information at all levels, so that the different *stakeholders* could have access to information and be trained in accident prevention. The results obtained by principles show that risk management is much better than monitoring in all the groups. The percentages obtained in the evaluation of the 1F-UPV building with the *stakeholders*' GRP3 and GRP4 responses were higher than those of the responses of all the *stakeholders*, since the planner and the organization holder have more knowledge than the workers and citizens.

Recommended techniques

Figure 4 shows an example of techniques or best practices that should be considered in the 1F-UPV building to increase the quality of the planner assessment in the emergency plan management (GRP-4), grouped by maturity levels. Only eight techniques are shown spread over three maturity levels, but the techniques increase as the stakeholder assessment is included.

Other aspects and recommendations

The results obtained in the 1F-UPV building gave us an overall view of its emergency plan management and the best practices that could be improved. In general, while 50% of the emergency plan management in this building is tolerable or acceptable, 45.2% of the activities need to be improved. This shows that the *QuEP* certification framework is viable, and can help organizations to improve their emergency plan management by looking at what can be improved and updated.

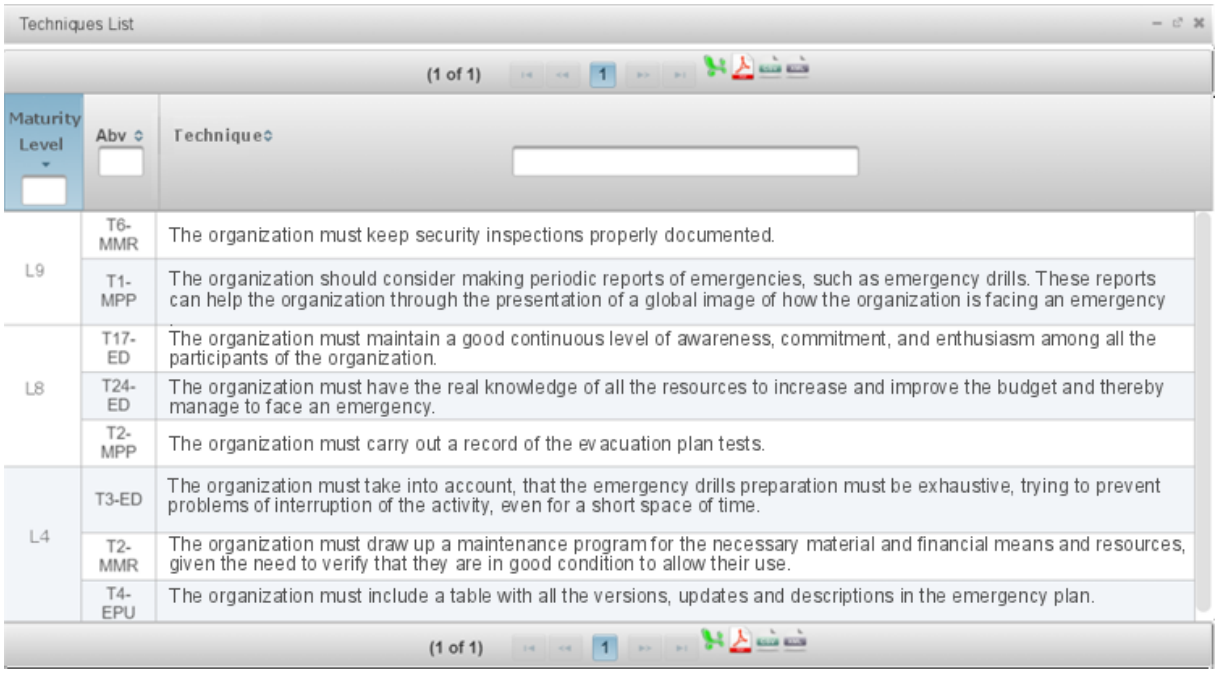

Figure 4. Recommended techniques after the evaluation of the 1F-UPV building (GRP4)

The assessment of the 1F-UPV building also showed that the emergency plan must be accessible to all the workers and not just to a group. For instance, the professors and Ph.D. students had better knowledge of the emergency plan because they are involved in research related to this domain. The Master students were aware of the emergency plan but did not have access to it. The citizens obtained better results than the Ph.D. students because the group of high school students selected had received training through annual simulations carried out at their school.

On the other hand, the emergency drills had not been carried out in the 1F building since 2011, after which the results were analyzed and conclusions were drawn, but no other action was taken. Most of the workers did not have a clear idea of the activities related to emergency drills. Further, after the 1F-UPV building assessment we considered it essential to obtain consistent results in the weights assigned to the *QuEP* questions on the expert evaluation (Núñez et al. 2016b) to give a degree of relevance to the different *QuEP* questions.

Consequently, adequate emergency plan management can increase the quality of all the activities involved, and organizations must focus on improving all the stages involved in the process.

CONCLUSIONS

The official certification of organizations about the emergency plan management is a work in progress. It can be viable as long as experts validated *QuEP* and assessed in real cases. For this instance, we have introduced the first proposal towards the certified through *QuEP*, and we have presented a study case in the 1F-UPV building. Next step is related to test the assessment by *QuEP* in more organizations and elaborate the final reports to each organization. As future work, we plan to contact public administration to propose the certification of organizations in assessing the emergency plan management.

ACKNOWLEDGMENT

We thank Raquel Garrido from the Planning Unit and Vicente Blasco from Departamento de Sistemas Informáticos y Computación of Universitat Politècnica de València (Spain), for their collaboration in the assessment of the 1F-UPV building with *QuEP-tool*. The work of M. C. Penadés is partially funded by MINECO under grant CALPE (TIN2015-68608-R) and the work of A.G. Núñez is partially supported by the Ecuadorian SENESCYT and IECE.

ABSTRACT

Giving adequate attention to training personnel within an organization to perform an activity of any kind determines its success or failure. Training in emergency management is a key point and the participants must have adequate preparation for each activity they carry out. The different activities in each emergency management phase generate the appropriate training according to the role performed by stakeholders. The training is provided through techniques and IT support tools that consolidate the knowledge imparted by the trainer. This paper describes the initial steps in creating a capability model to support the training of stakeholders and ensure the effectiveness of the response teams, as well as the appropriate actions of workers and citizens in an emergency. Knowledge is consolidated through training, evaluation and feedback from practice. The proposed model is being integrated in the QuEP framework to guide organizations in assessing and improving the management of their emergency plans.

Keywords

Capability Model, Training, Emergency Management, Stakeholders, QuEP.

INTRODUCTION

Emergency training methodologies evolve somewhat later than significant changes in educational methodologies. The training is initially focused on developing the response team's skills. At present, training for emergency management is aimed at developing capacities to respond to emergencies adequately or prevent disasters; it is essential to understand the causes of disasters, risk analysis, and response procedures. The causes of disasters must be analyzed to find the different factors that determine threats and vulnerability conditions (Ferradas et al., 2006).

Appropriate training of participants is of vital importance in all emergency management phases. Although there are general techniques and dynamics for training and improvement of skills (Suixiong P., 2009), we think that customized training in the field of emergency management is essential for organizations. Emergency management should be customized for each of the participants involved in each stage, so that investment in training for emergency management benefits both the person who receives it and the organization that trains them, which will be better prepared to deal with an emergency (or incident). Likewise, the support of Information Technologies (IT) tools in training is important for the continuous improvement of disaster prevention, emergencies, and reconstruction. The main problem is how to improve the training of the people involved in emergency management. Currently, the training is mostly theoretical or based on the experience of the stakeholders, and an evaluation with the corresponding feedback is not carried out after a training. In addition, the use of IT tools to

support training, reduce the high costs of drills and make it possible to apply the evaluation/feedback techniques to improve the training.

This paper proposes a capability model for organizations to define the customized training of all the stakeholders in each stage. This capability model establishes the guidelines to be followed in order to plan, train, validate, evaluate and obtain feedback from the training in an iterative manner, thus achieving the continuous improvement of the stakeholders teaching-learning process in emergency management. This process will be support by IT-tools.

The paper is organized as follows: Section 2 reviews the main concepts related to emergency management, training techniques and the dimensions of training involved in emergency management. Section 3 describes our proposed emergency management capability model, and Section 4 concludes the paper and outlines further research.

TRAINING FOR EMERGENCY MANAGEMENT

The knowledge acquired in training helps people not only to improve their knowledge but also to face emergencies or situations that arise unexpectedly. In fact, to avoid obsolescence of knowledge, periodic training should be carried out as recommended in the training plan. According to Strube (Strube et al., 2011), a training plan is based on activities that can help in collecting information about prospective new systems and the support of resource investments. The training content must contain theoretical information, experiences, and practices (Xing et al.,2010). Other authors, such as Das (Das, 2018), indicate the learning objectives, specify the learning outcomes and the skill and knowledge to be imparted to the learner. Ferradas (Ferradas et al.,2006) indicates the need to identify the study domain from which the contents of the training plan must be defined. From our perspective, good training not only involves a set of activities to be carried out periodically but also includes learning objectives, so that we therefore introduce the concept of the capability plan, which includes both aspects.

Techniques and tools that support the capability process can be applied to implement a capability plan. For instance, Fernández (Fernandez, 2005) indicates that it is necessary to consider the objectives pursued, the participant or group, its maturity, its training, physical environment, psychological environment, and the trainer capacity. Different authors have proposed different training techniques. For example, Ferradas (Ferradas et al., 2006) defined techniques such as interviews, participant observation, life stories, surveys, discussion groups, participatory diagnosis and identification of roles. Suixiong (Suixiong P., 2009) identifies other techniques such as lectures on theories, demonstration and training, individual and group practices. In this work we use the training techniques defined by expert trainers in (Adibi, 2000), who identifies six techniques, including *on-the-job training, conferences, role-playing, audiovisual, programmed learning,* and *simulations.*

The on-the-job training technique consists of assigning new employees to the experienced workers or supervisors who are in charge of actual training. There are several types of this training, the best known being: direct instruction and rotation of the position. The *conference* technique is practical and easy to implement and is a quick and easy way to provide knowledge to large groups. It can be accompanied by printed materials to facilitate learning. The *Role-playing* technique is used to teach sales techniques, interview techniques, to address groups, resolve conflicts and achieve negotiations or hold positions of greater responsibility and consists of having the professionals carry out roles according to the position or tasks they perform. *Audiovisual techniques* are related to the presentation of information to employees through audiovisual techniques such as films, closed-circuit television, audio or videotapes. The *programmed learning* technique consists of presenting a set of questions or facts for the student to answer, then it reviews and compares the answers and repeating the questions with wrong answers until all have been answered correctly. This technique is effective because it gives the employee immediate feedback on the accuracy of his answers and on the learning he is achieving. *Simulation* is a technique in which employees learn in real or simulated equipment the execution of their tasks, for example, simulated handling of machines, vehicles or airplanes. This training corrects errors without actually placing the students in dangerous situations and is almost a necessity in positions where it is too expensive or dangerous to train employees directly.

As technology influences the effectiveness of the training contents and training programmes, the organization should plan and arrange such training contents for the participants to motivate and benefit them. For example, e-training provides many opportunities for business organizations and employee as learners (Singh et al.,2015). The various opportunities include effective use of IT, delivery of updated knowledge and technologies anytime, anywhere and to anyone, cost cutting of training and the just-in-time philosophy. Other tools simulate serious games, as explained in two case studies in Heldal (Heldal, 2016). The first case is a simulated evacuation of a ship on fire and the second case the simulator provides response training in a train crash.

In the emergency management field, the purpose of training is to develop local capacities to respond to unexpected events and/or to prevent disasters. For this reason, it is essential to start from an understanding of the causes of

disasters and their consequences, which takes us to risks analysis. Cause analysis is necessary to determine the different factors that constitute threats and vulnerability to the population.

Ferradas identified the training dimensions in areas such as *Education*, *Social*, *Technical*, *Legal* and *Institutional*, and *Economic*. *Education* deals with the risk management theory and planning for development, disasters and livelihoods, rehabilitation and reconstruction in the perspective of development and minimum standards for humanitarian aid. The *Social* dimension refers to the organization and leadership, ethics and values, memory and history of disasters, perceptions of risk, prevention and adaptation strategies, the prevention culture, information needs, communication media, informal communication, information networks and information campaigns. The *Technique* dimension is related to risk assessment, the preparation of risk maps, the use of databases for geo-referencing and geographic information systems, preparedness and emergency response plans, technologies for disaster prevention and emergency response, early warning systems, damage and needs assessment, psycho-social rehabilitation, operational emergency management and the implementation of temporary shelters. The *legal and institutional* dimension refers to the existing legislation applicable to disaster prevention and response, law and regulation of Civil Defense, local laws and state policies in emergencies, priorities, support systems and distribution of aid. Finally, the *Economic* dimension deals with the economic impact of disasters and the profitability of investment in disasters.

Our proposal to improve emergency management training thus begins by defining a customized capability plan, which should contain learning objetives, activities, and contents classified by dimensions, techniques and tools.

CiET: TOWARDS A CAPABILITY MODEL FOR EMERGENCY MANAGEMENT

We has defined the capability model for emergency management, called the CiET model *(Continuous improvement for Emergency Management Training),* Our work is based on this model which allows customizing the training contents of each activity and emergency phase for each of the participants. The importance of optimal training translates into better resilience in emergency management, as well as reducing the number of victims and costs resulting from an unexpected event. The first step in building a capability plan is to identify the general parameters, such as the dimensions and techniques of the training, the phases, and activities of the emergency management and the expected learning objectives.

The second step considers the importance of the preparation of participants in emergency management. We based this on the Ferradas training dimensions and on the Fernandez techniques and expert trainers to define a capability model that emphasizes the customization of training contents for each of the activities of each phase, considering three phases: pre-disaster, response and post-disaster (Aligne, 2009).

We identified the main contents that will be taught in the training process regarding the activities of the emergency management phases, as shown in Figure 1. In the *planning or pre-disaster* phase, participants should be trained to identify the type of emergencies, to identify means of protection, to know building structures, to know the emergency plan, to know the legal and institutional regulations of the organization, to detect crisis, to carry out risk analysis and to identify an alert (crisis alert). In the *response* phase, participants should be trained in vital issues such as knowing the evacuation routes, identifying signs and using fire extinguishers. The response team should also be trained to use communication and rescue equipment and to give first aid and to act efficiently until the return to normality. In the *analysis or post-disaster* phase, participants should be trained to provide psychological support to victims, analyze damage costs, to improve their resilience to disasters and to identify future risks.

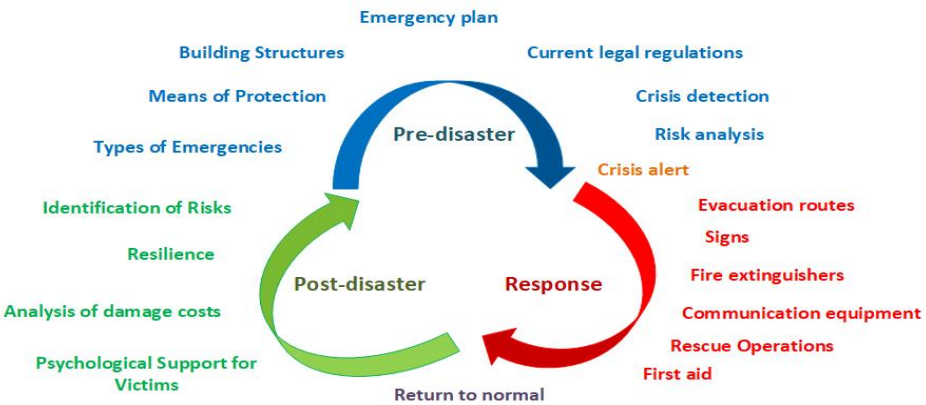

Figure 1. Training in emergency management

The third step was to identify the participants in the capability process, for which we referred to the following classification: organization, planners, workers, responders and citizens (Núñez et al., 2015). In the capability process there are two identified roles, the *trainer* and the *learner*. Organization, planners and responders can play the role of trainer and all the stakeholders fulfill the role of learner. There may also be an external trainer, who is an expert in the subject to be trained and who is not part of the mentioned stakeholders. Table 1 defines the responsibilities of each of the stakeholders and their role in the capability process. The *trainer* is an active participant in this process; this role can be played by some of the stakeholders (organization, planners, response teams). An external expert may also be required, who should be a professional in the subject. The *learners* are all stakeholders trained in the capability process.

Table 1. Stakeholders in the Capability Process (Based on Núñez et al., 2015)

Stakeholders	Responsibilities	Capacitation role
Organization	Access to emergency management legislation. Plan registration. Validation. Education.	Trainer and learner
Planners	Plan design and generation. Notification of planning activities to the organization. Use of planning support tools.	Trainer and learner
Workers	Participation in the planning activities. Education and training.	Learner
Citizen	Access to plans. To follow the instructions of responders.	Learner
Responders	Access to emergency plan. Education and training. Response	Trainer and learner
Expert Trainer	Expert in a specific topic.	Trainer

The fourth step was to relate the stakeholders that participate in the training with the training content and dimension. It is important to be clear about the contents, the dimension to which they belong and the people who should be trained, since adequate training can reduce costs and improve the resilience (Penadés et al., 2017) of people in emergencies (see Figure 2).

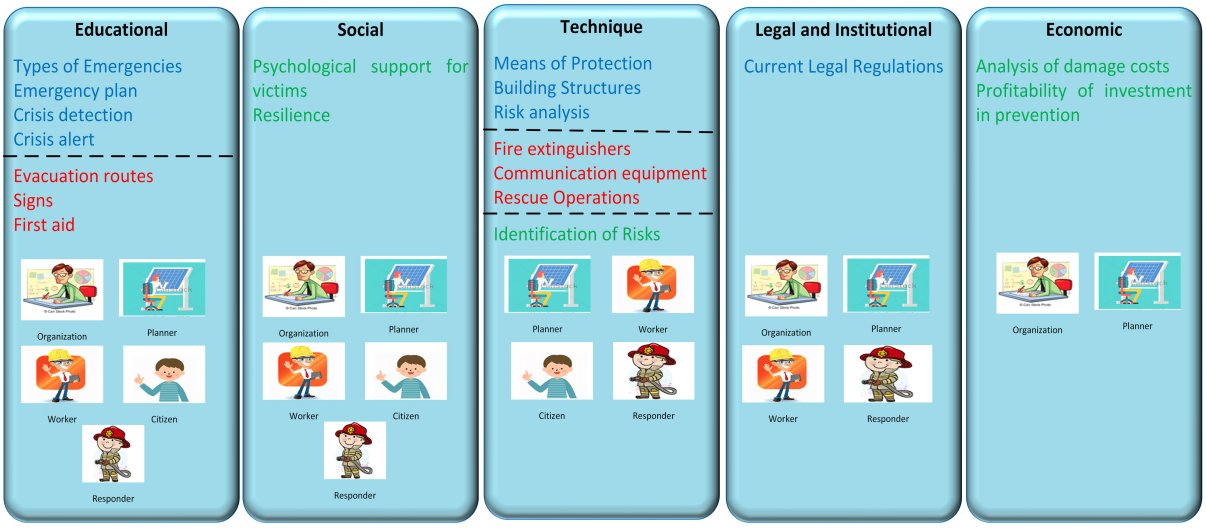

Figure 2. Dimensions, training content and stakeholders

In the Educational dimension all the stakeholders are trained in contents of the pre-disaster phase (emergency types, emergency plan, crisis detection and crisis alert) and the response phase (evacuation routes, signs and first aid). In the Social dimension all the stakeholders are trained in contents of the post-disaster phase (psychological support for victims and resilience). In the Technique dimension all the stakeholders, except the organization, are trained in the contents of the pre-disaster phase (means of protection, building structures, risk analysis, the contents of response phase (fire extinguishers, communication equipment and rescue operations) and the identification of risks in the post-disaster phase. In the Legal and institutional dimension all the stakeholders, except the citizens, are trained in current legal regulations of pre-disaster phase. Finally, in the Economic dimension, the organization and planner must be trained in contents of post-disaster phase (analysis of damage costs, profitability of investment in prevention).

CiET Capability Model

Figure 3 summarizes the proposed CiET capability model as a UML class diagram. A capability plan (represented by the *CAPABITY_PLAN class*) is a set of learning objetives (*LEARNING_OBJETIVE class*) related to the phases of emergency management (*EM_PHASE class*) with their respective activities (*EM_ACTIVITY class*). The training contents (*CONTENT_TRAINING class*) are specified in each of the emergency management activities, according to the dimension (*TRAINING_DIMENSION* class) to which they belong. For each content one or more techniques (*TRAINING_TECHNIQUE class*) and IT tools (*TRAINING_TOOL class*) can be applied. Supporting the learning of the stakeholders (*STAKEHOLDER class*) of the organization (*ORGANIZATION class*) through evaluation (*EVALUATION class*) provides feedback and the continuous training of stakeholders.

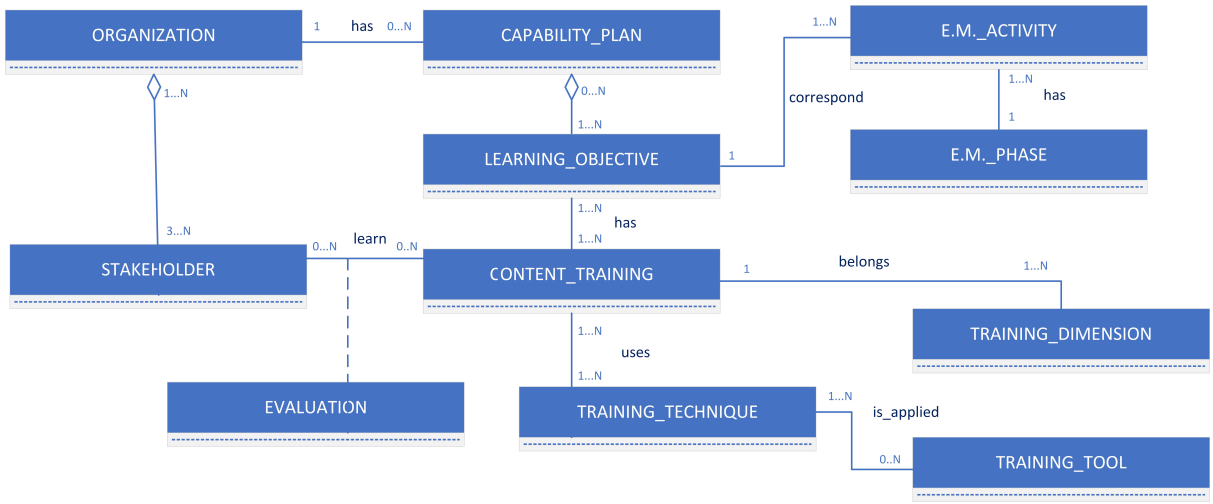

Figure 3. CiET Capability Model

An organization defines the customized capability plans of the stakeholders according to the learning objetives established in the selected emergency management activities. The most relevant aspect the capability plan is to evaluate the training contents and measure the fulfillment of the learning objectives established. If the training contents and learning objectives are not met, the training content should be reinforced, and the evaluation repeated to provide feedback to the learning process and redesign the capabiltiy plan if there are deficiencies in the contents or unreal learning objectives.

Defining CiET capability plans

An organization will define their customized capability plans according to the CiET model. For instance, Figure 4 illustrates different capability plans for the learning objective "Evacuation Routes". CiET Plan 1 is for citizens and CiET Plan 2 for responders. The CiET Plan 1 covers the educational dimension, and the CiET Plan 2 covers the technical dimension and the educational dimension. The trainer in CiET Plan 1 can be an expert trainer or a responder trained, but for CiET Plan 2 must be a expert trainer. Therefore, in CiET Plan 2, the contents are broader and deeper, and the techniques used in each content are more oriented to simulations, audiovisual and practical learning. Finally, it must be evaluated and provide feedback through conferences and IT tools that allow repetitive training and evaluation with comparative results to reinforce the shortcomings found and achieve the learning objectives set.

Evaluation-Oriented Training

One of the main weaknesses of training activities and processes in disaster prevention and response continues to be the evaluation of such activities and the impact of the educational process in general. The evaluation may be related to a specific educational action or to the more comprehensive training process. The evaluation must be done in three stages of the training process. At the beginning, the training process is carried out to identify what knowledge or skills the participant has and adjust the training to the needs of the group (leveling). During the training process it is used to follow up the progress achieved by the participants. In order to assess the levels of knowledge of the beneficiaries and the effectiveness of the training methods, it is necessary to implement ongoing assessment programs during the training and, if possible, to implement any corrective measures. The final evaluation is the most frequently used and can verify whether a sufficient level of knowledge and skills has been reached.

Figure 4. CiET Capability Plans

Evaluation-Oriented Training

One of the main weaknesses of training activities and processes in disaster prevention and response continues to be the evaluation of such activities and the impact of the educational process in general. The evaluation may be related to a specific educational action or to the more comprehensive training process. The evaluation must be done in three stages of the training process. At the beginning, the training process is carried out to identify what knowledge or skills the participant has and adjust the training to the needs of the group (leveling). During the training process it is used to follow up the progress achieved by the participants. In order to assess the levels of knowledge of the beneficiaries and the effectiveness of the training methods, it is necessary to implement ongoing assessment programs during the training and, if possible, to implement any corrective measures. The final evaluation is the most frequently used and can verify whether a sufficient level of knowledge and skills has been reached.

Consequently, the key to evaluation-oriented training is feedback. We understand by feedback the answers and comments that are given to stakeholders after performing a training content or evaluation. Feedback has the potential to support academic achievement, promote motivation, self-regulation and self-efficacy, allowing stakeholders to reduce the distance between current performance and desired performance (Seel, 2012).

Feedback is a good way to determine the effectiveness of the training process and the degree of satisfaction of the stakeholders in order to have an accurate idea of what should be improved and where additional training may be necessary. It can be done at the end of each session or at the end of the training. The results obtained from the evaluation and feedback can measure the fulfillment of the learning objectives and achieve the continuous

improvement of the capability process and the CiET capability model.

Finally, the proposed CiET capability model is related to the improvement of the organization's capability. As the CiET model is the basis for defining a process of continuous and customized improvement of the stakeholders' training, it is not simply an isolated proposal to improve training in emergency management, but can be integrated into frameworks for improving emergency management, such as QuEP (Núñez et al., 2015). We are now working on integrating the CiET capability model into the QuEP framework – Level 5 (People) which assesses the participation of the people involved in emergency plans generation and enactment, principally via training and education activities (see Figure 5). This QuEP assessment includes a set of best practiques to improve in each level. The CiET model provides a solution to applied the QuEP recommendations and practices. The main aim of this integration is to obtain an integral and effective solution to improve an organization's emergency management and the capability of the stakeholders by providing customized plans, training techniques and tools, an evaluation process and feedback. The CiET Model can be applied to an organization after its evaluation using the QuEP framework to improve the level 5; the organization needs to implement a capability model for its human resource or for improvement the personal training in emergency management. The validation of the capability model will be done through training experiments to groups of stakeholders, according to QuEP. The experiments will be evaluated to obtain the feedback and apply the continuous improvement of the training and the CiET model.

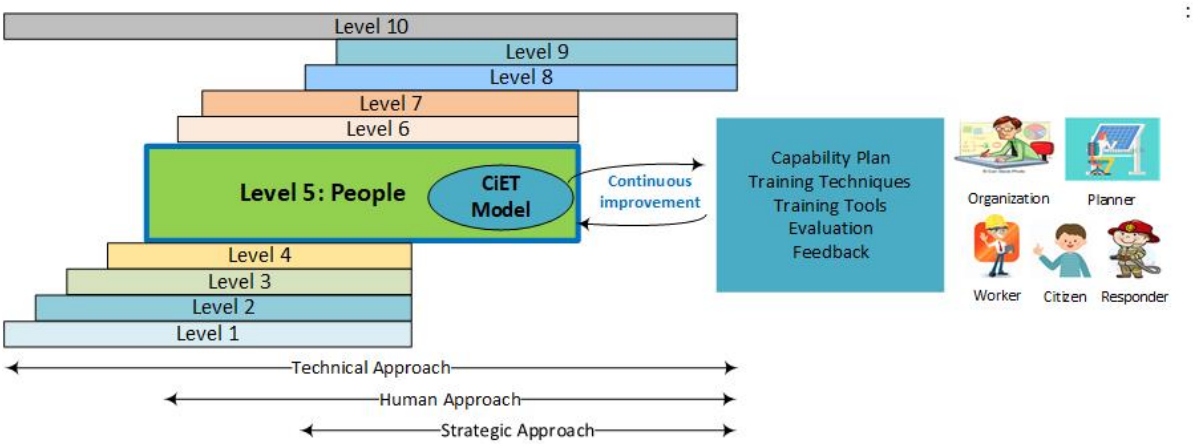

Figure 5. Integrating CiETModel with the QuEP framework (Based on Núñez et al., 2015)

CONCLUSIONS AND FUTURE WORK

The CiET capability model proposed here can identify the elements and stakeholders participating in the improvement of training in emergency management. Training contents are customized and unambiguous for each stakeholder, which means that organizations are better prepared and trained, and the victims, damage and costs are reduced after an emergency. As work in progress, the CiET capability model is being integrated into the QuEP framework to improve emergency management in organizations. In future work, the CiET proposal will be expanded, not only to improve the model and validate it with real case studies, but to develop support and IT tools that support its implementation and implantation.

ABSTRACT

To deal with a crisis situation, experts must undertake a chain of activities, called process, to minimize crisis consequences. To assist the expert in making decision in crisis resolutions, authors propose a method aiming at discovering crisis response processes. This method is based on a two-step strategy: the first step classifies the system's traces, representing stakeholders' past actions, into different sets, where each one represents a set of response processes according to a specific context; the second step uses process mining algorithm to discover the corresponding response plan process model based on the obtained chain of activities for each previously classified context. These response plans will be a referenced aid for experts while making crisis resolution, according to each context. The proposed approach is illustrated on the traces issued from the crisis caused by the 2010 Xynthia storm in France.

Keywords

Crisis management, traces, response plan, clustering, process mining.

CRISIS RESOLUTION: SHOULD IT BE AUTOMATIC NOWADAYS?

Disaster and crisis are real challenges in a practical life. They often are unpredictable (Maryam & Kamran, 2016) and they may cause damage to human lives and have environment and economic consequences. According to (Nikolai et al., 2015), a crisis is defined as "*any event that threatens to, or actually does, inflict damage to property or people*". Crises can be small or large scale, they can happen at any time and their consequences can be very different (Nikolai et al., 2015). Crisis origins are extremely diversified Sauvagnargues, 2018), it can be natural (flooding, storm, *etc.*), environmental (fires, explosions linked to infrastructures, *etc.*), human (terrorism, arson, *etc.*) or technological (virus, computer failure, *etc.*). Few years ago a survey involving 1430 companies worldwide showed that "*despite a significant increase in risks from both external and internal sources, only 47% of companies consider that they are sufficiently prepared to the crisis situations*" (Leblond, 2004). More recently, in (Recovery, 2017) authors claim that "*companies that do not have a crisis management plan are far less able to minimize the crisis's impact*". Over the past few years, we realise that whatever the crises' origin is, the crisis's understanding and the reducing of its damage become more and more important. Moreover, the complexity and the dynamicity of crises make it difficult to understand crisis situation and to elaborate the most appropriate response to it.

To deal with this issue, the term of *crisis management* emerged at the beginning of the 20th century, but it had not been really used till the 1960s. The crisis management encompasses all tasks aimed at resolving crises and reducing their impacts. In the literature, the crisis management is structured in several phases. In (Tufekci & Wallace, 1998), authors proposed an approach with two phases: *before-crisis* and *after-crisis*. The *before-crisis* phase is a prevention and preparation phase that sets up an immediate response to resolve the crisis. The *after-crisis* phase consists in rebuilding and re-establishing the crises' damages. Another approach also involves two phases (Sundar & Sezhiyan, 2007): a *crisis phase,* aiming at mitigating and preparing for crisis occurrence, and

[1] Dr. Ho is now at Kereon Intelligence, France - hoang-nam.ho@kereon-intelligence.com.

a *response phase* that represents all of the actions needed to be carried out as soon as possible to face the crisis. Hereafter, we focus on the response phase in the process of crisis management.

In order to cope with crisis situation, different actors and resources need to collaborate to efficiently respond to the crisis. Actually, actors involved in a crisis resolution perform consecutively their activities following a coordination of the crisis situation called *response plan*. This plan is a kind of workflow that contains activity sequences performed by one or several actors during crisis situations. To model the response plan, many notations have been defined over the past few years. We have chosen BPMN (Business Process Model and Notation) as a notation language for end-users[2] (Object Management Group, 2011). BPMN is a powerful modelling method that can easily model complex real processes such as response plans. It provides a standardized matching between real processes and mathematical formalism that helps authors to be more flexible in manipulating and validating all kinds of business processes. Figure 1 gives an example of a process corresponding to a response plan that describes some prior activities to be carried out at the beginning of a crisis occurrence.

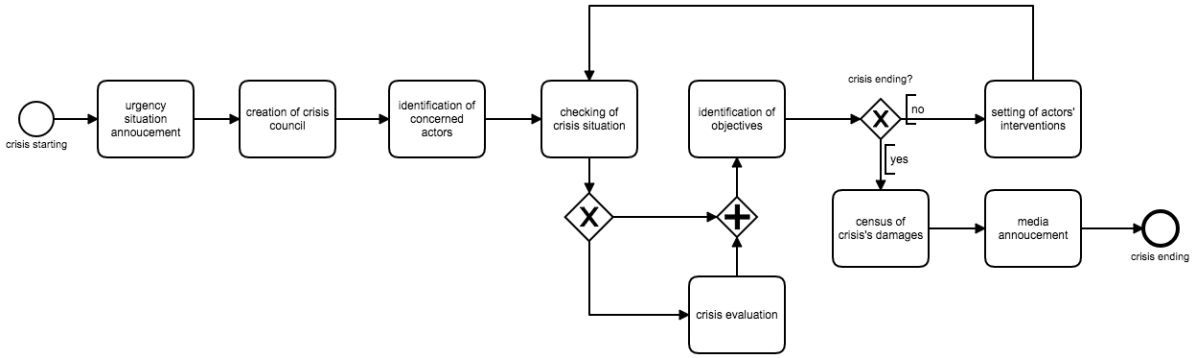

Figure 1. Example of response plan (BPMN) for first time of crisis situation

Crisis's experts are involved as soon as the crisis arise. They supervise the crisis to plan and they decide what should be done to resolve the situation. As depicted in the Figure 2, at each moment, a crisis context is observed. Experts choose a response plan to face the observed context and they must adapt this plan according to the situation changing. The adopted response plan is often based on experts' experience. They are trained to deal with the crisis situation and are able to decide the appropriate activities to carry out. However, there may arise sudden and unpredictable situations that experts have not forecasted. In that case, it takes more time to formulate a suitable plan according to the unexpected circumstances and the lack of immediate knowledge may be another impediment for real-time reactions in experts' decisions. Furthermore, the response plan should be tailored to specific circumstances of various situations that may locally occur during a crisis. As consequence, experts have to develop different response plans to face different crisis contexts.

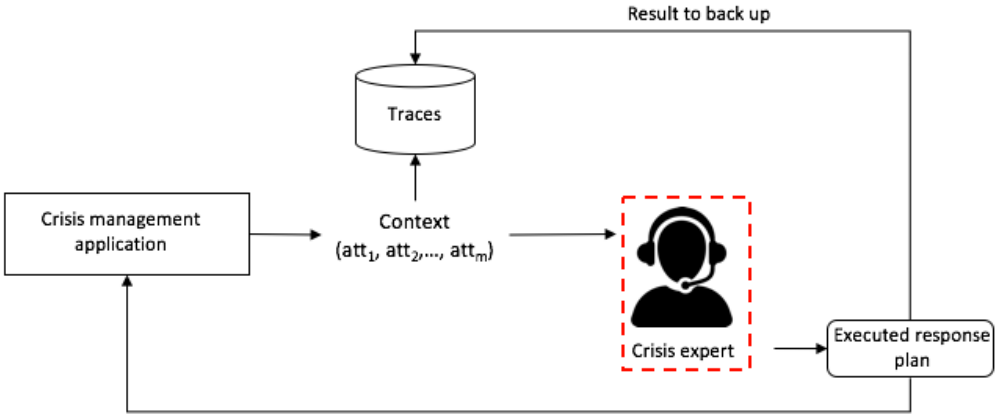

Figure 2. Expert's crisis participation in Crisis Management System

The aim of our work is to assist experts in their decisions. Authors propose an approach that helps experts design a response plan based on collected data from previous crises.

Authors assume that there is a crisis management system at the crisis time. This kind of system includes a database that records all observed events and performed tasks, called *logs*. Observation and evaluation of the

[2] Throughout this research, all of the considered response plans will be denoted in BPMN format.

recorded logs are often based on analysis of large volumes of data representing the contextualized information collected during system's execution, called *traces* (George et al., 2016).

- A *trace* is a sequence of data generated by any action regarding an object or an event occurring during system's execution. It is a set of temporally situated elements.
- Each trace can be associated to a model called *trace model*, that formally represents the corresponding traces. It contains the attributes concerned by the traces, as: *time*, *date*, *user id*, *performed action*...
- The component that allows to collect, handle and analyse traces is called a *Trace-Based System* (Settouti et al., 2009; Lebis et al., 2016).

The traces help us to analyse the previously performed workflow in order to discover the response plan applied at that crisis time. The question is: how to explore the recorded traces in order to get a response plan (workflow type) during the crisis's situation? *Process mining* (van der Aalst, 2016) emerges in the literature as possible response. It represents a set of techniques that could discover business processes from available traces. In our work, a process corresponds to a response plan to a crisis situation.

Authors intend to combine the two aspects introduced above, system's traces and process mining, in order to achieve their main objective: develop a method to assist crises experts in making a response plan at crisis time. The method combines technics from both domains in the crisis management issue. The paper especially focuses on the experimentation of the proposed approach on a real crisis to demonstrate its efficiency and its ability of producing a real-time response plan for crisis situations.

The paper is organized as follows. Next section briefly presents how the crisis resolution is made in the recent years. Then, the case study based on Xynthia windstorm crisis, occurred in February 2010, is presented. It will be used to illustrate the approach and to show its performances. The approach is explained just after, followed by some experimental results and discussion Finally, we conclude the paper and give some guidelines for further research.

HOW WAS CRISIS RESOLUTION MADE IN RECENT YEARS?

A response plan can be seen as a process composed of a set of ordered activities to deal with the crisis situation. The activities and their execution order are described in a predefined scenario or in available official plans. According to a given situation, a concrete response plan must be selected from a set of available alternatives and applied in order to solve the crisis. Over the last years, this topic has risen in importance. In this section, we will examine how responders do in a crisis situation and how to make a response plan to deal with it.

(Le et al., 2017) stated that an activity-oriented process is considered to make a response plan during a crisis. The obtained process model represents activities and exchanged messages between the actors involved in a crisis. Authors have used the α-algorithm (van der Aalst, 2011) to discover the process model from a log file. In (Kushnareva et al., 2015), the BPMN model is implemented to face the flood crisis. This model is predefined based on the collaboration between several actors involved in flood resolution, as the police taskforce, fire brigades, authorities for emergency situations, *etc*. Another application of this approach is used to represent the response plan to face the tsunami in Ho Chi Minh city (Thanh et al., 2013). Authors explain clearly the roles and the tasks of each stakeholder (local administration, local civil defence forces, communication unit, police and health units). The plan assures coordination between these actors. A common drawback in these approaches is that they are based only on textual documents. They specify how to face a crisis and then researchers model the available documents to build a response plan in a process-based notation. It is static and does not take into account past experience: what was done in previous crises and how the predefined procedures were adapted to a given crisis and its contingencies. It is an important source of knowledge that needs to be considered.

Concerning the use of past information to build a response plan in a crisis situation, few works address this issue. In (Negre, 2013), the author exploits the knowledge acquired in past experiences to recommend the best action to deal with the current crisis. A United Nations report points out that former experiences should be taken into account in order to improve the response plan making (United Nations, 2006). The use of past information is also mentioned in (Hanachi et al., 2016). Authors analyse the interactions collected from involved actors during the crisis situation. With this information, authors can discover a meaningful coordination patterns that reflect the organizational structure and the interaction protocols, which are part of the considered response plan. Authors have used process mining techniques (van der Aalst, 2016) with the extension of organizational and interactional dimensions. Another research aimed to discuss the application of process-based in emergent situation (Ariouat et al., 2016). Authors claimed that the collaborative processes in crisis management require a context description for process flexibility. They used the definition of context description in crisis management (Rosemann et al., 2008). Context is defined as the minimum of variables containing all relevant information that

describes it. Context observation allows deciding what should be done to adapt actions to the current situation. Furthermore, a case study of disaster response and emergency management is presented in (Valcik & Tracy, 2017). Authors identify all actors involved in crisis response, but it is a manual work and it is still based on hard-copy documents describing the experiences from other crises experts.

To the best of our knowledge, very few researches deal with the problem of making a response plan in crisis situations. Building automatically such plans is the motivation of our research work. By combining different existing aspects in this domain, we propose a strategy, which is the main purpose of this article, aiming to discover a response plan for each crisis's context based on the recorded traces. We propose to combine two complementary points of view:

- The first one is to use the crisis context to differentiate activities performed by several actors involved in previous crisis situations.
- The second one is related to the use of process mining technics to discover the response plans. Based on the process mining, we can extract the set of response plans corresponding to different past crises' contexts. This set will be used to assist crises' experts during future crises.

The proposed approach is based on traces generated and collected during previous crises, we start by introducing the case study use illustrate our proposed methodology.

CASE STUDY: XYNTHIA WINDSTORM 2010

To illustrate our approach, we consider data sets collected during Xynthia crisis. It was a violent European windstorm that crossed Western Europe from February 27th to March 1st, 2010. In France, civil authorities consider Xynthia as the most violent storm since December 1999, at least 51 persons were killed, and 12 more said to be missing. It reached its highest warning level (red) for five French administrative departments: Charente-Maritime, Vendée, Deux-Sèvres and Vienne.

The Trace-Based System used by the fire-fighters allowed collecting various data. The data set records 274 interventions of fire-fighters for the Charente-Maritime and 277 interventions for the Deux-Sèvres. Each intervention may involve one or several vehicles depending on intervention contexts. In the sequel, we describe how the traces were collected and transformed.

Traces collection

In the considered crisis management application, experts interact with the system by controlling a sequence of activities to respond to the crisis situation. Observation and recording of crises' information has to be done exhaustively. Data retrieved from this step contains all information observed during a crisis. There may be information on the crisis location, information from the crisis operation centre. Besides, experts should choose one response plan according to the current context at each crisis moment. All of these types of data should be captured and analysed to extract the relevant information.

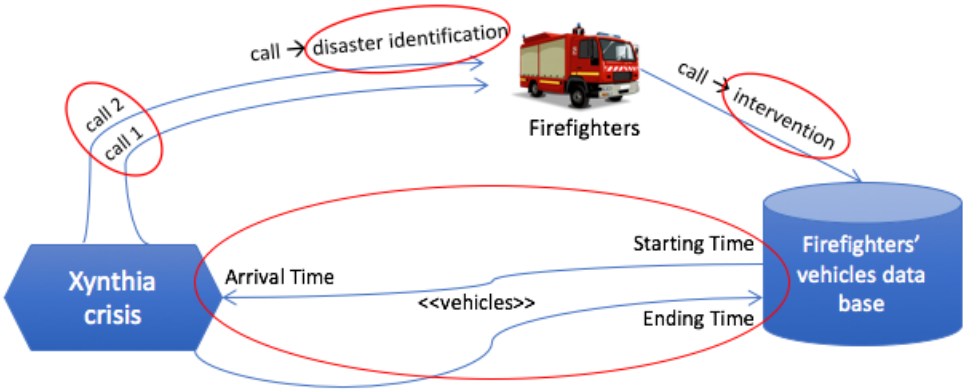

Figure 3. Traces collection in Xynthia crisis

For instance, Figure 3 describes the fire-fighters traces collection process of Xynthia crisis. Citizens and possible victims call the fire-fighter's switchboard to report about the disaster and possibly ask for help. The Fire-fighter's Operation Centre (FOC) receives the calls and based on the caller declarations identify the type of disaster or local crisis situation. According to its classification (*event type*, *severity level*…), FOC creates the corresponding intervention to resolve the reported disaster. Each intervention sends one or several vehicles to

the crisis place to deal with the disaster. The set and the chaining of used vehicles are considered as the response plan for the FOC. Figure 4 gives the model of traces collected during Xynthia crisis. These traces are then used in the *transformation* step.

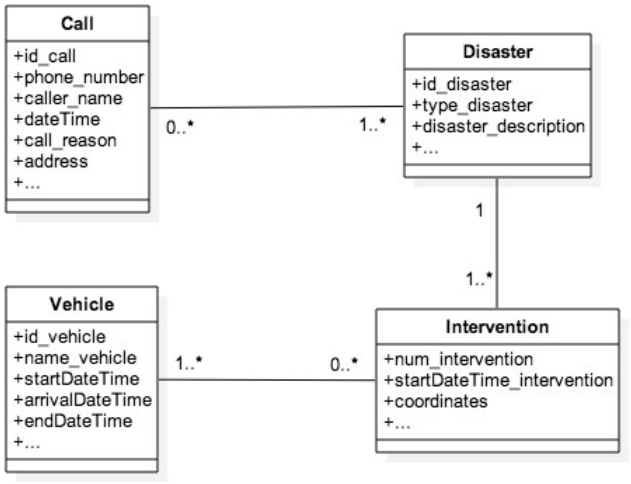

Figure 4. Class diagram of the Xynthia data set

Traces transformation

During this step, collected traces are handled in order to extract the necessary information for the process mining that follows. 3 actions are performed:

- Data filtering: experts should choose one response plan according to the current context at each crisis moment.
- Temporal ordering of filtered data for each intervention: authors need to order temporally all of a_i in A to get a temporal sequence of performed activities. Figure 5 depicts a sample of traces after performing the filtering and the ordering.

Figure 5. Sample of primary traces of the firefighters' intervention during Xynthia storm in France

- XES conversion: to use process mining techniques, authors need to transform all of the performed activities into eXtensible Events Stream format[3].

Figure 6 shows a part of the transformed traces that describe the performed activities for the intervention 4257. There are three activities that are executed successively: VTUHR[4], LPS[5] and VSAV[6]. Each one represents the used vehicle at some moment during Xynthia.

RESPONSE PLAN DISCOVERY IN CRISIS SITUATION

The previously obtained transformed traces base is then analysed. In this paper, the traces analysis constitutes the proposed approach and is described in the following. Our strategy to build a crisis response plan from the traces is depicted in Figure 7. We use the transformed traces base T_T obtained in the previous section. The method contains two steps: context classification and mining of the response plan.

[3] IEEE 1849-2016 XES Standard (http://www.xes-standard.org).
[4] VTUHR (Véhicule Tout Usage Hors Route): all-purpose off-road vehicle
[5] LPS (Lot Premiers Secours): first aid bundle
[6] VSAV (Véhicule de Secours et d'Assistance aux Victimes) : victim emergency and assistance vehicle

The first step classifies the transformed traces base T_T into different clusters. Different activities were carried out during the crisis in order to respond to one or several different contexts. Classification's purpose is to gather activities related to each specific context. As a result, we obtain the set of h clusters that will be used in the next step. Each cluster represents the chain of activities performed in the corresponding context.

Figure 6. Example of transformed firefighters' traces during Xynthia

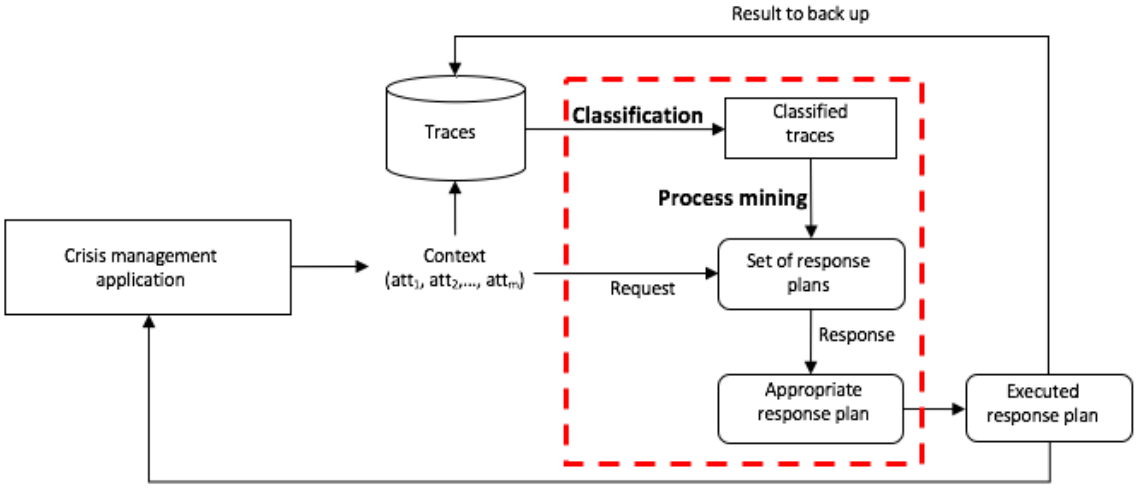

Figure 7. Process of Assisting Automatically a Resolution in Crisis Situation

The second step computes, for each cluster identified above, the response plan corresponding to its context. The discovery of the response plan is based on the chain of activities and is done by applying process mining. Among the available process mining techniques, authors have chosen the Inductive Miner (Leemans et al., 2014). At the end of this step, we discover the entire response plan that has been followed for each context in the recorded past crisis.

The two steps are detailed in the following subsections.

Context classification

The transformed traces base T_T is divided into different clusters according to different contexts distinguished by their attributes. For each context, each concerned actor creates one or several interventions that contain one or several activities to perform. The context classification works as follows. At starting point, it initializes the first record in T_T as the first cluster. Then it computes the centroid context for the first cluster, denoted by $\hat{c}_1$ and obtained by applying the formula (1) on the cluster of N records. It then computes the distance d between the context of the second record in T_T and the centroid $\hat{c}_1$ of the first cluster. The distance $d(context_i, context_k)$ between $context_i=(att^i_1, att^i_2, ..., att^i_m)$ and $context_k=(att^k_1, att^k_2, ..., att^k_m)$ is computed in (2).

$$\hat{c}_h = \left\langle \frac{\sum_{p=1}^{N} att_1^p}{N}, \frac{\sum_{p=1}^{N} att_2^p}{N}, \ldots, \frac{\sum_{p=1}^{N} att_m^p}{N} \right\rangle \quad (1)$$

$$d(context_i, \hat{c}_h) = \sqrt{\sum_{q=1}^{m} (att_q^h - att_q^i)^2} \quad (2)$$

If the distance is less than some predefined threshold s, the second record is added to the first cluster and the value of $\hat{c}_1$ is updated. Otherwise, a new cluster is created with the second record, associated to the centroid context $\hat{c}_2$. The method iterates for all records in T_T and the distance is computed with the centroid context of each already created cluster to determine their respective clusters. At the end, we obtain the set of distinct context clusters.

Traces of the use case are classified according to different contexts by applying Algorithm 1. $C^{Charente\text{-}Maritime}$ and $C^{Deux\text{-}Sèvres}$ are respectively the set of classified contexts of Charente-Maritime and Deux-Sèvres and are the input sets for the next step, mining of the response plan.

Table 1: Context classification result

Department	Number of classified contexts
Charente-Maritime	size($C^{Charente\text{-}Maritime}$) = 25
Deux-Sèvres	size($C^{Deux\text{-}Sèvres}$) = 30

Each element in $C^{Charente\text{-}Maritime}$ and $C^{Deux\text{-}Sèvres}$ is a set of activities performed by fire-fighters in the specific context. For instance, the context type 119 found in the data set concerns 5 fire-fighter's interventions. Figure 8 gives the corresponding traces description.

Figure 8. Example of the five interventions in the context (type 119)

Mining of the response plan

To mine a response plan for each cluster, we apply on the set C above a process mining technique to extract the corresponding process model (representing the response plan) that has been applied in the previous crisis. Among existing process mining techniques, authors have chosen the Inductive Miner algorithm because:

- Crisis traces are always real-life data; they represent exactly what happened in a crisis situation. Inductive Miner algorithm is sound and adaptable for real data.

- Inductive Miner output (process tree) can be easily converted as BPMN.
- Inductive Miner is currently one of the leading discovery approaches thanks to its flexibility, formal guarantees and scalability.

The detailed description of the Inductive Miner's advantages and algorithm is given in (van der Aalst, 2016).

IM is applied to Xynthia crisis's data set to discover a response plan according to every crisis's context. The input of this step is the obtained results of the context classification phase, C, the set of h clusters of traces. For each cluster C_i in C, IM creates a directly-follows graph $G(C_i)$ based on discovered relations between activities in all of cluster records. Then IM selects a type of cut to split $G(C_i)$ into different sub-graphs. An n-ary cut of $G(C_i)$ is a partition of $G(C_i)$ into n pairwise disjoint sets $G_1, G_2, \ldots, G_n$ with $G(C_i) = \cup_{i=1 \text{ to } n} G_i$ and $G_i \cap G_j = \varnothing$ for $i \neq j$. A cut in IM is denoted $(\varepsilon, G_1, G_2, \ldots, G_n)$ with $\varepsilon \in \{\times, \rightarrow, \wedge, \circlearrowleft\}$.

The resulting set P of response plans corresponds to the known contexts. If a new crisis arises, the crisis's context(s) will be observed and compared with recorded contexts to check if there is an adequate response plan previously used in former crises that could be applied in the current crisis. Current and every referred context in P are compared using formula (1). According to this distance, we may suggest response plan from P to resolve the current crisis. It is important to note that the response plan proposed by this approach is still a suggestion for crisis's experts. They could change the response plan or adapt it in any way according to additional real-time data that they may have. Actually, each crisis situation is never really the same as some previous one and there are often unexpected events that arise during the crisis time.

Inductive Miner algorithm is now applied to extract behaviour processes for each context of our use case. The resulting process tree is given Figure 9. In the presented example, intervention 3 involves activity VTU[7] followed by activity LEPELEC[8], in the intervention 4 VTU is followed by LEPELEC and the intervention 5 involves only VTU. The null activity models the fact that sometimes VTU is followed by LEPELEC and sometimes not. This is the reason why we obtain the black rectangle in our process tree. Its formalism is: $\times$ (*VLCG, VTUHR,* $\rightarrow$ (*VTU,* $\times$ (*null, LEPELEC*))).

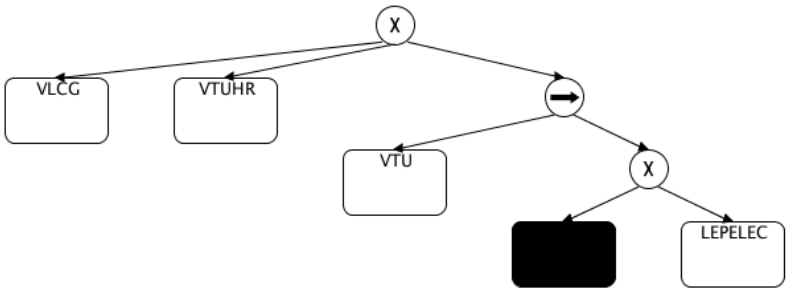

Figure 9. Process tree of the context (type 119)

Finally, the process tree is converted into BPMN. Figure 10 shows the result of this step on the example of Figure 8 and represents the response plan for the context 119. It summarizes what was done by the fire-fighters to face the context type 119 during the Xynthia crisis. The resulting plan becomes a referenced help for the fire-fighters for the next crisis's context of type 119.

The presented example is based on 4 traces, so it produces a relatively simple process tree and response plan. However, with more data more complex process models may be obtained. For instance, the context type 61 that contains 14 traces is modelled by the response plan depicted in Figure 11.

EVALUATION

Authors have assessed the performance of the proposed approach by different tests to evaluate the quality of discovered processes (response plans). Authors focused on the four quality dimensions generally used to evaluate an obtained process model that are:

- *Fitness*: this measure assesses the extent to which the obtained process model could reproduce all the available traces. To measure the fitness, we can replay the recorded traces on the obtained process model to identify mismatches between them. The formula to compute this quality can be found in (van der Aalst, 2016) and (Buijs et al., 2012).

[7] VTU (Véhicule Tout Usage) : all-purpose vehicle
[8] LEPELEC (Lot Épuisement Électrique) : electrical exhaustion bundle

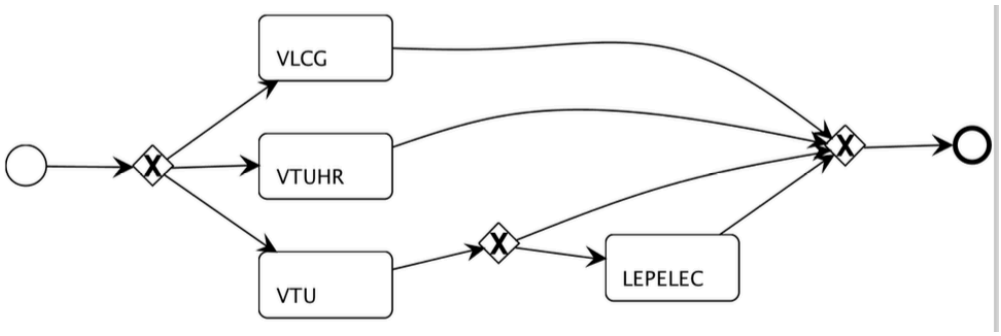

Figure 10. Response plan (BPMN) of context (type 119)

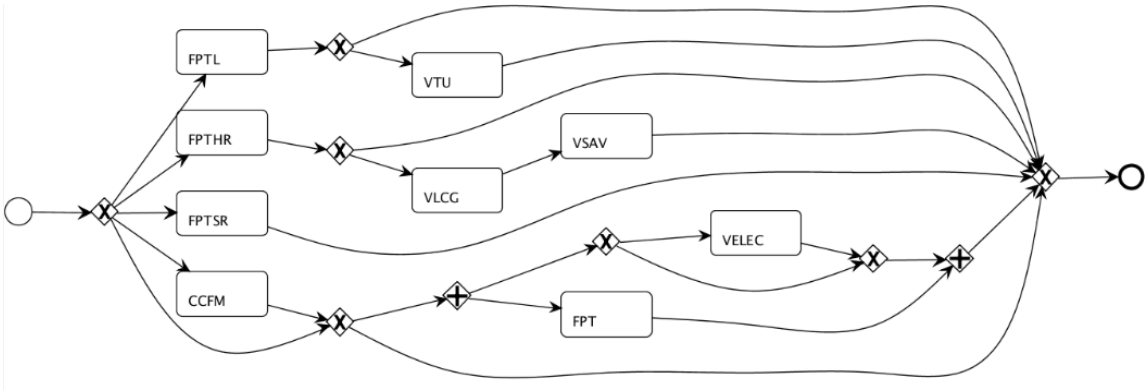

Figure 11. Response plan (BPMN) of context (type 61)

- *Simplicity*: this value represents the structural extent of the process model. This aspect is intuitive and still discussed in the community. The simplicity evaluation depends on the users' point of view. There exist a variety of methods to compute the process model simplicity. We have chosen the structural characteristic to evaluate model's simplicity (Rozinat & van der Aalst, 2008).
- *Precision*: a model is precise if it does not allow too many different traces (Buijs et al., 2012). In other words, precision describes the fraction of the activities allowed by the model but not seen in the traces.
- *Generalization*: this kind of process quality quantifies the extent to which the obtained process model will be able to reproduce the future traces of the process (Buijs et al., 2012). In different terms, the model should generalize and not restrict to the available sequence of activities seen in the already collected traces (van der Aalst, 2016).

The value of these metrics ranges from 0 to 1, close to 1 the quality is more satisfied. It is very difficult to find a balance among the quality dimensions above. For example, precision and generalization cannot be satisfied simultaneously. Four metrics were computed on the obtained process models in order to assess these qualities. However, we especially would like to insist on the fitness quality. Our main research idea is to extract the response plan from the available traces. Authors need a response plan that should represent all of the past activities. The fitness dimension assesses this property.

Figure 12 and Figure 13 are respectively the obtained results on the four quality dimensions above for French departments Charente-Maritime and Deux-Sèvres. Authors focus mainly on the capacity of modelling process based on available traces. If a process obtained by the method is able to replay all the traces, we conclude that the mined process fits well with the past activities (the fitness metric is represented by the blue column in and Figure 13). Authors emphasize that on the two obtained results, the value of fitness is always satisfied (equal to 1). This result illustrates that the process model discovered by the proposed method synthesizes all the processes performed in the past and that the obtained response plan accurately represents what fire-fighters do in previous different crisis's contexts.

The three remained qualities also impact the obtained results in the process mining domain. Based on the number of traces in each cluster, authors could discover a simple or complex process. When the number of traces increases (for instance, context type 47, 22, 118 of the Charente-Maritime and 34, 52, 2 of the Deux-Sèvres), the resulting process model may be very complex (the value of simplicity is always under 0.5). Nevertheless, the more complex the process is, the more its generalization quality deteriorates (the value of generalization is always over 0.5 for contexts mentioned above). Furthermore, the experimentation shows that it is very rare to get

a process model with both high precision and high generalization qualities.

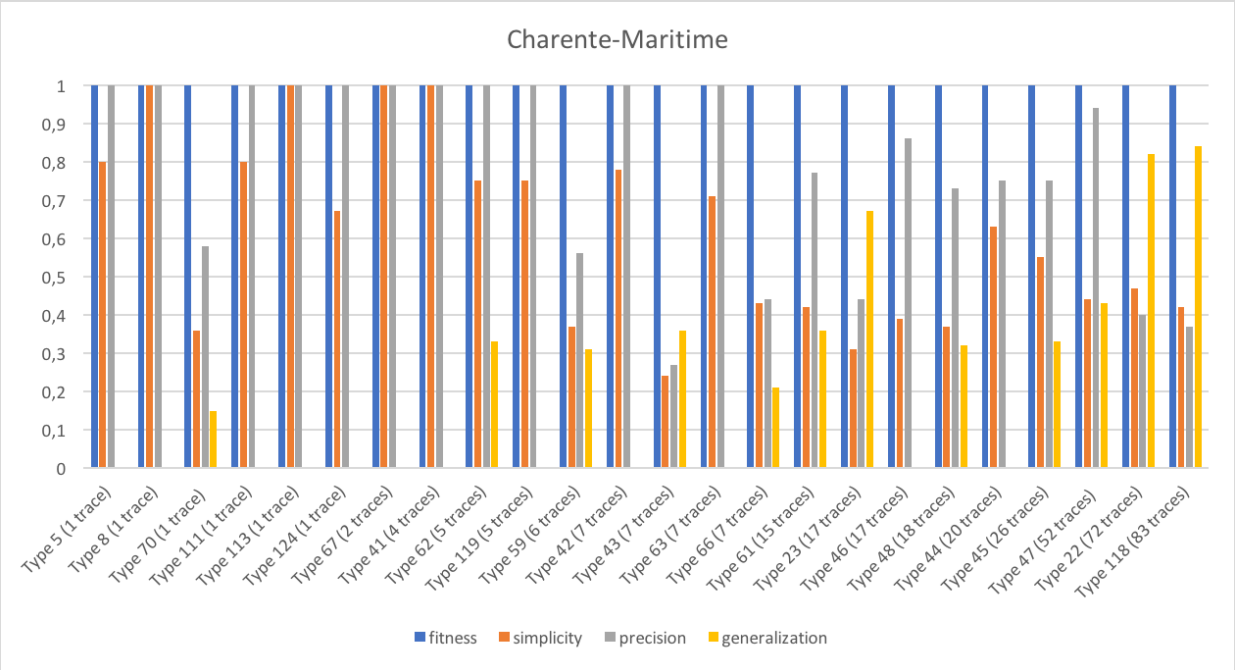

Figure 12. Four quality dimensions on the obtained results (Charente-Maritime department)

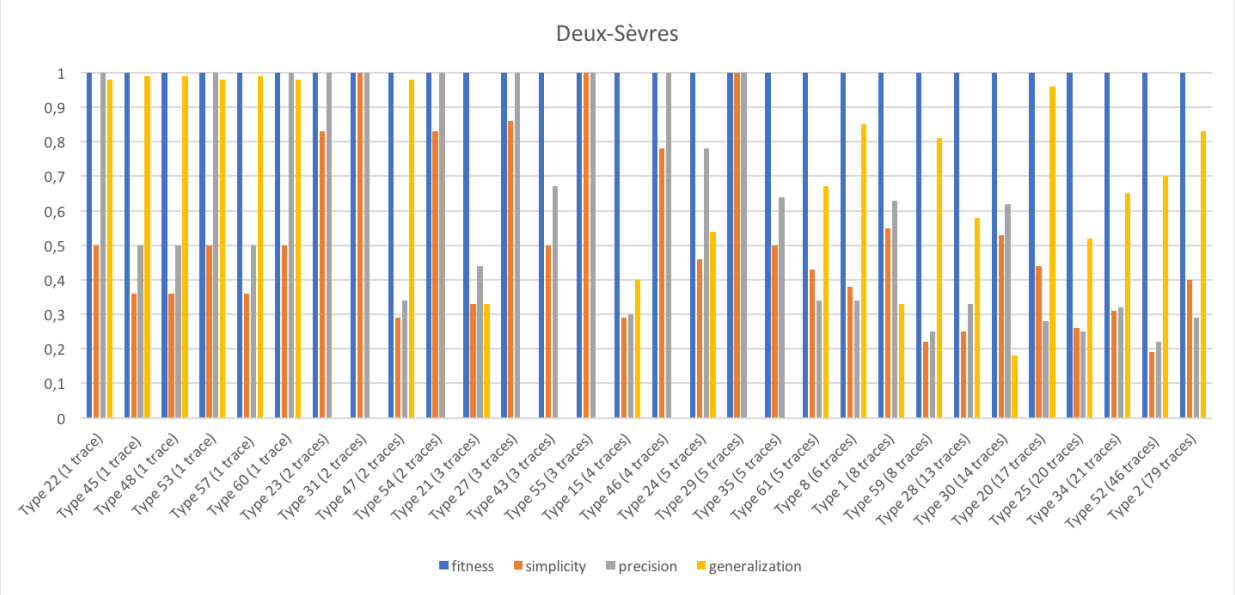

Figure 13. Four quality dimensions on the obtained result (Deux-Sèvres department)

To summarize, the obtained results illustrate that the proposed approach could assist experts during crisis situation. By integrating the context classification in the proposed approach, authors could classify different performed activities for every different context in crisis. By applying Inductive Miner, authors proved its efficiency on modelling a response plan (process) based on activities classified traces.

LIMITATIONS

The approach has some limitations. It is efficient only if enough traces are available. If there is not enough data, we cannot obtain a general process model, the quantity of the available traces directly influences the relevance of the resulting response plan. It is the reason why an expert is always required to assist the response plan validation throughout the time of crisis. In case of non-relevance, expert could change the suggested response plan and adapt it to the current crisis situation.

Another key issue of the proposed method concerns the context classification. This step computes a distance

between a current context vector and each centroid context vector. The value for each attribute in this vector should be numerical in order to apply the Euclidean distance. However, to describe a context of crisis situations, we may have a vector that contains different types of attributes that could be discrete or continue. The used distance formula may not be suitable. In terms of semantics, this type of distance does not take into account the semantic difference between two contexts. The distance computation should be adjusted to overcome this limit. Moreover, each attribute in the context vector has its different relative importance. An attribute may be considered as important in some crisis, but it may be not important in another one. Therefore, multi-criteria weighting (Ho et al., 2014) should be performed to estimate the relative importance between considered attributes in the context vector for each type of crisis in order to overcome this issue.

CONCLUSION

This paper presents a strategy for assisting experts to make a response plan for a crisis situation. The approach is based on the analysis of traces collected during previous execution processes in past crises. A Trace-Based System was adapted to crisis context in order to collect and transform the recorded information. The proposed approach is applied to extract the response plan for each identified crisis context. The approach first classifies the context and the performed activities in past experiences into different sets of activities according to different discovered contexts. Then Inductive Miner, a process mining technique, is used to discover the process model based on the set of previous activities. The resulting process represents the response plan that is suggested as a reference aid for experts to resolve the current crisis.

The proposed approach answers the problem stated at the beginning of this paper: how to automatically discover a response plan in crisis situations? In terms of methodology, we have described in detail how the proposed approach strategy works. Besides, we applied the approach on a case study of fire-fighter's interventions in French departments Charente-Maritime and Deux-Sèvres during Xynthia windstorm crisis in 2010 to assess approach's efficiency.

As perspectives to the presented work, authors intend to overcome the mentioned limitations to get a suitable strategy to different crisis contexts. On one hand, the presented methodology will be included in a crisis management environment under development. This environment aims to provide to experts and to different actors a set of centralized data collection, data visualization and communication tools to deal with crisis situation. On the other hand, we seek to generalize and improve the classification procedure especially by defining a more general and more precise distance computing function including multi-criteria attributes weighting. Furthermore, authors underline the importance of experts' role in crisis situation. Even though, the number of traces will automatically increase over time since the trace-based system of the crisis management environment will accumulate crisis data when new crises arise, authors propose to combine the response plan obtained from the proposed approach with experts' skills and experience. Since the expert remains the qualified decision taker for crisis management.

ACKNOWLEDGMENTS

The research was conducted as part of the GeDyCRisM ERDF-ESF project in collaboration with Systel SA, a french company proviging technology expertise especially for Fire & Rescue Services. Authors particulary wish to thank Fabrice Lainard for his valuable technical feedback.

ABSTRACT

The main goal of this WiPe is to analyze a wicked problem of disaster management, to offer an external evaluation on how the emergency system worked and to plan a foresight exercise able to design a personalized emergency response services to citizens. The first part of the paper is rather a hindsight analysis regarding disaster management of "Colectiv 2015", one of the worst manmade disasters in the recent Romanian history. After four years of investigations and reports and many recovery measures "Colectiv 2015" is still a complex problem that needs external evaluation. The second part of the paper is a two-tier research: an intermediary analysis of the wicked problem, using Barry Turner's framework and a design of a foresight exercise. In the Conclusions of WiPe we propose a design of research meant to: 1) better understand the causes and shortcomings of disaster management and failure of foresight and 2) help the Emergency System in Romania build a disaster resilience mechanism.

Keywords

Disaster, emergency management, wicked problem, Delphi, personalized emergency system.

INTRODUCTION

"Colectiv 2015" was one of the worst manmade disasters in the recent Romanian history, by impact. An accidental fire that lasted a couple of minutes, ignited on October 30, 2015, in a rock club triggered a disaster with 64 people dead and over 150 people injured that eventually led to the massive revolts in the streets of Bucharest, 3 days of national mourning and resignation of the Government. The ongoing criminal investigation opened three files/grounds with 11 people arrested. Further investigation is underway with many conflicting views and interests that lead to the conclusion that "Colectiv" file is a wicked problem that needs external analysis (Arafat, 2016).

On the other hand, the extreme event has been taken into consideration by the Romanian Emergency System in planning but the impact was a major one. An investigation of Zulean and Prelipcean of perception of leaders regarding the risks and preparedness revealed that natural disasters such as earthquakes or large-scale forest fires were considered the most probable and the Emergency System are the most prepared (Zulean and Prelipcean, 2013) while industrial disaster has a marginal attention.

The main goal of this paper is to describe and explain the wicked problem, to offer an external evaluation on

how the emergency system worked (planning, response and recovery) and do a foresight exercise to make the Romanian Emergency resilient in coping with the unexpected events. This will be an academic study of an actual occurrence of the unexpected by examining the unexpected situation, the human roles and actions they took and the results.

The first part of the paper is dedicated to the presentation of the event from the response to recovery. The second part will describe the results of investigations and lessons learned based on Turner's analysis framework. The last part will propose to use a collaborative methodology to analyze the causes of disaster, starting from the results of the Turner's method, and the solutions for coping with unexpected and to improve effectiveness of Emergency System.

"COLECTIV 2015" DISASTER: RESPONSE AND RECOVERY

The unexpected fire occurred on the evening of October 30, 2015 during a concert in the Colectiv Club, where around 350 people were present, according to the participants' estimates, in a place improperly arranged for such activities, as the available data and subsequent investigations showed, fire caused by the fireworks used during the concert, fireworks that led to the ignition of the polyurethane sponge (easily flammable) used for soundproofing on a pillar of the building. Flames expanded very rapidly throughout the club, causing injuries and deaths, through combustion, asphyxia, carbon monoxide intoxication a.s.o., to a significant number of concert participants.

Tragedies such as the Collective Club are not singular, to apply Normal Accidents Theory to understand the extreme events and correct the Strategic Planning process. Several years ago similar type of fire broke out in the Kiss Club in Santa Maria, Brazil on January 27th, 2013, in which 233 people died, and another 630 people were injured (BBC, 28 January 2013). Brazilian police stated that the fire began from a pyrotechnic device that ignited flammable acoustic foam in the ceiling.

Another similar incident took place at a shopping mall in the Siberian city of Kemerovo on 25th March, 2018. The tragedy in 64 dead people, including 41 children (Hayes, 2018). The shopping center was developed in a former candy factory, and the fire safety rules / procedures seem to have been ignored, possibly also as a result of officials' corruption. Another fire occurred more recently, on January 4th, 2019, in an "escape room' game in Koszalin, Poland, killing 5 teenage girls and seriously injuring a man (BBC, 5 January 2019).

Even though considered a "black swan", such events are happening quite often and this led us to deepen the studies and look them from a different perspective, possible as accidents that could be predicted and even prevented by implementing certain rules and procedures.

The Colectiv Club was one of the approximately 50 companies operating in an old hall in the former four-story building of the "Pionierul" factory, starting on May 2013. Changes in the structure of industrial activity have determined that many buildings belonging to former industrial firms change their destination, making possible the emergence of new economic activities in these unused spaces. There is nothing unusual and the economic activity has experienced several episodes over time. Generally, these facilities change their destination, requiring new space improvements and arrangements, and, finally, new operation permit.

The magnitude of the event led the MAI to establish the Red Plan of Intervention, and the Romanian Government decreed three days of national mourning. As a result of the massive protests following the fire, Victor Ponta and his government resigned on November 4, 2015, as well as the Mayor of Sector 4, Cristian Popescu Piedone.

Both from the perspective of the analysis of the events and the existence of theories and practices in the field, it is necessary to analyze the way of intervention, but also the aspects that made possible the functioning of the club as a concert hall and the lighting of fireworks in a closed space, respectively, of what happened in Romanian hospitals and how other countries and international organizations reacted to help our country.

The chronology of events shows the very short fire time, 113 seconds, between 22:30 and 22:32. In another 10 minutes, the first ambulances and firefighters trucks arrived at the scene and the victims were transported to the hospitals, 11 hospitals in the Bucharest-Ilfov region, and in the coming days, on the basis of bilateral agreements, to hospitals abroad. The Red Plan for Intervention at the IGSU level has been activated. Only a few of these 11 hospitals activated the White Plan, a plan that is equivalent to the IGSU Red Plan, but not all hospitals had this White Plan of Intervention (the hospital response plan in the event of a massive influx of patients following a collective accident, etc.). Moreover, there was no centralization and coordination at that time at the Operational Center for Emergency Situations level. At 23:15 came the first news on TV about the incident at the Colectiv Club that initially talked about an explosion with several wounded and dead, and then

about a raging fire. Parents, relatives and friends of some of those who participated in the concert have arrived at the scene asking for information about the victims. The police intervened at 23:30, sealing a perimeter of several streets around the club building, the streets being filled with intervention cars, fire brigades and ambulances. The announcement was initially made by Raed Arafat at 23:55 with a brief press statement: a fire with more injured and 18 dead. At 0:08 Minister of Internal Affairs, Gabriel Oprea, has taken the communication and announced that the number of deaths reached 25. Also, it was made available to people relatives a phone number to receive information and then, at 2:00, the Minister of Internal Affairs reported new data on the fire.

Has the IGSU Red Plan been activated too late, what happened from the operational level - the White Plan of Intervention - in the hospitals, whether or not, in the event of such disasters, would it be the unique coordination at the level of the National Center for Integrated Management, the fire from the Colectiv Club required the activation of the EU Civil Protection Mechanism?

THE LIMITS OF EMERGENCY MANAGEMENT

The presentation of the collective club accident leads to its categorization into the disaster category as an accident involving multiple victims, a collective accident, far beyond the situation of an emergency, defined as the situation where the resources and capabilities exist for each victim/ patient. Therefore, being the most serious civil emergencies incident in recent history of Romania, it is necessary to identify the causes and factors that facilitated the fire, so that recommendations on the measures to be taken to ensure that such "black swan" incidents (low probability - high impact) are eliminated, if possible.

In order to identify the causes of disasters, but also to highlight the limits of emergency management, the analysis can be started from both the past and the future. It is difficult to accurately quantify what involves an exercise of foresight, but we believe it should be an element in triangulation of the results.

The impact and the complexity of interventions in such situations need new approaches and efficient solutions for decision making process in disasters management. Decision makers in extreme risk environments should respond in a different manner because of a new complex and changing global environment and also decision making in critical or special situations is very complex.

Amir Hossein Gharehgozli et all (2016) recommended a framework to deal with wicked problems. However, that is not applicable to “Colectiv” case due to the lack of historical records of past disasters to compare with. So, we found out that Barry Turner’s framework applied by Panos Constantinides to explain the failure of foresight in crisis management for the case of Mari disaster (Constantinindes, 2013).

Most crises are perceived as unexpected events, but several precursors or warnings are usually identified on hindsight by the media or crises investigators. This paradox is at the heart of Barry Turner's failure of foresight framework, who emphasized the process leading up to a disaster, by proposing the following six stages of crisis development which can unfold over long periods of time: Normal starting point, Incubation period, Precipitating event, Onset, Rescue and salvage and Cultural readjustment (Constantinides, 2013). Next we will employ Turner’s framework to clarify the wicked problem of “Colectiv 2015” disater.

Stage I - Normal starting point (1990-2015)

Romania is a country in transition from a Communist organization to a Capitalist way of life and democracy. As mentioned elsewhere, the transition required institutional transformation, privatization and autonomous institutions, including the Emergency System. A set of norms and regulations that address the emergency preparedness and civil protection where designed before 2007, when Romania joined the EU and the implementations continued afterwards. The Colectiv Club was located in a former factory’s hall, being built of reinforced concrete, without windows and having as single available exit a small door of only 80 centimeters. Changes in the structure of industrial activity have determined that many buildings belonging to former industrial firms change their destination, making possible the emergence of new economic activities in these unused spaces. There is nothing unusual and the economic activity has experienced several episodes over time. Apart from being wrapped inside with a soundproof polyurethane sponge, a highly flammable material, it had on the ceiling dry pinewood grilles, which can also sustain fire.

Stage II - Incubation period (2013-2015)

The Colectiv Club was one of the approximately 50 companies operating in an old hall in the former four-story building of the “Pionierul” factory, starting on May 2013. It seems that the existing fire norms and procedures were almost entirely neglected or mimicked since there were hundreds of persons participating in other past events hosted by the respective club, well above the declared number of 80 seats, and the polyurethane sponge on the ceiling was cleaned, most likely with flammable substances. With only three small fire extinguishers and

no water sprinklers, the club operated based on the declaration of responsibility of its owner, without the neccesary approvals for the security in case of fire. However, officers from Emergency Situation Inspectorate were at least 3 times at the club, without taking any concrete steps to ensure the customers' safety.

Stage III - Precipitating event (September - October 2015)

On Friday night, October 30, 2015, a free concert of Goodbye to Gravity rock band was organized. About 350 people were present at the event, according to some participants' estimates.

Stage IV – Onset (30 October 2015, between 21:00 - 22:30)

At 21:00, the concert started and, at 22:30, a new song begun with pyrotechnic effects. The fireworks were installed in the Colectiv Club by two authorized experts. However, the fireworks appear to have not been put at the proper distance to a pillar packed with polyurethane sponge and it began to burn. The flames quickly spread to the club's ceiling and became violent. A dense smoke filled the club and the incandescent pinewood grilles from the ceiling begun to fall over those left in. There was panic and the crowd began to run towards the single available exit. The victims were burned, suffocated or intoxicated with smoke or the emitted gases.

Stage V - Rescue and salvage (30 October 2015, 22:32 – November 2015)

At 22:32, the first call to 112 was recorded and, at 22:42, the first two ambulances and firefighter's trucks arrived at the Colectiv Club. The fire was extinguished quickly, while the medical staff from the ambulances and a new born hospital, located nearby, gave first aid to the severely affected persons and those in the cardiorespiratory stop, the victims being resuscitated in the street. The magnitude of the event led the Ministry of Interior to declare the Red Plan for Intervention and, in the next few minutes, more than 20 ambulances arrived. At around 01:00, the last wounded persons were transported by ambulances or friends' cars to the designated hospitals.

After the first news about the incident appeared on television, on 23:15, parents, relatives and friends of some of those who participated in the concert have arrived at the scene, asking for information. A phone number was allocated in this respect and the Secretary of State for the Emergency Situations, Dr. Raed Arafat, as well as the Minister of Interior, Gabriel Oprea, made press statements to keep the people informed about measures taken in the aftermath of the incident.

Following the fire in the Colectiv Club, 64 people died and another 186 suffered different injuries, 146 of whom were hospitalized. Several people died at relatively long period of time from the incident itself (in some cases, even after few months) due to the complications that occurred, many of which were caused by the improper conditions in the Romanian hospitals, as some independent sources of information say.

Stage VI - Cultural readjustment (November 2015 - today)

Following the incident, three days of national mourning were declared and, on the background of the massive protests, the Prime Minister Victor Ponta and his Government resigned, together with the Mayor of the 4th District of Bucharest, where the Colective Club was located.

Several investigations have been conducted so far, but none have managed to offer a comprehensive picture and provide an objective understanding of the facts. These include two criminal investigations, an extensive Report of the Romanian Government, as well as a Report of the Department for the Emergency Situations and several media investigations.

The first Public Prosecutor Charge was instrumented by the Prosecutor of the High Court of Cassation and Justice against the owners of CLUB COLECTIV S.R.L. and GOLDEN IDEAS FIREWORKS ARTISTS S.R.L for unintentional killings, body injuries and failure to take legal measures of safety and health at work, 8 people being indicted (Ministerul Public, 2017). Among the indictments there were facts such as allowing a large number of people to enter the club, lack of multiple emergency doors and running an improper pyrotechnic show in a closed space. The file is judged by the Court of the District 4, Bucharest.

The second Public Prosecutor Charge was instrumented by the National Anticorruption Directorate for several offences, allegedly committed by people in charge with taking decisions and issuing authorizations in the City Hall of Sector 4 Bucharest, such as: abuse of office if the civil servant obtained for himself/herself or for someone else an undue benefit, forgery when drawing up documents (DNA, 2015). A third charge is under review for the death in the hospitals after the recovery stage.

The newly appointed Prime-minister Ciolos tasked a control team that eventually elaborated an 84 pages report about the "Colectiv" disaster (administrative capacity of the emergency system, its response and management of victims after the medical intervention). The conclusions of the Report were that the response was not well

coordinated with improvisations due to: lack of exercises on major disasters; legislation loopholes and lack of equipment and material resources (Guvernul Romaniei, 2016). As far as the institutions involved their activity has been assessed as properly for the Prefect and Special Telecommunication Service and modest for Emergency Unit "Dealul Spirii" (responsible for the area), Department of Emergency Situations and hospitals involved in intervention.

The Prime-Minister's Report received immediately a response from the secretary of state for Emergency, Dr. Raed Arafat, who elaborated a counter-report of 143 pages with annexes (MAI, 2016). In his conclusions, Dr. Arafat claimed that the PM Report don't uses enough evidence and it is based on media reports, don't understand the terms and the PM final proposal of a radical re-organization of the emergency system is not grounded on a well-established expertise.

A third Report on lessons learned from "Colectiv" has been presented in March 2016 to the public by the Department of Emergency Situations (MAI, 2016b). The Report is based on personal and institutional reports of the people involved in response to the disaster. It analyzes each operative situation since the first call, problems identified, relevance level, lessons learned and proposals. The conclusion of the Report is that the issues were very specific and didn't identified structural causes. However, it suggested an independent analysis by experts to avoid the subjectivity.

From the several investigations and reports, one can identify many causes and shortcomings of response and recovery. Thus, the club was built of reinforced concrete, without windows, and wrapped inside with a sponge for thundering, a highly flammable material, had a single exit, a small 80-centimeter door. On the ceiling there were dry wood grilles, a flammable material.

The club had three small fire extinguishers, but only one was used to try to extinguish the fire at an early stage, but it was not equipped with sprinklers (fire sprinklers) that automatically trigger fire. The representative of the company that dealt with the club's soundproofing said the club's owners refused to buy fireproof material because it was too expensive. Moreover, a month and a half before the event, the clubs' representatives would have washed the sponge on the ceiling, most likely with flammable substances. Secretary of State Raed Arafat confirmed that the Colectiv Club was functioning without the fire brigade's approval for fire safety and the pyrotechnic show. However, 2 officers from ISU Bucharest, George Petrică Matei and Antonia Rad, were at the Collective club headquarters 3 times, without taking any measures to ensure the safety of the clients.

After the immediate response and institutional analyses a set of measures and activities were proposed and implemented for recovery from disaster and to improve of the Emergency System (extract from Government Reports).

a. at the national level the measures were mainly related to the improvement of the IGSU activity: change and adaptation of the legislative framework in the field of emergency situations for the national improvement of the risk types management and accountability of the institutions with attributions in the field; reconfiguration of the integrated emergency response system to streamline the activity of the emergency structures by unifying under the same command the prevention and intervention levels; improving the existing information flow through the integration of emergency and ambulance structures dispatchers; increasing the level of endowment with special vehicles and specific equipment for emergency and disaster interventions to reduce reaction times/ intervention at events and increase the quality of missions, etc.; the establishment of strict rules on the authorization and verification of biocidal products obliging distributors and manufacturers to re-authorize with efficacy tests carried out in accredited laboratories.

b. regarding authorization procedures, where the IGSU can resort to the measure of closing the non-compliant commercial spaces when it finds that the number of clients exceeded by more than 10%, in case of suppression or reduction of evacuation routes or dismantling of special fire extinguishing, signaling and warning, etc. or the requirements for obtaining a fire safety authorization, which regulates the minimum space required for the various activities. As far as the medical interventions in extremely serious situations by adopting a plan of measures to reduce the intervention time consisting in the possibility of triggering the Red Plan by IGSU dispatchers, when there is information about the high probability that the event is a major one from the victim's point of view or by the alert of the ambulances in block, by introducing a unique code, and not individually.

c. lately, the Chamber of Deputies adopted the draft for the completion of Law no. 307/2006 on fire protection, known as the "Colective Law", which establishes an obligation for those who work with the public and who do not have a fire safety authorization to make it clear at all entries.

Those solutions represent just an optimization of ES based on lessons learned from the disaster and not a systematic and sustainable solution to avoid, anticipate or mitigate the wicked problem.

To sum up, we can identify and cluster the causes of disaster in all phases as related with: corruption, legislation, malfunctioning of urban development and emergency systems. All are ingredients of a wicked problem that needs an objective analysis using scientific methodologies.

The Barry Turner's framework in case of the "Colectiv" Club fire rigorously/ scientifically demonstrates that the problems were very specific and the structural causes were not identified by the past investigations. Thus, in our opinion too, an independent analysis should be carried out to avoid subjectivity in trying to unveil the truth about the proper incident and its aftermath.

CONCLUSIONS AND FURTHER WORK

This WiPe paper described the most important manmade disaster produced as a collateral effect of emerging economy without testing the resilience of Emergency System. Despite the fact that there are three files in the courts and at least 8 people arrested, that government itself and the Department of Emergency realized thorough analyses the understanding of "Colectiv" disaster and its causes is far from being clarified. Some stakeholders such as government understood it as a normal accident (Perrow, 1999) and recommends a radical change of emergency system while the leaders of Emergency System denied the failure of the whole system and understand it from the perspective of High Reliability Organization Theory (Roberts, 2010).

This is a clear fact that we faced a complex or wicked problem, with many stakeholders involved and many views about the disaster. Dr. Raed Arafat himself recommended an external analysis (MAI, 2016b). A wicked problem is one where the planning to address adverse events is difficult or impossible to solve because of incomplete, contradictory, and changing requirements that are often difficult to recognize.

On the other hand, Zulean and Prelipcean presented in a TFSC paper how the Romanian Emergency System succeeded to change dramatically on institutional level and strategic planning level and incorporated a knowledge management system (KMS), with the World Bank help (Zulean, Prelipcean, 2013). The Emergency System local leaders expressed an interest in developing an integrated framework under the National Management Information System for Emergency Situations, capable of supporting emergency decisions and ensuring a better interoperability between emergency agencies (emergency unit, police, health sector, and civil protection) in order to provide better support for decision makers. It is surprising that no report mentioned the role of KMS in planning and response to the Disaster.

So, a two-research needs to be done further. A Delphi methodology for both hindsight and foresight to design a personalized emergency response services to citizens.

The first part will be dedicated to deep understanding of the "Colectiv 2015" disaster. That can be part of a hindsight analysis based on a classical Delphi. Our research will use a similar analysis by Panos Constantinides to explain the failure of foresight in crisis management for the case of Mari disaster (Constantinindes, 2013) but will be based on a Delphi questionnaire.

A second stage of the research will use the same foresight exercise based on a Delphi to find out how to increase the disaster resilience of Emergency System in Romania, drawing the research from the TFSC special section "Moving forward to Disaster Resilience". Eventually we will use the Cross-Impact Analysis (CIA) and the Interpretive Structural Modeling (ISM) to build scenarios as tested by Banuls and Turoff (Banuls and Turoff, 2011) and integrate the results into KMS.

Starting from the experience and database of the previous Delphi (Zulean, Prelipcean, 2013) we will design a three-round classical Delphi online, based on Linstone and Turoff (1975) Handbook and experience we developed in Romania a decade ago based on a consultancy and training of professors Murray Turoff and Roxanne Hiltz.

The sampling strategy is determined by our goals: to tackle the wicked problem regarding the causes and mis-management of "Colectiv 2015" disaster and designing a better procedures and preparedness for Emergency System. The main groups to be consulted are: leaders of local emergency units, national leaders of government, associations of victims of disaster, experts in law and civil emergency.

This type of research is not a case study without a significance. As mentioned earlier in the paper, similar accidents, such as Kiss Club (in Santa Maria, Brazil), Kemerovo (in Russia) or Koszalin (in Poland) happened recently but they were considered "black swans". However, our hindsight and foresight will try to find out patterns, will explain the implications for Emergency Systems and will offer policy recommendations for Information Systems.

ABSTRACT

Security-critical processes of emergency response are part of a complex system of people, organisation and technology. They are often characterised by their own dynamics, interconnectedness and information deficits. In addition, a wide variety of stakeholders, some from different organisations, work together, each specialising in a specific area. In order to capture this (process-) knowledge in risk management, information from the experts is necessary. However, experts are difficult to access, often separated locally, cost-intensive and usually have little time (discussion-) capacity. A pictogram-based process visualisation was developed within the risk management concept. The method could be validated within a European project in an expert workshop. This was done using the example of a CBRN mass casualty incident. By using the methods presented, very good qualitative and quantitative results can be achieved from the perspectives of various organisations and their experts. The limited resource ”expert” is used optimally.

Pictogram-based process visualisation, risk management, risk identification, emergency response, CBRN

INTRODUCTION

Risk management is a management area, which is described in different areas. It is often not uniformly defined, contains different procedures and is integrated in different ways. In civil security organisations, organisational risk management (RM) is often inadequately described and given little consideration (Montag *et al.*, 2017, pp. 38–40; Kern & Hartung, 2013, pp. 113–114). A consistent approach to operational risk management, which combines strategic and operational risk management in particular, has so far not been conceptualised enough (Kern & Hartung, 2013, p. 114). In addition, retrospective risk assessments are often not carried out methodically, inadequately or sustainably - this presents a major problem.

The current state of research offers numerous sources on risk management, which, however, mostly describe risk management in an industry-specific and different way. It was not possible to establish a direct link to emergency response that would describe an overall concept. Even quality management (QM) is not yet widespread in civil emergency response or it is controversially discussed. (Becker, 2013, p. 15) Therefore, the question arises whether a holistic concept can be developed which can be applied in emergency response. It can be assumed that a sustainable, effective, applicable, accepted and resource-saving concept can be developed from the combination of different concepts.

Standards are the basis for such an approach. Their contents are analysed and brought together under the objectives of the concept for emergency response. Moreover, appropriate methods are highlighted and validated. In addition to the standards and their data, practical experience is available as a basis for information.

RISK MANAGEMENT CONCEPT

The risk management concept considered here is taken from SANDER (Sander, 2018) and is based on the comparison and combination of various elements of ISO 9000 (DIN Deutsches Institut für Normung e.V., 2015), ISO 31000 (ISO International Organization for Standardization, 2009), ONR 49000[1] (Austrian Standards, 2014) and HERCZEG's (Herczeg, 2014) remarks.

None of the risk management concepts in the standards can be fully understood and implemented in terms of emergency response. The concepts can be linked to each other and partly overlap in content. The most important element of ISO 31000 and ONR 49000 is the risk management process (RM process), which contains the risk assessment. For its implementation, ISO and ONR indicate various methods and their evaluation, whereby only the evaluation and description of the methods is comprehensible in ISO. ONR adds emergency, crisis and continuity management as additional elements to the RM process. It consciously deals with the fact that events are not 100 per cent prevented. HERCZEG defines risk as complementary to safety, which is one of the most important qualities. It considers the occurrence of events and their analysis and states that risks are identified and dealt with when designing process control systems and that the risk analysis is part of the event analysis. ISO 9000 considers risks in the form of risk-based thinking in the planning phase of the plan–do–check–act (PDCA) cycle of the QM system. Therefore, the positive aspects of the different standards of SANDER were combined to the following Risk Management concept (Figure 1). (Sander, 2018, p. 94)

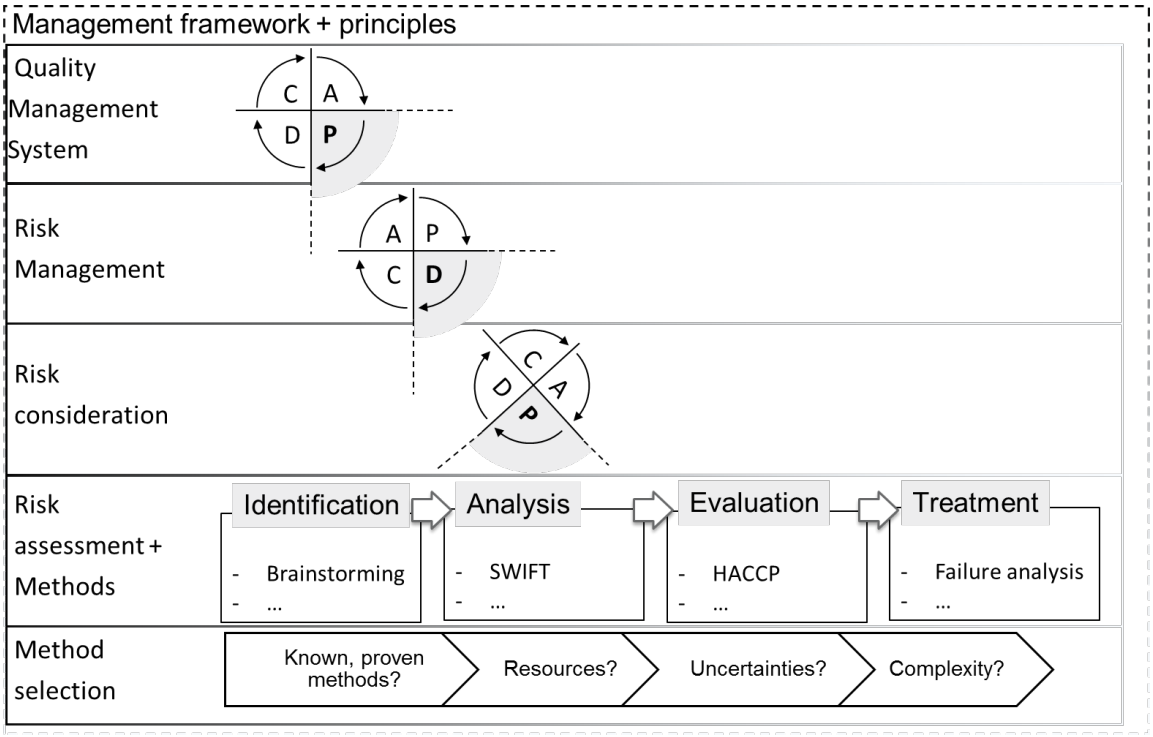

Figure 1. Risk Management concept (according to Sander, 2018, p. 99)

The *management framework* defines the principles and basic framework conditions for a management task in an organisation (e.g. company, institution). It is only intended to provide assistance in integrating the components into the organisation-specific overall management system. The principles are derived from the context, the stakeholders and their expectations of the organisation. The management framework and the principles are set by the top management and are determined by the specific responsible persons. The principles apply at all times and throughout the organisation. (ISO International Organization for Standardization, 2009; Sander, 2018)

Quality management (QM) is a basic management system of the organisation. QM is characterised by its typical PDCA cycle. QM deals with aspects such as the definition of the quality policy, the creation of processes for the implementation of the quality policy and the QM system. In addition, limits and the scope of application are defined as well as regulations for documentation and communication. It is to be implemented at all times and throughout the entire organisation, whereby changes can be incorporated regularly (PDCA cycle). (DIN Deutsches Institut für Normung e.V., 2015; Sander, 2018, p. 96)

[1] Risk Management for Organizations and Systems - Terms and basics - Implementation of ISO 31000

Risk Management (RM) deals with all risk-relevant aspects of the management framework and the QM system. The risk management level in the whole concept corresponds approximately to the risk management framework listed in ISO 31000. The RM is also characterised by its PDCA cycle, which is part of the planning phase of the QM cycle. The RM defines risk policy, agrees risk criteria and establishes a risk culture. This applies at all times and throughout the complete organisation, whereby changes in the RM are also caused by the PDCA cycle. (Sander, 2018, p. 96)

The *risk* consideration (Figure 2) comprises all processes and procedures that are necessary for the proactive and reactive contemplation of risks. On the proactive side, potential risks are minimised in advance and on the reactive side, risks (events) that have occurred are dealt with. Risk consideration is also characterised by a PDCA cycle, which represents the DO phase of risk management. In the planning and implementation phase of the risk consideration, the risk management process is carried out for proactive monitoring. The Check phase consists of the occurrence and noticing of an event. The Act phase is the reactive phase. In this stage, the events are dealt with in concrete terms (according to Herczeg, 2014, pp. 197–198). Risk consideration is the first operational level (from above) that does not take place at management level. It refers to a specific observed process (e.g. production order, production) and can be applied before or during this process. (Sander, 2018, pp. 96–98)

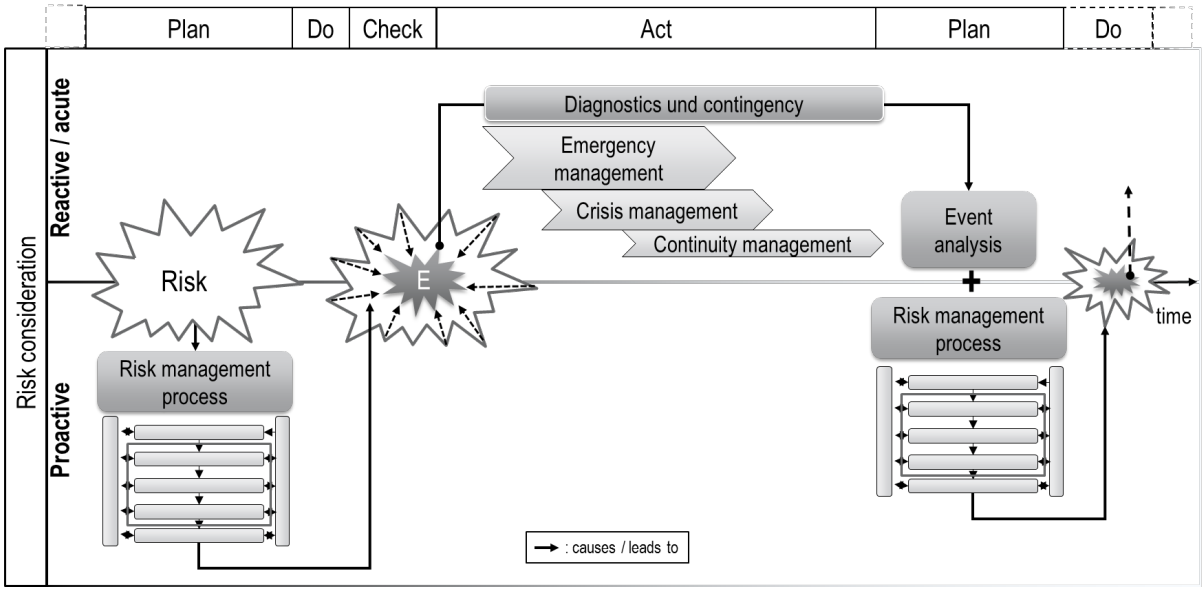

Figure 2. Risk consideration (according to Sander, 2018, p. 98)

Risk assessment is a sub-process of the RM process and an integral part of the planning phase of risk consideration. It represents the lowest level and forms the foundation of the concept presented here. The risks are identified, analysed, evaluated and treated. It is important that *one* risk assessment only applies to the observed process (e.g. production order and production) and the current point in time. Therefore it is part of the PDCA cycle of risk consideration and must be repeated regularly. (Sander, 2018, p. 98) A complex and volatile process should therefore be assessed closely.

When selecting methods, the criteria of known methods, resources, uncertainties and complexity (Figure 1) are applied. The criterion of "known methods" states that methods are to be chosen which are systematically imparted, applied and improved in the organisation of the risk assessor (Herczeg, 2014, p. 155). The nature and quantity of resources required refers to the time and level of expertise, data demands and costs involved. The method(s) to be selected here are those that correspond to the availability of resources in the risk assessment. The nature and degree of uncertainty about the information available and the complexity of the methods chosen must be acceptable to the risk assessor. An evaluation of the methods with regard to the last three criteria mentioned can be found in DIN 31010, so that the risk assessor must compare these with his capacities and guidelines. (DIN Deutsches Institut für Normung e.V., 2010, p. 19, 2010, pp. 21–25)

RISK IDENTIFICATION CONCEPT

Risk identification is part of the risk assessment in which risks are recognised and described. Risk identification lays the foundation for further risk assessment (risk analysis, evaluation and treatment). Since all further steps are based on identification, quality also plays a backward role. It is therefore particularly important to carry out risk identification in a correspondingly good quality.

In this phase, internal and external process risks can be defined and differentiated. The internal risks originate within the process, i.e. within the sphere of influence of those involved in the process and external risks outside the process and the sphere of influence. This means that the identification of risks should not be restricted to those directly involved in the process. The participants (experts) in risk identification should be broadly positioned. For example, in the CBRN process direct process participants (fire brigade) and indirect participants (chemical experts or technology experts) will be involved in risk identification.

When risks occur, one talks about events and their effects[2]. The direct effect of an event can cause consequences, so that events can be defined as the concatenation of causes and effects. (Austrian Standards, 2010, p. 10; Herczeg, 2014, p. 15) A recognised risk can thus be effect and cause too equal.

Risk identification is the process of searching for, recognising and recording risks. More specifically, it is a matter of finding out which circumstances influenced the achievement of the objectives and how these circumstances in turn could be influenced. The risks identified in this way could be events as well as situations and circumstances. In addition to their causes and sources, the consequences of the risks must be determined in their "nature". (Sander, 2018, p. 57; see DIN Deutsches Institut für Normung e.V., 2010, p. 10)

The aim of the risk identification is to develop a list of risks based on events that affect the achievement of objectives in any way. All important and far-reaching causes and consequences should be considered, using tools and techniques adapted to the organisation's objectives, capabilities and risks. (Sander, 2018, p. 57; see ISO International Organization for Standardization, 2009, p. 17)

Risks therefore arise from one or more sources. These constitute uncertain influences from various areas (internal, external) with the participation of a wide range of stakeholders. Risk is the result of a combination of likelihood and impact. At the same time, it represents the link between cause and effect. From this it can be deduced that risks and their identification represent a very complex construct. Depending on the goal, perspective and observer, different results can emerge or risks can be identified. In addition, identification requires a high level of knowledge (expert knowledge) about the object under consideration (e.g.: process) and a lot of development time. This is in direct contrast to reality. There are only a few experienced experts for certain safety-critical processes. They are also difficult to access, often separated by location, cost-intensive and usually have little temporal (conversation) capacity.

Methodological sequence

The methods for risk assessment and risk identification presented in ISO and ONR all have an implicit prerequisite: *a common understanding of the object under consideration* (here, below: process). This is achieved by the following concept. The consideration can refer to different questions or goals, e.g. risks, requirements. The methodological procedure is shown in the following diagram (Figure 3).

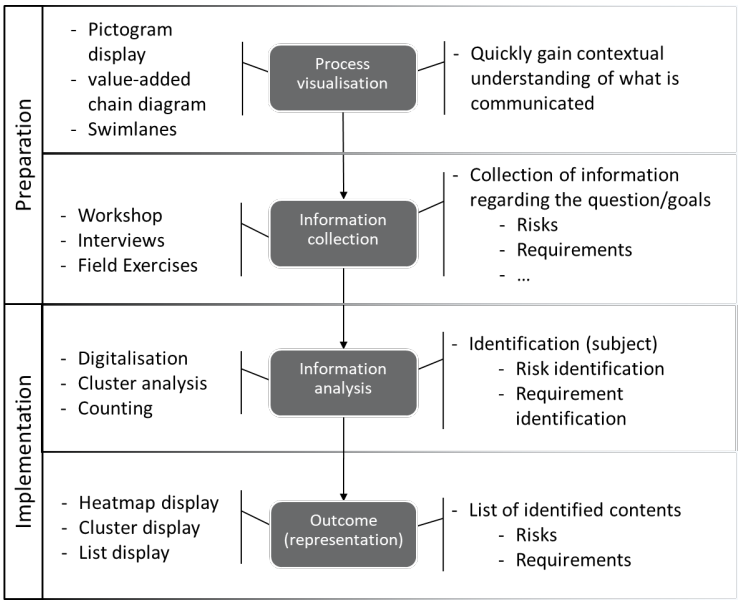

Figure 3. Methodical process of risk identification

[2] An effect is the outcome of an event affecting the targets. Austrian Standards (2010, p. 10)

The first step of the visualisation lays the foundation for a common communication. It is essential to ensure that the same things are spoken of in the following steps. Due to the different experiences of the individual stakeholders, a detailed information collection is connected to the visualisation in order to consider all possible aspects. In the analysis of this information, the actual identification takes place. The identified objects must then be presented in a final step as a result of the process.

Process visualisation

The emergency response situations fulfil the Hofinger characteristics of complexity (according to Hofinger, 2013, pp. 3–8) and can therefore be described as complex situations. Complexity is characterised, among other things, by a high degree of inherent dynamics, a high degree of interconnectedness and a lack of information. It follows from this that the actual problem cannot always be determined. In their search for a scientific basis for such problems, Rittel and Webber have defined the "Wicked Problems" (Rittel & Webber, 1973, pp. 155–169) in the field of planning processes. With the "Wicked Problem" the concrete description of the problem and thus also its solution eludes the observer. This description can therefore also be assumed for emergency response.

If problems and their solutions are not explicit, there are many possible courses of action. These can be implemented in the process visualisation in two ways. On the one hand, there is the possibility to limit or define the actions or the problem by framework conditions and thus to enable a detailed representation. On the other hand, the representation can remain abstract in order to consider as many options for action as possible and thus possible risks. In the case of the holistic view, with many stakeholders, of processes of emergency response, an abstract representation should therefore take place.

The more a process diagram explains, the less it is understood (Herrmann, 2012, p. 170). In order to avoid this, an intentional incompleteness is created in which the critical segments are represented disproportionately present and at the same time other details are omitted. Thus the goal of the representation is emphasised, the complexity of the process is reduced and the comprehensibility is increased. At the same time, the abstract representation creates an open image that leaves room for free thinking, e.g. for risk or requirement identification. The omission of explicit descriptions prevents the discussions from drifting into a kind of "definition discussion" and becoming resource wasters.

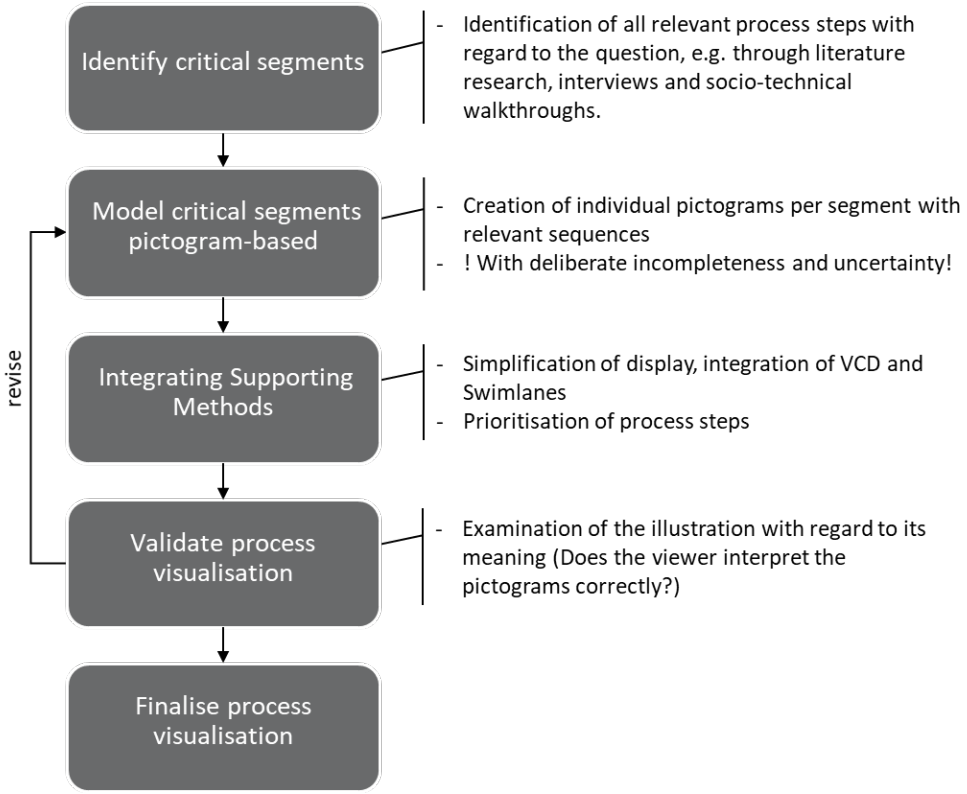

Figure 4: Procedure for process visualisation

This approach to process visualisation (Figure 4) makes it possible to create a simple representation (Figure 6) which simplifies complex topics and presents them in an understandable way so that the information can be used effectively. In addition, it is easy to use, quickly available and can be adapted individually. This makes it possible

to reach a good quantitative and qualitative result with several experts in the information collection in a short time. The focus in process visualisation is on pictogram-based presentation.

Pictograms serve as part of a visual world language of the transmission of information. They have a simple form of design with a character of challenge and visual language and are application-specific. By using pictograms, relationships and dependencies between processes can become more understandable for the end user. Pictograms can be iconic, symbolic, or hybrid. Iconic pictograms depict objects or situations that are very easy to understand. Symbolic pictograms, on the other hand, use characters that must be defined and learned. Hybrid pictograms combine these two types and are supplemented by text elements. (Hasselbring, 1998, pp. 217–218; Böhringer *et al.*, 2011, p. 411)

Thus the pictograms concerning their use in the process representation fulfil the requirement of a fast comprehensibility after HERMANN (Herrmann, 2012, p. 156). The type of presentation has references to the already existing world of experience, its syntax and semantics are simply structured, no high memory performance is required and it provides simple means of expression.

The pictogram-based visualisation serves as a reference process for the various expert groups (Figure 5). It represents the function of information collection and communication by forming the "bridge" between the different expert groups and thus connecting them with each other. The processes are made comparable on an abstract level. Even if the process flows look different in detail for the individual stakeholders, they can still be assigned to a reference process step. On the one hand you can communicate directly without prior definition description, e.g: "In zone 2 we always have the problem of ...", on the other hand individual information (e.g.: risks) can be assigned directly. Stakeholders are divided into four groups. Internal and external describes the affiliation of the respective stakeholders. The affiliation can relate to different areas, such as Project staff, company affiliation, working groups. (Partial) process knowledge and process unfamiliarity describes the level of knowledge of the respective stakeholders about the object (process) under consideration.

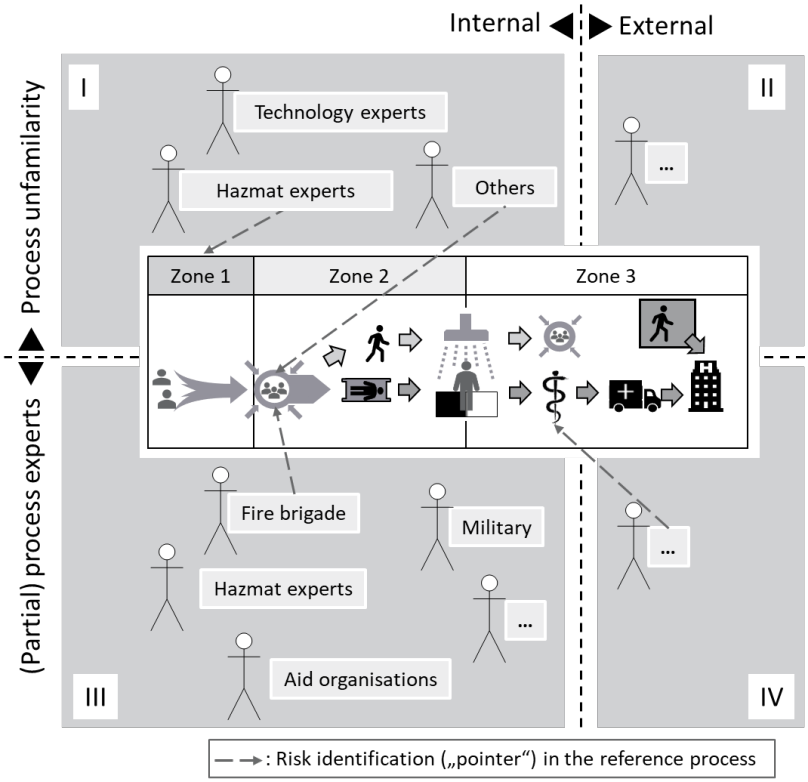

Figure 5: Information collection function of the reference process (example: CBRN process)

The process visualisation can be optimised in addition to the pictogram-based representation by integrating the following methods.

The method of *Swimlanes* is a concept for organising and structuring processes through separate visual categories. This type of spatial planning is used to further simplify the visualisation. The description of the swimlanes is not bound to any conventions.

Value-Added Chain Diagrams (VCD) represent the process compared to the pictograms in a text-based form. With

this form of representation, additional relationships and information can be visualised alternatively. In addition, other process levels can also be displayed. (Amelunxen *et al.*, 2018) This enables process modeling for a detailed analysis of the processes. It should only be used for support and should not undermine the objectives of the abstract representation.

The process representation (Figure 6) shows the different visual methodological contents described above. Here the vertical swimlanes divide the process according to the spatial order. They offer the possibility to discuss the process in an even more abstract way. Independently of this, the horizontal swimlanes allow further options of classification. The pictograms or process steps can also be moved into the respective lanes. A special case of spatial decoupling of process steps is represented by an inserted block within a lane in order to be able to form a basis for discussion here as well. If it is necessary to consider the temporal course of a process or sub-processes, different versions with the respective changes are created. (Amelunxen *et al.*, 2018)

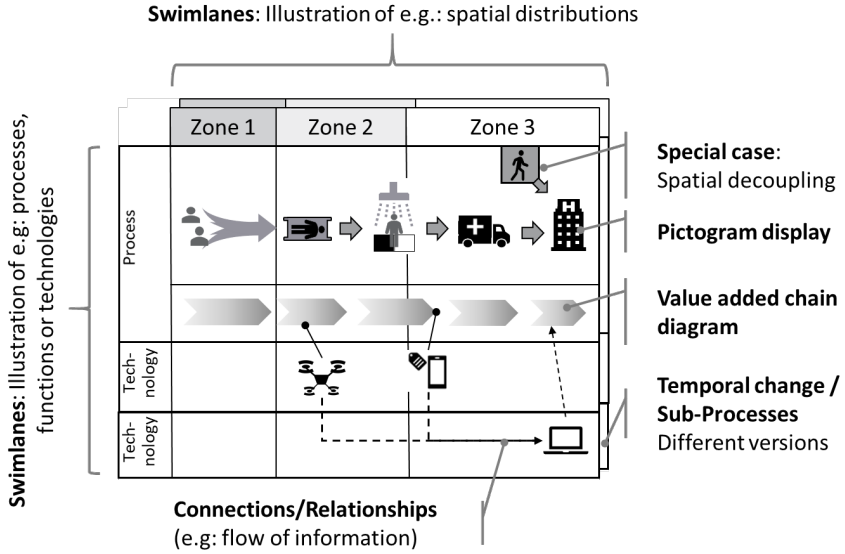

Figure 6. Process visualisation using the example of the CBRN reference process with technical systems (according to Amelunxen *et al.*, 2018)

RISK IDENTIFICATION IN THE EU PROJECT „TOXI-TRIAGE“

Within the European project „TOXI-triage[3]“ an adaptive European triage process for CBRN layers in connection with new technologies is being developed and improved. It is an interdisciplinary European project in which different native languages are spoken. The CBRN process is subject to various national laws and is described, implemented and executed by various stakeholders.

In Germany alone, for example, a total of 64 laws regulate the decontamination of injured persons at federal state level. In principle, four different legislations are involved: the Police Act, the Fire Brigade and Fire Protection Act, the Disaster Control Act and the Rescue Service Act. The 16 federal states each describe this in two to six different laws. (Densow *et al.*, 2005, pp. 28–33)

If one extrapolates this number of laws to the European levels, it quickly becomes clear that it is difficult to establish a common definition. It is therefore important for risk identification to address the question of how the process can be communicated on the one hand and how it can be ensured that all stakeholders have the same understanding of the subject under discussion on the other. To generate this common understanding, the CBRN process is visualised.

The above-mentioned properties of pictorial information transmission are implemented here. In the information collection (risk identification) different groups of persons from the project meet, e.g. from different occupational fields, organisations and countries. In particular, their communication is sometimes fundamentally different with regard to designations and definitions, which leads to problems. In order to counter these problems, the above-

[3] Integrated and adaptive responses to toxic emergencies for rapid triage: engineering the roadmap from casualty to patient to survivor (TOXI-triage); This project has received funding from the European Union's Horizon 2020 (H2020) research and innovation programme under the Grant Agreement no 653409.

mentioned method of process visualisation is used. This keeps the introductory phase of the workshop, in which a common understanding of the object under consideration is generated, extremely short.

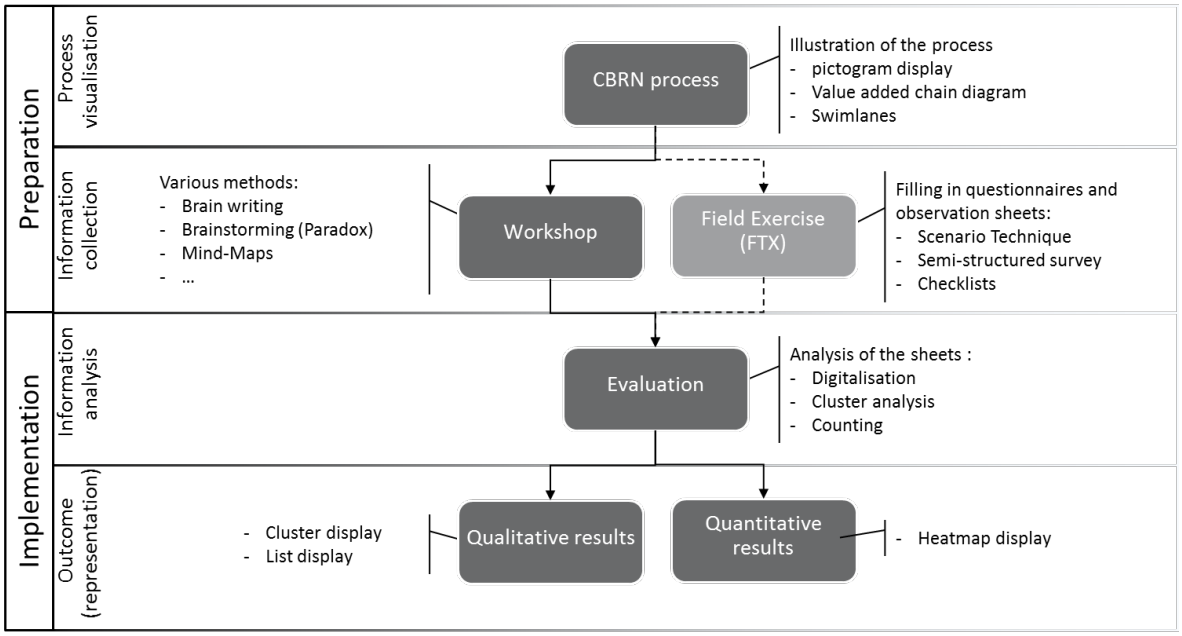

Figure 7. Risk identification procedure

Different methods were selected for the information collection in the framework of the EU project TOXI-Triage. The methods are used in modified variants in order to be able to use the already pre-planned project activities. This minimises the additional effort and counteracts the scarcity of resources (resource: process knowledge). Basis of the risk identification (Figure 7) is first the *process visualisation* for the CBRN process, which should serve as discussion basis and reference model in the inter-European environment.

The process visualisation is inserted as a template in the workshop and as an orientation aid in the questionnaires as well as in the observation sheets of the Field Training Exercises (FTX). The workshop and the exercise take over the information collection step. They work with creativity techniques as well as the scenario technique, the checklists and the semi-structured survey. The information collection as well as the information analysis and the presentation of results for the workshop have already been completed and are presented below.

Workshop

Risk identification through the workshop (method according to (Rupp, 2007; BMI/BVA - Bundesministerium des Innern/Bundesverwaltungsamt, 2018)) is implemented through various creativity techniques (Figure 8) (Nöllke, 2015; Rupp, 2007). The workshop[4] was attended by 59 experts from the fields of fire brigade, medicine and rescue, military, research and others. The participants worked in nine small groups on the tasks set by moderators and guided by them. The moderators with practical experience in emergency response were prepared for the workshop according to the moderation method (BMI/BVA - Bundesministerium des Innern/Bundesverwaltungsamt, 2018).

[4] A Workshop/Master Class on Triage & Toxicity, August 30, 2017, Düsseldorf (Germany)

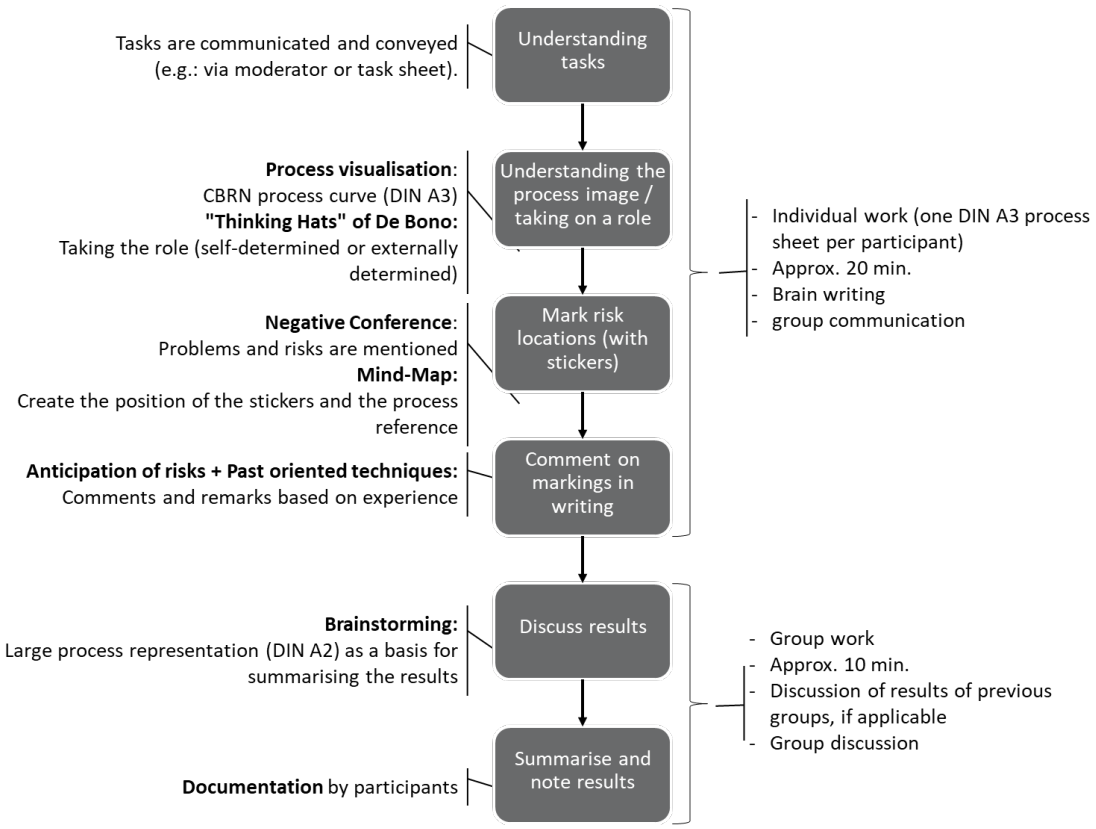

Figure 8: Workshop procedure

At the beginning, each participant received a DIN A3 image of the visualised CBRN process and stickers for the four technology types used in TOXI-triage as well as exclamation marks to label risk points. Participants provided some personal information and the perspective from which they viewed the process. In the following, the largest risk locations were to be marked and, if possible, commented on in their own process image for later evaluation. Following this 20-minute individual work phase, a 10-minute discussion was moderated in which the most important results of the table groups were summarised and noted on a DIN A2 process map. (Amelunxen *et al.*, 2018)

As a result of the workshop the used DIN A3 (A2) sheets with the process representation, the comments and stickers of the participants were available. The analysis of these sheets was divided into two parts for quantitative and qualitative results.

Quantitative evaluation and presentation of results

As a quantitative evaluation method, the number of stickers in each CBRN process step is counted and displayed in separate "heatmaps" (Figure 9). A heat map is a type of analysis that quantitatively visualises results and differences with colours. The results of the analysis should serve as preparation for further investigations and support the improvement of the CBRN process. For each sticker type and each subgroup, a heatmap is created and presented in relation to the segments of the CBRN process structure. The visual distinction of the meaning of a sticker ranges from red (highest number) to violet (lowest number). The following is an example of the heatmap of the risks over the rolls. For this purpose, 59 workshop sheets with a total of 620 stickers (138 risk adhesives) were evaluated. (Amelunxen *et al.*, 2018)

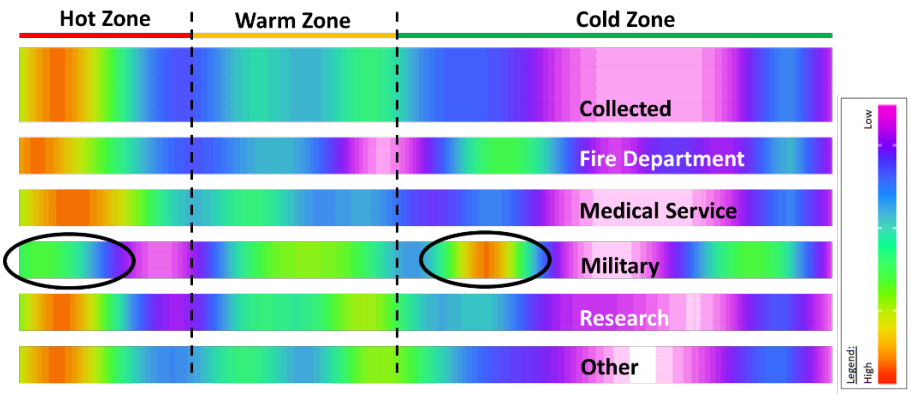

Figure 9. Extract: Risk-Heatmap with conspicuous deviations after rolls (Limper & Rammert, 2017)

This type of presentation allows conspicuous features, risk emphases per role or even deviations to be easily derived. In the following analyses, you can concentrate on these special points and analyse them more deeply. This 2D heatmap can be extended by another dimension. On another axis, for example, the probability of occurrence of the risk can be displayed. (Amelunxen *et al.*, 2018)

Qualitative evaluation and presentation of results

For the qualitative analysis of the workshop results, a concept was first developed to ensure that risk identification was completed and risk profiles or risk clusters listed at the end of this process.

The aim of risk identification is to obtain a list of all risks. For this purpose, the comments on the workshop forms were analysed according to the following procedure (Figure 10).

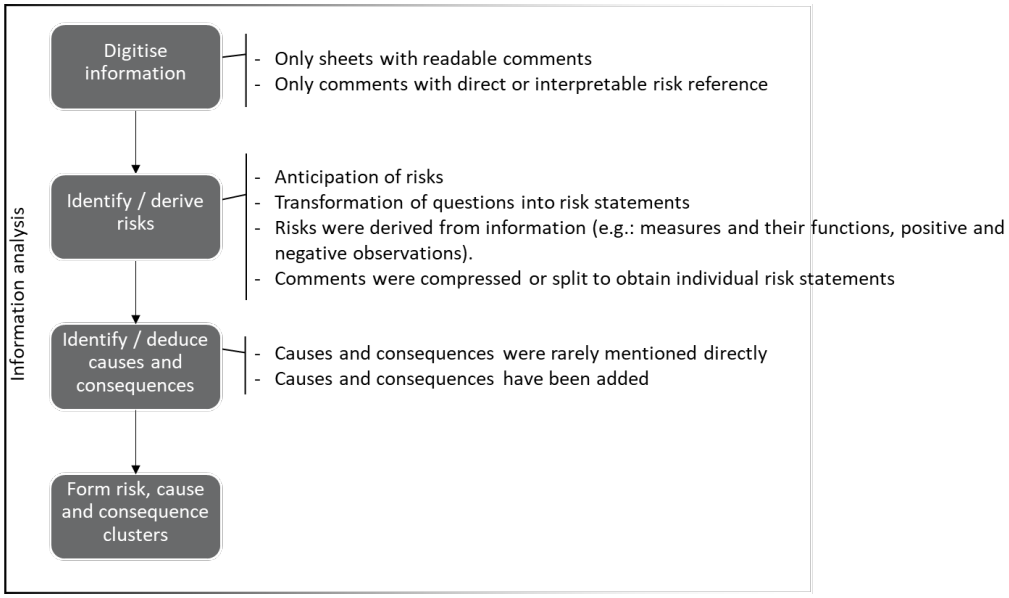

Figure 10. Procedure of qualitative information analysis

In a first step of *digitisation*, the readable comments with a direct or indirect reference to risks were recorded digitally and in written form. Questions were converted into risk statements and risks derived from measures. Long comments were compressed and divided into individual risks. There were 134 risks that were clustered (Figure 11).

Cluster analysis is a mathematical multivariant analysis. It can be assigned to the field of segmentation, which is defined as follows: The objects to be examined are combined into classes on the basis of similarities in the significant or important characteristics. When forming groups, *intuitive* or *formal* clustering can be used. In the intuitive clustering used here, the performing scientist uses his intuitive, non-explicit or explicable understanding of similarities. Greater objectivity is offered by the formal variant, which provides for a formal procedure. (Amelunxen *et al.*, 2018; Bradtke, 2003, p. 168; Eckes & Roßbach, 1980, p. 15)

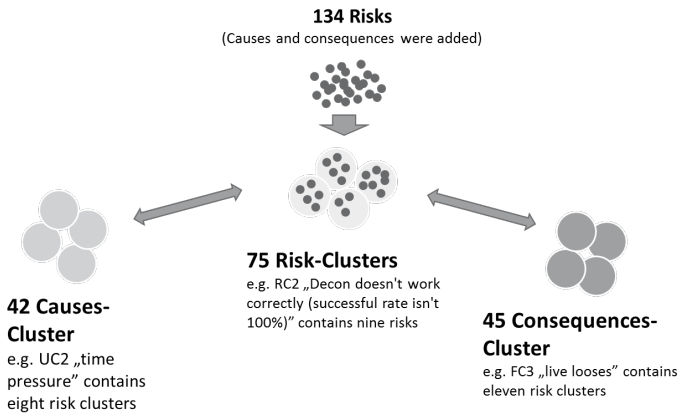

Figure 11. Procedure and results of the cluster analysis

The first cluster analysis bundled the risk descriptions and formed risk clusters. For many risks, these can be grouped into risk profiles (Austrian Standards, 2010, p. 11). These risk clusters correspond to the risk profiles defined in ISO 31000. All causes and consequences for the cluster have been collected and sorted according to the number of risks they contain. The risk clusters were then bundled according to cause or consequences and sorted according to the number of risk clusters contained. There were 42 cause clusters and 45 consequence clusters.

A large number of risks can be identified by the *risk identification* procedure. Depending on the level of detail of the analysis, a very complex system of cluster relationships emerges. This procedure promotes the understanding of the process solely on the basis of the execution of the analysis. Statements can be made about the probability of occurrence and the consequences based on the number of entries. (Amelunxen *et al.*, 2018) The biggest advantage is the optimal use of the available time of experts in the workshop. The time recording (Figure 12) of the qualitative risk identification carried out here shows that only a small part of the total time falls back on the experts.

Step		Time in hours	percentage
Process visualisation		35	55,1%
	Editing, visualisation, meetings, etc..: (several persons involved) >30h		
	Workshop Preparation >5h		
Information collection: **Expert w**orkshop (3 groups each 30 min.)		1,5	2,4%
Information analysis (qualitative result analysis)		27	42,5%
	Digitisation of diagram sheets 15h		
	Clustering 12h		
Total time requirement		63,5	100,0%

Figure 12: Time recording of qualitative analysis

OUTLOOK

The FTX[5] in TOXI-Triage is used for a second type of information collection. As Figure 7 already shows, the information is obtained via an observation sheet (Technology Evaluation Observers sheet), two questionnaires (End-User Evaluation of Usability and End User evaluation of technology aims) and the transcript of a debriefing (Post FTX Debrief open discussion).

The *information analysis* in FTX corresponds to the analysis from the workshop (Figure 10). In the second step of risk identification, a meta-analysis of the externally created questionnaires is also carried out. The questions indicate potential risks that the creators have identified in advance. Furthermore, the documents are first analysed

[5] TOXI-triage - FOCUS exercise, October 17, 2018, Athens (Greece); The FOCUS scenario simulated a chemical incident in an airport.

and all risk-relevant contents are listed. This includes the questions on the questionnaires and the comments of the observers. These include those that represent a direct or interpretable reference to risks.

A striking feature of the information analysis in comparison to the workshop is that causes and consequences are relatively frequently stated and the consequences outweigh them. In addition, risk statements can be made by naming causes (e.g. "Technology was observed many times scanning fluidly and easily despite glare and PPE being worn").

Preliminary results of the information analysis are 92 listed risks with a focus on technical risks. Risks are mentioned several times and overlaps with the identified risks of the workshop can be identified. What is striking here is that possible measures/solutions are also mentioned relatively frequently. The technical focus of the results can be traced back to the questions which correspond to the project objective of TOXI-Triage. The next step in the analysis of cluster formation has not yet been completed. Following the cluster analysis, the risks from the workshop and those of the FTX are compared. From this, conclusions are drawn on the applicability and their differences to the information collection.

Once the risk identification has been completed by the workshop and the FTX, a *risk analysis* can be carried out. The risk analysis analyses the causes and sources of risks. Various combinable analysis methods are used for risk analysis. These methods could be designed qualitatively, semi-quantitatively and quantitatively. Qualitative methods work with so-called significance levels such as "high", "medium" and "low" and require a clear legend. The semi-quantitative methods, on the other hand, worked with a numerical classification. For quantitative methods, estimated values are used. However, these methods are often not used due to a lack of information or the high effort involved. (Sander, 2018, p. 57; see DIN Deutsches Institut für Normung e.V., 2010, p. 11) Based on the risk management concept presented above (Figure 1), the methods are selected.

CONCLUSION

For the risk identification in the EU project "TOXI-Triage", a pictogram-based visualisation of the CBRN process, which was elaborated in detail, provided the basis for a resource-saving risk identification. In the current project, the first half of the risk identification process has already been completed with the collection of information through a workshop. Extensive and very complex interrelated risks were identified. At present, the first information collection by FTX has already been completed and the analysis is being carried out. A second information collection by FTX is currently in preparation. A concept for the risk analysis is currently being developed.

The presented concept shows the approaches for a holistic risk management in the area of emergency response. The focus here is on the integration and use of pictogram-based process visualisation. For risk identification and analysis, a high degree of methodological knowledge is sometimes required (Figure 13). This includes all methods presented. The advantage here lies in the good learnability, which does not require explicit process knowledge.

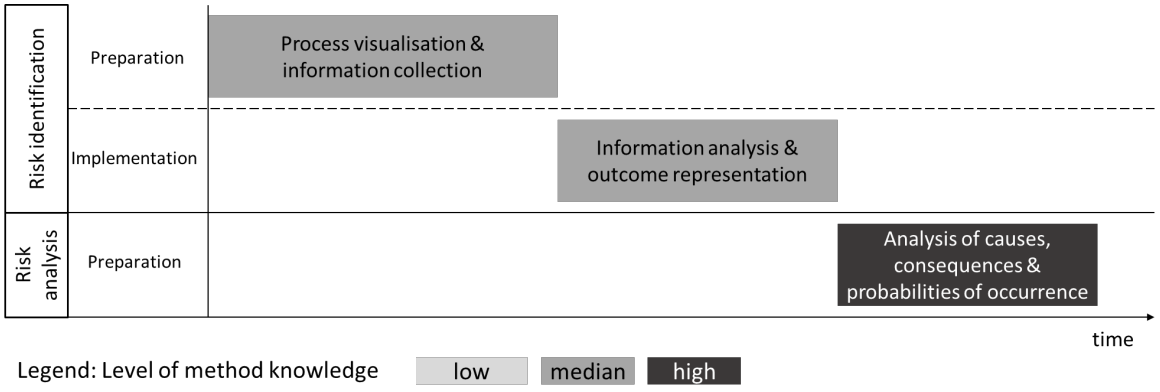

Figure 13. Resource needs of risk identification & -analysis – Resource "method knowledge"

The time intensive preparation of the risk identification with the elaboration of the process visualisation requires a low process knowledge (Figure 14). The resource "process knowledge" is only required to a large extent for the collection of information for a (very) short period of time. For the information analysis and the outcome presentation, medium or low process knowledge is sufficient. The depth of detail of the information analysis depends on the objectives of the following risk analysis. Due to the often complex dependencies on causes, risks and consequences, the need for resources can increase massively. The following risk analysis requires a high degree of methods knowledge and expert knowledge in order to gain detailed knowledge about the risks.

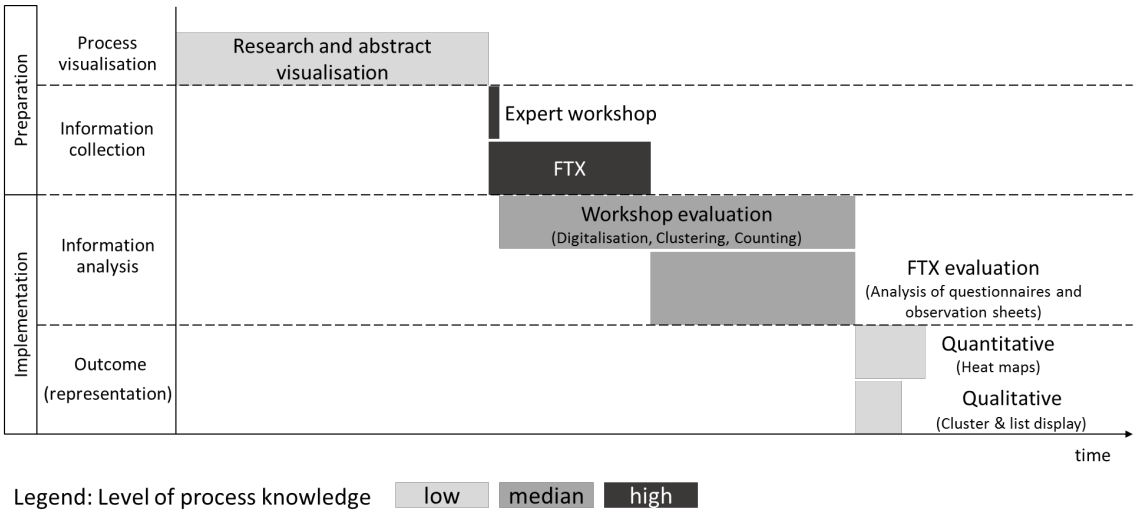

Figure 14. Resource needs of risk identification & -analysis – Resource "process knowledge"

The concept presented here shows a holistic concept, which is strongly characterised by the abstract process visualisation. The concept achieves good quantitative and qualitative results in a short "expert" time and can be flexibly applied to various questions/objectives. In addition, the information collection can also be integrated into project activities planned by third parties. The time available to experts is used highly efficiently. This is made possible by intensive preparation without the presence of experts. The further validation of the results is carried out against the results of the FTX.

A possible weakness of this method lies in the preparation phase. For the creation of the process visualisation sufficient information must be available, e.g. information about the considered object, the users and their knowledge as well as the goals. In the evaluation of the results, errors may occur in the interpretation of statements. These weaknesses can be counteracted by increasing resources and expert knowledge. . In the following it is also necessary to examine in which areas this type of process representation can additionally be applied and how or with which information systems it can be linked.

ABSTRACT

Disaster Risk Reduction is a complex field in which a huge amount of data is collected and processed every day in order to plan and run preparedness and response actions, which are required to get ready and to effectively respond to natural disasters when they strike. This paper, which targets a wide audience, focuses on the design of a mobile application that aims to integrate the crowdsourcing paradigm in current Disaster Risk Reduction processes. The design process is integrated in the User Centred Approach, which we apply through a co-design methodology involving end-users, iterative prototyping and development phases, and five in-field evaluations of the implemented solution. We describe both the design activities and the results obtained from end-users' feedbacks focusing on the perspective of first responders.

Keywords

Disaster Risk Reduction, Crowdsourcing, User Centred Design, Mobile Interface Design, Usability evaluation.

INTRODUCTION

The higher frequency and severity of natural hazards is increasing the complexity of all prevention and management activities. The whole set of methods, practices and activities aimed at preventing and reducing the impact of disaster, as well as managing their residual risks are referred as Disaster Risk Management and Reduction (DRR). DRR practices aim to reduce disaster risks also through a systematic data collection and analysis on disasters causal factors, which are used to orient a wise management of environmental and local resources so as to improve preparedness and response capabilities to future adverse events (UNISDR, 2009). DRR processes involve several organizations at various administrative and operational levels, each of which is equipped with specific ICT systems and services that serve different strategies and procedures. This implies a high complexity, also because local operational procedures vary a lot across administrative regions.

In this scenario, heterogeneous data are considered core enablers throughout all phases and functions of the DRR (Vieweg et al., 2010). The introduction of new ICT solutions able to collect and fuse data from multiple sources can have a positive impact on current operations and procedures, which could benefit from an improved data integration and management. Actionable data sources include remote sensed imagery, forecast models, environmental sensor networks, social media, and also novel mobile applications. In particular, social media platforms such as Twitter and Facebook are commonly used by citizens to collect and share unstructured information about incoming or ongoing crises. This represents a valuable opportunity for authoritative organizations, which could integrate such data into current DRR processes. Nevertheless, the cost to systematize, clean, sort and filter such unstructured and unreliable information flow makes the integration of crowdsourced data a very difficult task.

In this work we tackle this challenge, presenting the design of a novel mobile application (app) designed for integrating a crowdsourced data collection and validation activity into DRR procedures. The design process is integrated in the User Centred Approach, which we apply through a co-design methodology involving end-users,

iterative prototyping and development phases, and five in-field evaluations of the implemented solution.

Even though the app targets a wide audience, including citizens, this paper describes the design and the implementation of features dedicated to First Responders[1].

This paper is organized as follows. First, we review related works about the interplay between DRR and ICT solutions, focusing on the crowdsourcing approach and on the user centred/co-design frameworks. Next, we detail the overall methodology we followed and we briefly summarize the results from the co-design activities (Nguyen et al. 2017). Then, we describe the app design and we evaluate the usability of the implemented solution from ad hoc questionnaires. Finally, we present the conclusions and future works.

RELATED WORKS

During incoming and ongoing hazards, citizens generate and exchange a big amount of information. If properly filtered and processed, such data represent a great value that can enhance the situational awareness of both operation managers and first responders acting in the field. The most recent DRR approaches invite to take advantage of the direct participation of citizens (Abbasi et al., 2010). In critical conditions, people need to seek and share information, primarily to stay in contact with their family and community. Mobile technologies allow the fulfilment of these needs and can support the application of crowdsourcing approaches. Information access and sharing are two core features of the crowdsourcing, which is nowadays a consolidated socio-technical paradigm that mainly leverages on: (i) the willingness of people to actively contribute to actions of mutual interest (De Albuquerque, 2016) and (ii) the availability of current technology where services and applications running on mobile devices are able to gather and exchange geo-located information about a crisis (Kanhere, 2011; Littledyke, 2008).

The combination of social needs and technological capabilities allows the crowdsourcing to bring in-field data from the local up to the organizational level. Nevertheless, it exhibits some critical aspects. One of the most important issues is the information reliability, because crowdsourced data can be affected by from disinformation, false judgments, social biases (Guo et al., 2104; Ganti et al., 2011). Other relevant issues are data accuracy, sampling, temporal coverage and precise geo-localization, all of which are crucial for integrating crowdsourced data into DRR procedures. The ability of contributors to produce accurate data is considered a key aspect for applications supporting the environmental surveillance and the natural hazard prevention (De Longueville et al., 2010). Validation techniques are required to guarantee the reliability of the data collected from the crowd. They can leverage on automatic systems based on Artificial Intelligence as well as on human approaches where experts and/or peers have to manually perform the validation. Both approaches can benefit from the integration of reputation systems that dynamically rate contributors (Pennachiotti, 2011). Finally, crowdsourced data require tailored visualization techniques as well as specific skills for data analysis and interpretation within emergency organizations willing to include them in their procedures.

A mobile application for crowdsourcing data collection and validation activities within DRR operations shall be envisaged as a tool enabling new forms of cooperation between local agencies and citizens without disrupting existing procedures. The knowledge of the operational context, of the end-user organization and procedures is essential for the mobile application design, which must define functionalities, interactions and interface characteristics. A deep knowledge of the destination context and an exhaustive understanding of the end-users needs, skills, culture, and context are core concepts of the User-Centred Design (UCD) approach (Norman et al., 1986). The UCD is a methodology that entails several tools and techniques to systematically collect and use qualitative and quantitative data, which are used throughout the design and development process. Among the UCD methods, *the participatory design (or co-design)* focuses on collaborative practices that actively involve stakeholders and end-users onto the design challenge. Note that the co-design implementation requires a careful planning and a wide understanding of target domain. In co-design method, participants are considered as designers (Stepanek, 2015), stimulating the dialogue on a common problem and on possible solutions that can evolve in prototypes or shared artefacts. Through dedicated techniques, the co-design allows non-designers to articulate design proposals as a useful starting point for further professional developments (Sanders et al., 2010). The collaborative design activities allow to widen the design team's vision and develop a situated knowledge of complex domains. Moreover, the engagement of end-users helps in the design of usable (effective, efficient and satisfying) solutions.

We consider all the aforementioned issues to design and implement a novel app for crowdsourcing data collection and validation activities for DRR.

[1] The features specifically dedicated to citizens are presented in our previous paper (Frisiello et al. 2017).

METHODOLOGY

In order to collect a deep knowledge of the user needs and to set the context of in-field data collection activities, we followed the co-design methodology described in (Nguyen et al., 2017) involving representatives of the DRR ecosystem, namely emergency operation managers, field agents, volunteers and domain experts. The co-design process included: (i) an online survey aimed to map the expertise, interests and needs of the participants; (ii) an intensive co-design workshop (two full days) supported by a dedicated toolkit that has been designed to guide the workshop activities and at the same time to systematically collect information; (iii) the analysis of the data collected to extract end-user requirements for the mobile app design and development. Both functional and non-functional end-users' requirements have been derived from co-design workshop, while the information collected on the organizational level has provided relevant hints to define the user's profiles to be implemented in the app and the related permissions in compliance with the real processes and roles. Finally, the specifications on the content architecture (functions and information) and the interaction patterns have been defined, and then prototyped at levels of fidelity, first wireframes and then mock-ups. The mock-ups have been created using as much as possible elements from the Material UI library, which contains a large set of UI components ready to use and already familiar to end-users because commonly adopted in all views of the Android system

The participatory approach has been applied along the whole process, including the user evaluation activities. In order to validate intermediate versions of the mobile app, five demonstrations and user feedback sessions have been conducted in five different countries (Croatia, Italy, UK, Spain, Finland) involving end-users in real context. The evaluation procedure applied is hybrid: it combines the data collection from in-device usage in real context and from post-task surveys via: (i) the System Usability Scale (SUS) (Brooke, 1996) to evaluate usability, regardless of the different stages of maturity of the solution (Muddimer, 2012); (ii) the Net Promoter Score (NPS) as indicator of the perceived maturity of the solution on the base of a ten-score scale (Reichheld, 2003); (iii) a set of ad-hoc questions to investigate specific aspects of the app, such as the visualization layout, readability, procedures sequences.

CO-DESIGN RESULTS

The co-design workshop provided detailed indications about the types of data needed in each DRR phase, the expected flow of information and the applicable roles and related permissions, as well as on the information flows and graphic user interface (GUI) (Linux Information Project, 2004) design. It resulted that the crowdsourcing is positively seen as an opportunity to integrate data from the field and to improve the environmental surveillance. This capability is considered particularly useful during the response phase, in which contextual data can provide a deeper situational awareness of hazardous factors and can support decision-making processes. Hazard related data, together with indications of damaged infrastructures and resources availability, are the most relevant ones. Additionally, the provided information must be linked with the identification of the reporter, i.e., the person who provided the information, whom should be classified according to its role (e.g. citizen, professional in order to acknowledge reliable data. It resulted that volunteers are considered as trustable as a professional, while citizens cannot be equally considered. These considerations have been taken into account in the app design to create a role-based role visualization and to differentiate the data collection as well the validation procedures.

The visual prototypes produced highlighted two equally important information flows: an informative data flow, from the system to the mobile app, and a generative data flow, from the app to the system. The first flow is initiated by the authorities and includes: (i) alerts to the field, (ii) geolocated data (e.g. hazard and risk forecasts). The second flow is centred on the crowdsourced data generated in the field via mobile devices and geographically shared with the neighbouring community as well as with control centres managed by the authorities. These capabilities bridge a gap between Decision Makers sitting at control room sand in-field agents.

The co-designed artefacts suggesting an almost univocal content architecture, which we translated into a visual layout placing the authoritative informative level on the upper part of the screen and the crowdsourcing functionalities in the lower section. Furthermore, we translated the data collected in high-level guidelines for the app design, namely modularity, context-sensitiveness and reliability. They are defined as follows:

- *Modularity*: the DRR processes includes several processes, scenarios and target users. The key approach to handle this level of complexity is the modularity, i.e., the possibility to selectively provide and activate functionalities to different organizations. By avoiding the 'one solution for all' approach, a crowdsourcing solution can be integrated within existing systems and regulations.
- *Context sensitiveness:* the co-design phase showed that understanding the context is a top priority for emergency organizations, especially in the Response phase. First responders expect a context awareness tool able to support field operations providing additional data. They consider reliable the data coming from the system and, at the same time, they are willing to send data back from the field. This bidirectional

communication flow can enhance the effectiveness of in-field operations, especially when tight time constraints exacerbates stress condition.

- *Reliability*: trustworthiness is key to establish an effective data exchange. Therefore, the data produced by the crowd must be validated in order to be accountable. This requires a specific and distributed validation tasks to be designed within the mobile app. Interestingly, participants indicated that data sorting would let to quick spot relevant information, easing the validation task.

All these guidelines have been fully considered in the design of the mobile app.

THE MOBILE APP DESIGN AND PROTOTYPING

In this section we describe the design of the app[2], which we organize in paragraphs following a top down approach, starting from the *Access* (login and home screen) and then detailing the main informative sections. First, we explain the *Map & Forecast* section, which visualizes map *Layers* and other *location-based contents* on the map, then we describe the *Communication* and the *Social Media* sections, which shows the communications from authorities (*Warnings* and *Report Requests)* and the content extracted from Twitter, respectively. *Report Requests* allows authorities to request a targeted in-field data collection activity from app users, selected by their role. Finally, we present the *reporting* (*Do Report*) and the *validation* procedures. In each paragraph we include both the textual description and the corresponding visual representation of the explained functionalities. *Technical choices*.

Access: to use the app, an active account is required. Professional users are assigned to a given organization units and can have several roles among: 'Decision Maker' (people working in the control room), 'Organization Responsible' (the responsible of the organization with respect to the app) and 'In-field agent' (people operating in the field). The Home (**Figure 1**, right), which appears after the Login (**Figure 1**, left), allows to access the main app informative sections, which are placed in the upper half of the screen, namely: '*Map & Forecast'*, '*Communications'*, '*Review'* and '*Social'*. In the lower half there are two other sections, namely '*Settings'* and '*Help'*. The 'Settings' section allows to set user preferences about the language, the base map style, the *time window* and a *distance* in kilometers. Note that all information in the app are retrieved according to a given temporal interval, identified by the *time window*, and to a geographical area, i.e. the Area Of Interest (AOI), which is computed as the bounding box that inscribes the circle having as center the user position and as radius the *distance* specified by the user. The 'Help' section provides supports for newcomers, presenting a quick tour of the app. Finally, the bottom area is dedicated to specific call-to-action buttons: the 'Do Report' and the 'Report Request'. Their procedures are described in the '*Do Report'* and *'Report Request'* subparagraphs.

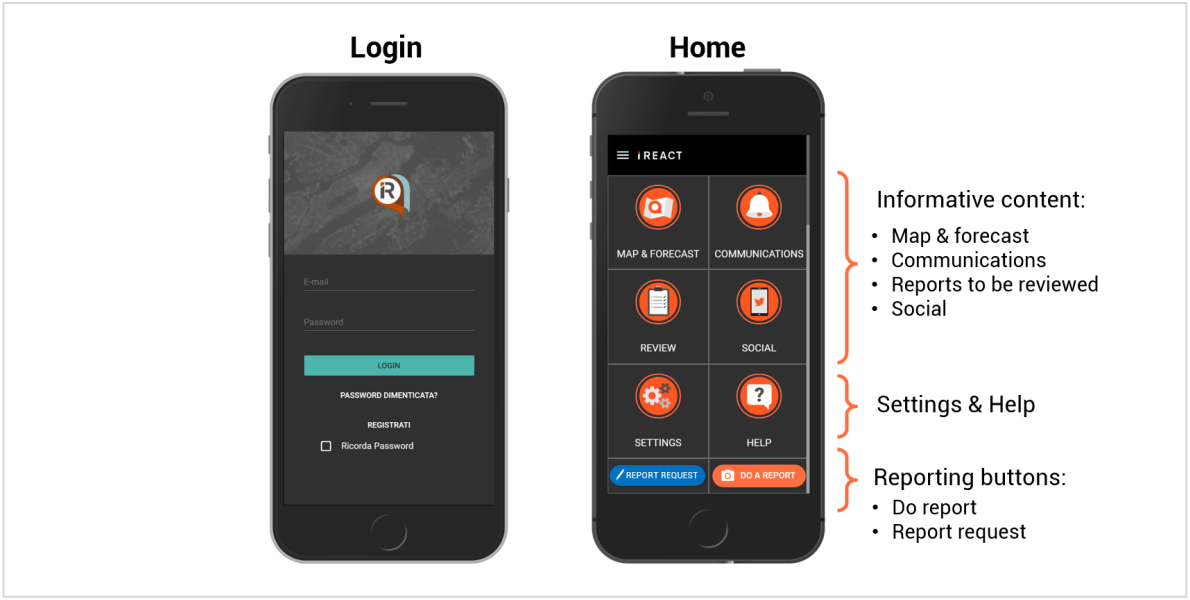

Figure 1 - Login (left) and Home (right) of the app.

Map & Forecast: location-based contents are made available in two different views: on the Map as color-coded pins and on a list-view. The Map enables a georeferenced overview of the current situation within the user's AOI.

[2] The app is named I-REACT

Every content available in the app (both incoming and outgoing information) is geo-localized and includes either a timestamp or a validity period. On the Map view, the user can pan and zoom the map. As the zoom level increases (zoom out) the pins are clustered in circles, where the center of the circles shows the number of the clustered elements and the circumference is proportionally colored according to the types of the clustered elements. The user can also click on a pin/pin cluster. If a pin is clicked, the map is centered on that pin and its informative card, which provides essential information about the pin, appears in the top part of the map. To access the full detail (Detail view) of a location-based content, the use must click on its card. If a pin cluster is clicked, the map is zoomed to that cluster until the cluster breaks into its sub-elements, which can be single pins or other clusters. This is a standard behavior and it is available in many other apps. In compliance with the co-design outputs, the main map controls are placed in the screen area reachable with the thumb (bottom part of the screen), which is known to be the most accessible (Hoober and Berkman, 2011). The bottom right controls let to center the map on the user position and start the report-creation procedure, while the left control lets the user to select the map layer to be visualized. A 'Compass' place in the top right portion of the map completes the set of controls. (Figure 2)

Given the very large amount of information potentially available on the app, the Map shows data solely on the user AOI (dotted line) and within the time window (showed in the green bar). In the app, all the spatiotemporal filters are editable from the Settings at any time.

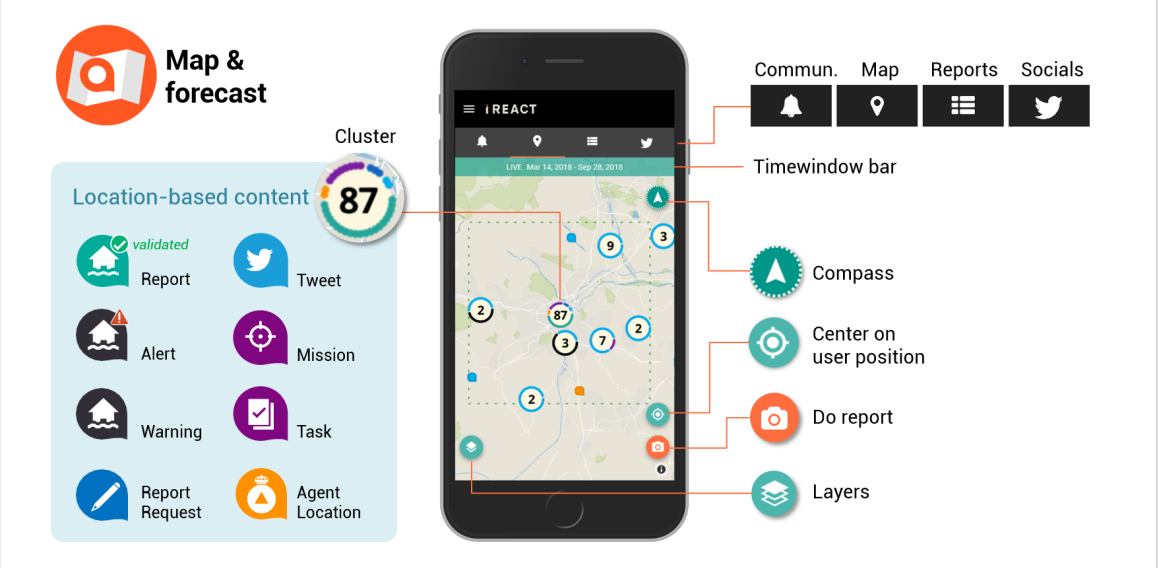

Figure 2 –Map & Forecast view: location-based contents visualized on the map together with map controls.

Layers. From the 'Layer' the user can select a map layer to be visualized on the map, one at a time. The detailed list of map layers available in the app, e.g. meteorological forecasts, is omitted for brevity. When a layer is activated, the app visualizes it on the map, enabling also the Legend button and the Player widget. The former allows to show the legend of the layer containing the association between the color and the values/classes of the layer data, while the latter enables the visualization of the temporal of the evolution of the selected layer, if any (Figure 3 shows an example of a temperature forecast). From the Player widget it is also possible to read the layer metadata.

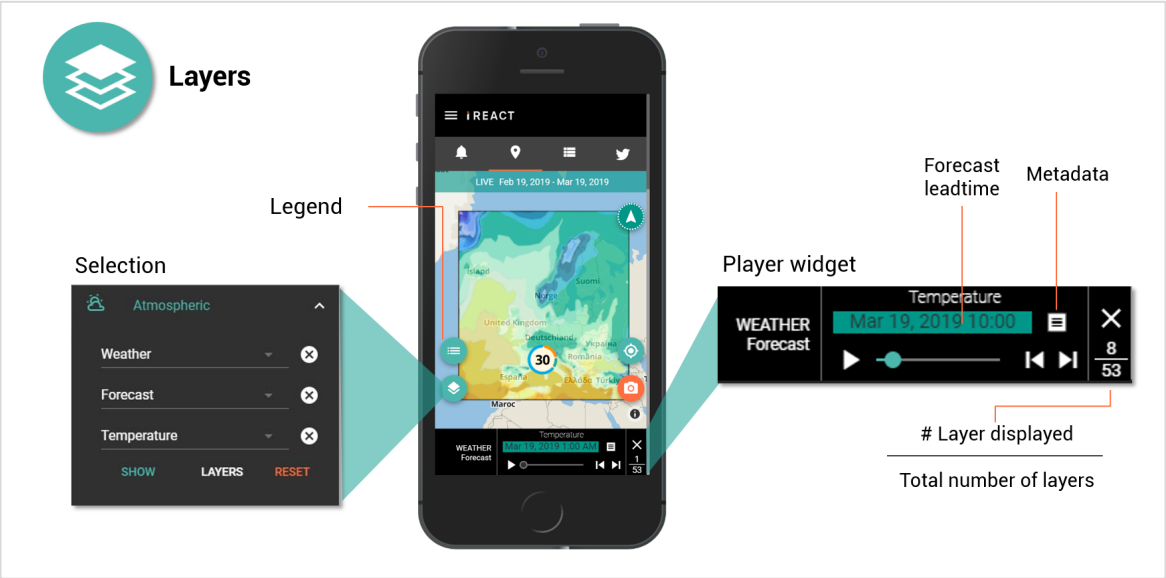

Figure 3 – Map view of a forecast layer (temperature): Layer selection (left), map view (center), player widget (right).

Communications: messages regarding Warnings (Alerts) and Report Requests coming from an authority or other trustable source (e.g. weather bulletins from regional/national authorities) are shown in this section (**Figure 4**). Warnings comply with the Common Alerting Protocol (CAP) (Standard, O. A. S. I. S., 2010), which is a standard format enabling the interoperability and the integration of alerts coming from different sources. Note that report requests are received by the in-field agents according to their location and the AOI specified by the sender. The request accomplishment is not mandatory, while the report request creation procedure is simplified as much as possible by a pre-selection of the requested parameters. The Communciation List view is omitted from brevity as it is very similar to the Report List views shown in **Figure 5** and **Figure 7**.

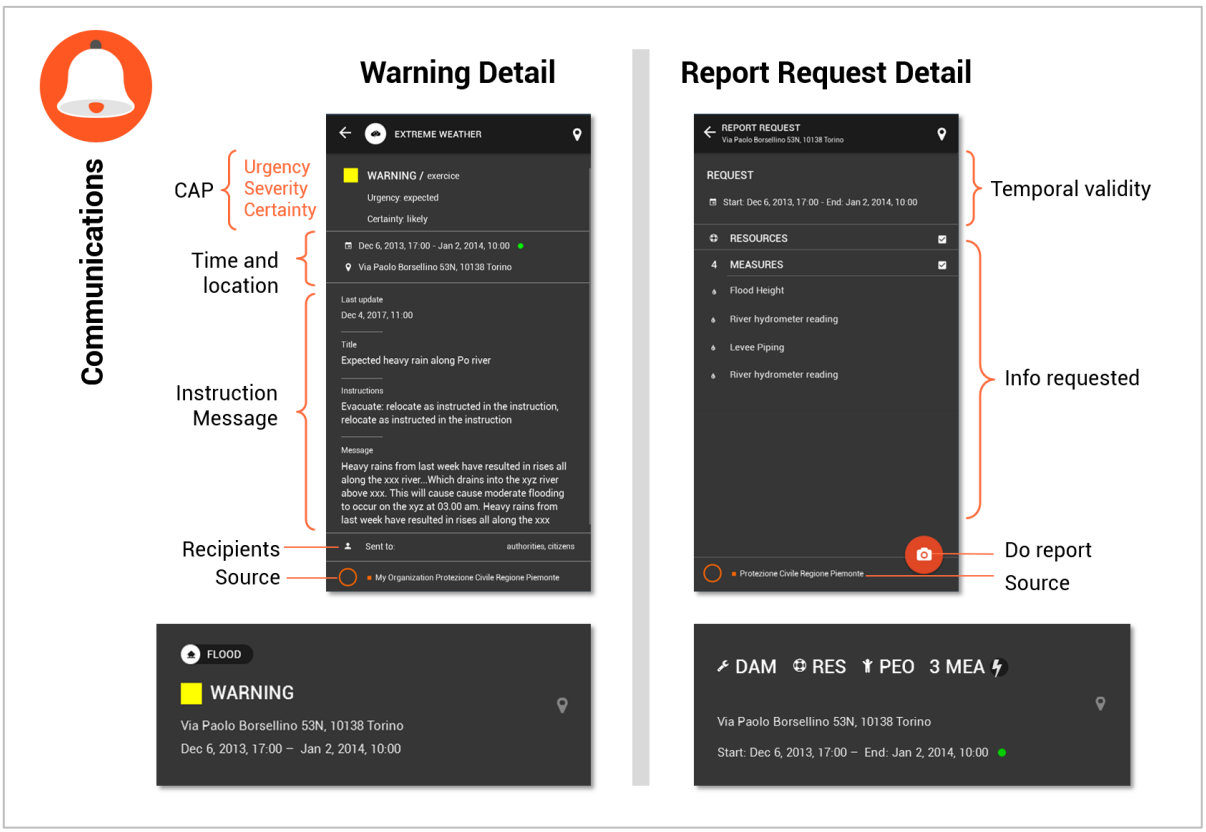

Figure 4 - 'Warning' (left) and 'Report Request' (right): card (bottom) and Detail (top) elements.

Social Media: this view displays automatically extracted hazard-related Tweets according to the user selection (**Figure 5**). The algorithm to extract and classify hazard related tweets is outside the scopes of this paper and it is detailed in Rossi et al. 2018. In the List view, quick filters allow to select the language, the time range, and the time sorting. Each extracted Tweets is also automatically classified with a set of labels, and the app allows users to give feedbacks in order to confirm or modify the automatic classification, which is structured into: named locations, hazards, information type (Affected Individuals, Caution and Advice, Donations, Emotional Support, Infrastructures, Volunteering), Informativeness (yes /no values), Panic (yes /no values). When Tweets are edited by a Professional, his/her feedback is considered as a validation, and the assigned labels are visible to all users, including citizens. If the feedback is given by a citizen, the system records it without propagating the user classification to other users. After a validation, no further amendments are allowed. All feedbacks contribute to iteratively improve the accuracy of the classification algorithm.

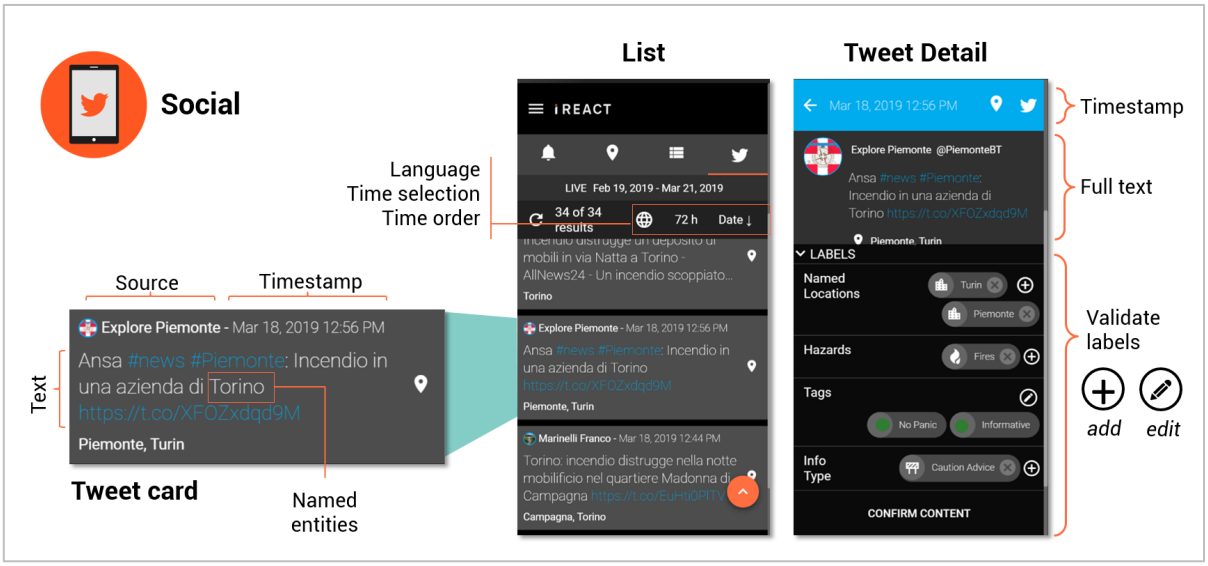

Figure 5 – Social media information: Tweet card (left), List (center) and Detail (right).

'Do Report' and report validation: being the collection of data from the field (Reports) the main activity supported by the app, the Do Report call-to-action has been included both in the Home and in the Map View. The report creation is a guided procedure in five steps: 1. Picture capturing; 2. Geo-localization; 3. Hazard description; 4. Information category; 5. Information details (**Figure 6**). The structured sequence replies to the need of having a pre-categorized and systematic data collection, and of minimizing typing errors, which are very common when free text inputs are used. The reporting procedure starts from the photo, since it has been indicated by organizations as the best format to quickly understand the situation described. Then, the geo-localization is acquired either through the device position (GPS) or with a manual selection of a point in the map. The latter possibility has been added to allow the reporter to stay at a safety distance from the hazardous point while doing the Report. A Report can include both quantitative and qualitative measures, which has been mapped using standard scales (e.g. Beaufort scale for wind velocity) when possible. The report form presents dynamically the set of measurement suitable according to the selected hazard, if any. Besides 'Measurements' it is also possible to report the presence of 'Damages', 'Resources' or 'People' by a multiple selection among listed items. These lists have been created after benchmarking multiple categorization across different emergencies organizations since a unique standard is not available and there is a great variability on the base of the hazard (e.g. water can assume opposite value whether there is a flood or a fire). The description of the report information categories is detailed in Frisiello et al. 2017.

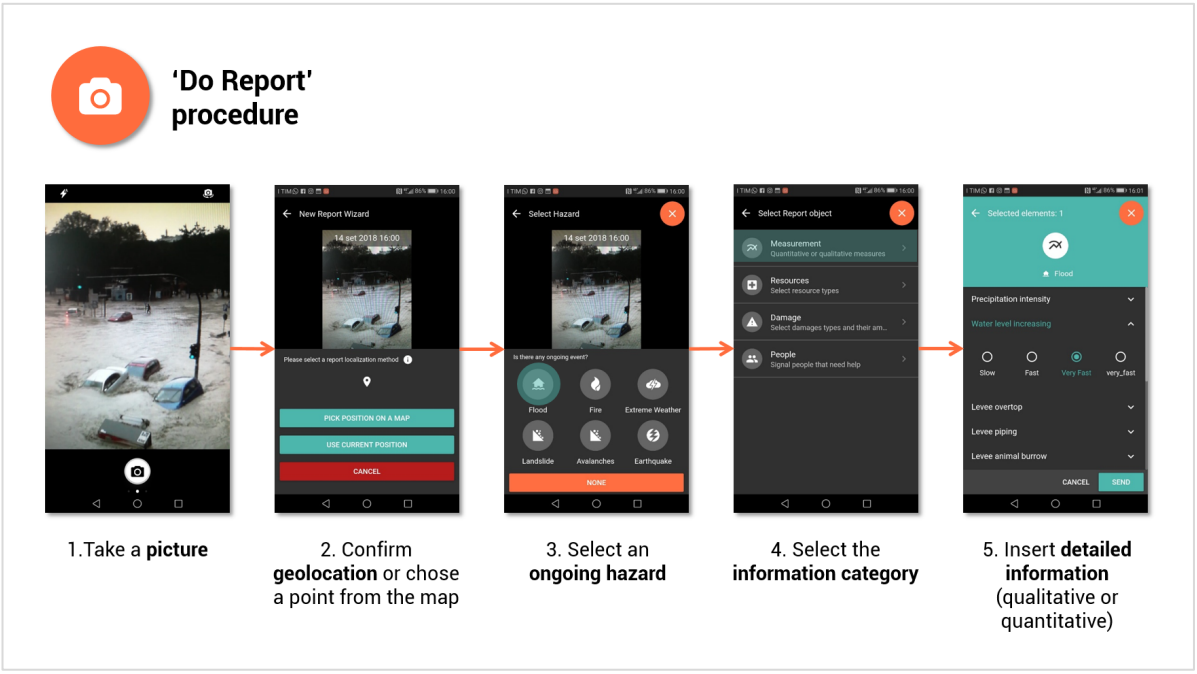

Figure 6 - Report creation procedure made of five different steps.

The report validation works at two different levels: citizens can peer-review other citizen reports by upvoting or downvoting, while specific professional roles, namely 'Decision Makers' and'Organization Responsibles', can validate/reject citizens' reports. All reports formats (Card and Detail) show a counter with upvotes and downvotes received by other citizens in the form of thumbs-up and down icons. The validation of a report is allowed only when consulting the Report Detail since a detailed evaluation is required (**Figure 7**).

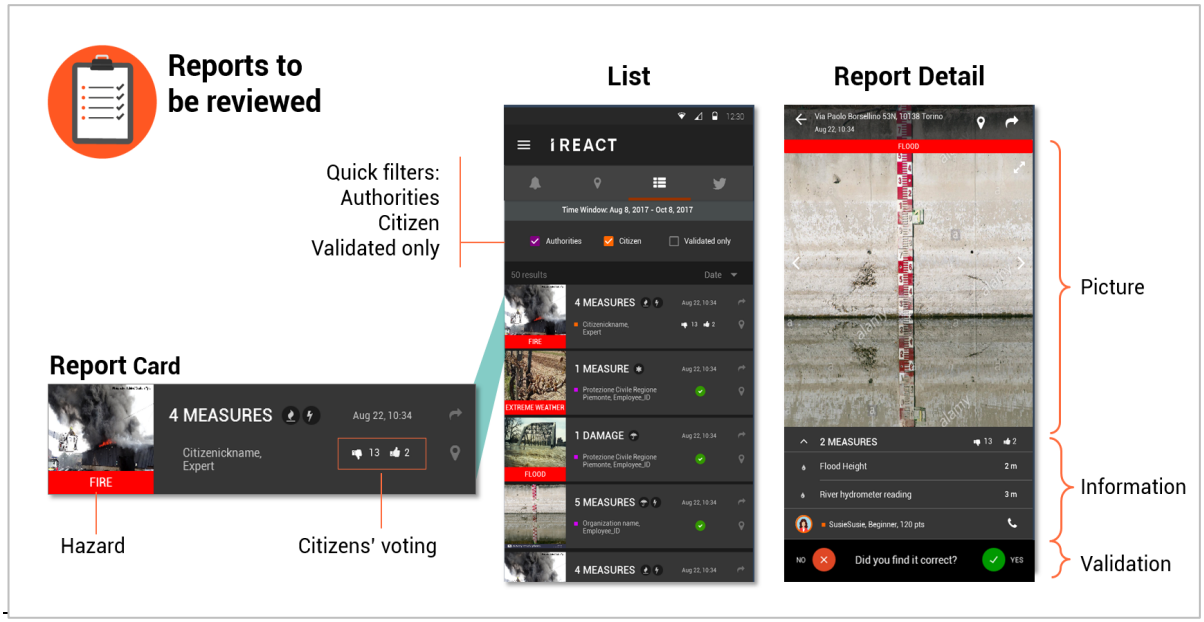

Figure 7 – Reports to be reviewed: Report card (left), List (center), and Report Detail (right).

USERS' EVALUATION RESULTS

The functionalities of the app have been implemented progressively and iterative user tests have been carried out to assess the app usability from the first responder's perspective. Over two-years, four training and simulations sessions in different European Countries (Sava Basin in Croatia, Cataluña in Spain and Helsinki in Finland) and one large scale exercise run by diverse European Civil Protections gathered in Italy have been the stages for the mobile app testing in the field. Realistic flood and fire disaster scenarios have been simulated envisaging the usage of the app, and immediately afterwards a feedback questionnaire was distributed to be filled online or on paper. 51 valid questionnaires have been collected from experts, professionals and volunteers from Public

Administration, emergency and environmental organizations at local, national and European level. The sample composition is heterogeneous per gender (27% female, 69% male, 4% not specified) and age (29% age: 25-35; 55% age: 35-55, and 16% over 56). In the following subchapters, we present the overall evaluation computed through the questionnaire as well as some comments received, which we structure according to the main app functionalities.

Overall evaluation

The overall satisfaction of the users has been computed after through the System Usability Scale (SUS), which has been derived from 10 questions exploring several features, including the ease of use, the experienced difficulty, the acceptance and the appropriateness for the tested app functionalities. The SUS output ranges from 0 (minimum) to 100 (maximum). The app received an average level of satisfaction (average SUS score of 62 in Table 1), which is slightly below the average according to the definition in (Sauro, J., 2011). It must be noted that the SUS is determined by several factors, including the level of a-priori experience, which generally results in an increase of SUS between 6% -15% (Muddimmer et al., 2012).

Table 1 - SUS overall scores

Min	37.5
Max	87.5
Average	62

Analyzing the replies on the single SUS variables, evaluated on a 5-points scale (1 very poor, 5 very good), it is possible to see that the integration of different data is the strength point of the app (Table 2).

Table 2 - SUS average per item

Item	Average
1 intention to use	3.6
2 complexity	2.6
3 easy to use	3.5
4 need of support	2.7
5 integration	3.8
6 inconsistency	2.3
7 desirability	3.4
8 cumbersome use	2.5
9 confidence	3.3
10 learning	2.7

The NPS, asking people to what extent they will recommend the app to others, confirms the positive attitude to use the proposed solution, in line with the SUS variable '1-intention to use'. The overall NPS scores computed across all demonstration is 6.8/10, while the NPS of the SAVA demo (the first one) and of the the Finnish demo (the last one) are 5.3/10 and 8.3/10, respectively. This is linked with the fine-tunings that have been made after each demo in order to improve the usability if the app functionalities. Therefore, most of the participants would recommend the app to other organizations. Some positive comments pointed out the good integration capabilities of the app and the possibility to engage citizens in the emergency procedures. Looking at other indicators, the full list of which is omitted for brevity, it resulted that users consider the app worthy (mean 3.9/5) and innovative (mean 3.5/5). Moreover, the graphic design is particularly appreciated (mean 3.9/5).

Ease of use of the main functionalities

Access. Enter the app results simple, but some crashes have been recorded and some delay was experienced in loading all the system information the first time. Therefore, adjustment have been made to improve performances reducing the bandwidth and memory requirements, e.g. the bounding box has been set to 50 km, which is enough to guarantee a good context awareness.

Navigation. The navigation structure is comprehensive and rich. It was appreciated that many phases of the emergency management cycle have been considered in the app design and in the content structure. Nevertheless, the information and the options presented are still too dense and users suggested some simplifications, e.g. reducing the layers categories and subcategories.

Settings. Time-window setting and layers activation are in general easy, with some negative comments o number of steps required in order to activate a map layer. Although a layer-button is present on the map, its findability is perceived as low. Changing the UI appearance (color and size) should be sufficient to highlight it. A further rationalization of the layer categories could make the selection and activation quicker.

*'Do report' and Report Request***.** Reporting have been tested in all demos in order to stress and evaluate the core functionality of the app. It has the highest success rate (87%) but also the high perception of difficulty (3.7/5) meaning that a training phase is needed to master the process and know the given options. The guided procedure has been appreciated but some comments were raised suggestion a simplified and shortened procedure, especially to target the general public. Another need would be to have a quick report option to send a simple geolocalized picture without content in very time constrained situations.

The *Report Request* works well, and it results very useful, but the scenario of reporting during an ongoing event might suffer the dependency of the system on the Internet connection. This is the weakest point of the app according to many users. The efficiency (effort spent, and number of steps required) is acceptable but it could be improved.

Validation. The procedure to validate reports is easy, it requires just a tap and hold on the proper button. Nevertheless, some details of the GUI could be improved. The used icons, designed to recall commonly known symbols, do not explicit well the specific types of actions available and their consequences. Reading the validation status of reports resulted very easy on both visualizations (map and list views).

Communications (alerts/warnings). The possibility to receive alerts/warnings is very interesting and important for the context of application of the app. Nevertheless, the notification should last longer when the app is in foreground as some comments claimed it disappeared too quickly. It is also difficulty to find the information after the notification. To improve this aspect the notification toast has been made permanent until the user selects one of these possible options: 'Close' to close or 'Ok' to go to the 'Detail' view of the alert/warning.

Social have been the last feature implemented and quite appreciated for context-awareness, with a slight preference for the map visualization that provides a geospatial overview (4.2/5) over the list browsing (3.9/5). The mechanism to provide feedbacks on the Tweet labels resulted not easy to do, but the GUI resulted clear, suggesting that an onboarding process could help to increase the social validation procedure.

In general, the organization of all functionalities have been appreciated with the need of simplification in some points, as the app is very rich in content. Comparing the two main information flows, the incoming data were quite clear to receive while the report creation showed a certain complexity of execution. Although the designed reporting has strutured the information exchange between the Decision Makers and the in-field agents, a certain degree of flexibility must be allowed to cope with emergency scenarios where it is better to have an incomplete report than not having it at all (for example only the picture with timestamp and position).

We observed pros as well as limitations of doing this kind of evaluation through simulated in-field demonstrations. On the one hand, we had the opportunity to test the app in the field and to immediately observe the app usage during a realistic operativity, involving simultaneously multiple users as it would be in a real emergency context. On the other hand, it was not possible to record video of the app usage. Another advantage of the simulated in-field demo is that it also allowed for informal talks with professional end-users. All the feedbacks were kept in the loop during the app fine tuning design, which entailed several revisions and feature improvements.

CONCLUSIONS AND FUTURE WORKS

The implementation of the co-design methodology based on the User-Centred Approach (Nguyen et al., 2017) resulted very effective to define key guidelines for the design of a crowdsourcing mobile solution for DRR scenarios and onboard the end-users from the very early stage of the design process. Regarding the iterative design, implementation and testing approach, we had the opportunity to use the demos to gather feedbacks that allowed to validate along the way the functionalities as they were released, distributing over time the changes and the management of the implementation complexity. The in-field demos confirmed that measures of onboarding were needed (both for professionals and citizens), which has been addressed by the 'Help' view integration in the final app to better explain the app functionalities to beginner users.

The main criticality seems to be the finding of the right balance between structured the procedures included in the the app so as to open the crowdsourcing to wide public while being integrated in existing emergency procedures

and systems. This suggests that group of citizens could have been engaged in the co-design together with DRR experts to collect complementary requirements.

Future works will be focused on the full implementation of functionalities for citizens. Among these, a gamification strategy for citizens (described in Frisiello et al. 2017) to increase citizens' awareness on natural hazards through educational contents and to foster citizen engagement is foreseen. The gamification strategy will allow to enroll citizens in structured data collection activities and features a solid validation criterion.

The app is called I-REACT and it is published on both the Android and Apple store. At present (15/02/2019) it counts 4.5k downloads from citizens.

ACKNOWLEDGMENTS

This work was partially funded by the European Commission through the I-REACT project (H2020-DRS-1-2015), grant agreement n.700256.

ABSTRACT

People use social media in various ways including looking for or sharing information during crises or emergencies (e.g. floods, storms, terrorist attacks). Few studies have focused on European citizens' perceptions, and just one has deployed a representative sample to examine this. This article presents the results of one of the first representative studies on this topic conducted in the United Kingdom. The study shows that around a third (34%) have used social media during an emergency and that such use is more widespread among younger people. In contrast, the main reasons for not using social media in an emergency include technological concerns and that the trustworthiness of social media content is doubtful. However, there is a growing trend towards increased use. The article deduces and explores implications of these findings, including problems potentially arising with more citizens sharing information on social media during emergencies and expecting a response.

Keywords

Emergencies; social media; Twitter; Facebook; representative study

1 INTRODUCTION

Interactive technologies play a major role in the context of peace and security (Reuter, 2019; Reuter et al., 2018b). This becomes obvious, recognising that social media is not only part of everyday life but is also increasingly used during emergencies or crisis situations (Reuter et al., 2018a; Reuter & Kaufhold, 2018). Our work tries to grasp exactly this specific scenario of social media usage, thereby following studies examining frequency of use of social media in situations of emergency. Relying on survey participants' answers, we chose to prioritise subjective perceptions of usage over numerical measuring of, for example, Tweets referring to a specific disaster. At the same time, focusing on subjective statements allows for an analysis of frequency and diversity of use, taking into account various sociodemographic factors. Furthermore, our study offers the possibility to establish an overview of the subjects' different reasons for social media use in emergencies.

Looking at the respondents' patterns of social media use in crises, we are also interested in their respective attitudes, not least with regards to their readiness to share data with emergency services or their assessment of social media as an effective means to look for and share information before, during, or after an emergency. Our research project EMERGENT, funded by the European Commission, involved conducting representative online surveys of citizens in the UK, Germany, the Netherlands and Italy. Here, presenting our case study, we focus solely on the results of British respondents. The case of the UK stands out because of its relative low frequency and diversity of use. This is not surprising because of the UK's image of an active emergency management and social media-friendly culture (Government, 2018; We Are Social, 2016). At the same time, the island is, like Italy and its history of earthquakes, rather prone to natural disasters (Lo & Chan, 2017; Salvati et al., 2014). Thus, we aim for a thorough understanding of the perceived behaviour of the British population, ground for action, and their subjective parameters for assessment of social media use in emergencies and emergency services' roles. As we are interested in the use and perception of social media determining factors, we looked for potential relationships between sociodemographic factors (age, gender, social grade) and ordinary social media use taking into account British respondents' perceptions on social media use in emergencies. In this article, we present the results of a

survey, involving 2,000 citizens living in the UK, conducted in October 2016. It is assumed that this allows for a more effective usage of social media and emergency applications during emergencies. We first aim for an understanding of different attitudes regarding social media usage in daily life, followed by focusing on individuals' assessment of use of respective channels in the context of emergency events. Third, we dedicate attention to use and evaluation of emergency apps, thereby assuming perceptions of such applications to be closely related to perceptions of social media use in times of emergencies. The presentation of results is succeeded by a discussion and concluding remarks.

2 BACKGROUND

During the last years, many studies on approaches for ICT in safety-critical environments, such as emergencies, have been published (Hendela et al., 2017; Hiltz & Plotnick, 2013; Starbird, 2017). They cover potentials of new technologies for safety-critical work (Norros et al., 2011), including the risk of information systems failures (Beynon-Davies, 1999). They also include approaches for coordination among emergency management units (Chen et al., 2008; Hill, 2010), support of awareness and team work (Carroll et al., 2006) and distributed collaborative situation-map making (Gunawan et al., 2011; Kogan et al., 2016). Other areas of research cover the design of emergency medical services (Kristensen et al., 2006), electronic documentation in medical settings (Sarcevic & Ferraro, 2017), and concerns against sensor-enhanced medical systems (Dahl et al., 2016). Newer approaches in emergency management work include the use and analysis of social media (Stieglitz et al., 2014). A review of the literature suggests that while there have been some quantitative studies exploring the attitudes of emergency services and citizens towards the use of social media in emergencies, there are only a few publications using representative samples to provide accurate estimates.

There are a few quantitative studies on authorities' perception of social media, and most are from North America. This includes one study (San et al., 2013) that analysed the results of a survey conducted in 2012 by the American National Emergency Management Association (NEMA). This survey asked staff members of emergency services from all 50 federal states of the US about social media use in emergency management. It found that most emergency services used social media to 'push information out to the community' during crises while lacking the skills and work force to access and analyse information shared by citizens on social media during such events. Additionally, mistrust of such information and lack of dedicated personnel to access such data were perceived as main barriers to more dedicated use of social media data. More recently, Plotnick et al. (2015) conducted a survey of 241 US emergency managers at county level in 2014 about usage patterns, barriers, and improvement recommendations for the use of social media during emergencies. It found that by 2014 only about half of these agencies used social media in any way and most did not have any formal policies to guide their use. Once again, the main barrier was found to be the lack of dedicated staff. Another survey that was conducted with English respondents further indicated a greater importance of political and organisational constraints (Shan et al., 2017). In contrast, the annual survey of the use of social media by IACP (International Association of Chiefs of Police, 2015) encompassing 553 law enforcement agencies, representing 44 states, found that 96.4% of agencies surveyed used social media in some capacity and that a very high proportion (85.5%) had used data from social media to solve crimes in their area. This could suggest either that social media use among emergency service is increasing or that police services place a much greater emphasis on it than other emergency services. Gray et al. (2017) examined Tweets in the context of three UK storms, and highlighted the importance of reducing information overload during multi-hazardous events, as well as demonstrating that sociodemographic factors could potentially influence social media usage during disasters.

There has only been one similar study conducted in Europe to date (Reuter et al., 2016), based on a survey of 2014 of 761 emergency service staff across European countries. It showed that in 2014 very few emergency services in Europe were using social media extensively; in particular, it was hardly ever used to receive information from the public. Thus, only 4% of survey participants indicated that they often receive messages from the public via social media during a crisis. While only 23% reported that they often use social media to gain situational awareness during emergencies, 46% said that they did at least occasionally.

Similarly, there are very few quantitative and recently published studies exploring citizens' attitudes towards using social media in emergencies. This includes a comparative study with over 1,000 participants conducted by the Canadian Red Cross (2012) and a similar survey by the American Red Cross (2012) involving 1,017 online and 1,018 telephone survey respondents. The latter found, for example, that around one-in-ten of the general population had used social media to find out or share information during an emergency. Furthermore, Flizikowski et al. (2014) conducted a survey with European citizens and public protection and disaster relief organisations (PPDRs) about perceptions and use of social media. Unfortunately, this was not based on a representative sample.

Reuter and Spielhofer (2017) conducted a similar survey, involving 1,034 citizens of the European Union. It found that while around two-in-five citizens had used social media to search for information in an emergency (43%),

only just around a quarter had used it to share information (27%). The survey also showed that 42% of citizens indicated that they would expect a response within an hour if they posted a request for help on an emergency service social media site and that 69% believed that emergency services should regularly monitor their social media channels to be able to respond immediately to such requests. An even more recent study, in 2016, was conducted by Reuter et al. (2017) in Germany. This representative study involved 1,069 citizens using an online-survey with similar questions regarding frequency and diversity of usage. The survey showed that nearly half (45%) of the respondents had used social media to share and/or look for information during an emergency, but only 16% had downloaded an emergency app. In contrast to these results, British and Northern Irish respondents showed lower percentages with respect to both questions.

However, apart from the survey conducted in Germany, there is a gap both in representative studies from across Europe (the study by Reuter and Spielhofer (2017) was based on an opportunity sample) and with respect to the UK and other European countries. In this paper, we focus on the UK as it poses an interesting case of relatively low frequency and interest of social media use during emergencies while it is suggested that ordinary social media use is comparatively at a medium level (We Are Social, 2016). There are various studies focusing on sociodemographic factors like age or gender with respect to social media use (Barker, 2009; Correa et al., 2010; Lin et al., 2014). Yet, our paper presents a first attempt to bring these variables together with ordinary social media use (Lev-On & Uziel, 2018), thereby trying to offer a bigger societal picture with respect to this specific scenario of social media usage.

3 RESEARCH DESIGN

The findings reported in this article are based on an online survey conducted by Opinium Research between 8th and 9th October 2016, with the research agency generating a diverse sample from a pool of volunteers. Respondents were offered a small allowance. The main goals of the survey were to explore UK adult citizens' (aged 18 or above) attitudes towards the use of social media for private, everyday life purposes and in emergency situations. It was conducted as part of a European project study. It consisted of nine sets of questions, most of them in closed-answer format, except for the last, open-ended, question. Questions addressed: (1) information about gender, age, social grade, working status and geographical location (UK region) of participants; (2) citizens' frequency of social media use; (3) their previous use of social media in emergencies to share or look for information; (4) if applicable, the types of information shared; (5) the expected responsiveness of emergency services to answer to messages posted via social media; (6) opinions about discouraging factors for using social media in emergencies; (7) the extent to which they had previously downloaded any smartphone app to be used in emergencies and, if so, what apps they had downloaded; (8) their expectations regarding the use of such apps in the future; (9) an open-ended question, asking them to provide further details about experiences with social media in emergencies.

A total of 2,000 UK citizens completed the survey, including 1,118 women (55.9%) and 882 men (44.1%). Most respondents (91.2%) were between 25 and 74 years old. Around two thirds of the respondents (66.6%) were in the social grade ABC1 and around one third (33.4%) in the social grade C2DE. These social grades refer to the classification system based on occupation and developed by the National Reader Survey (2019). Social grades A, B, and C1 are combined to represent middle and upper class, which therefore can be distinguished from C2, D, and E, representing working and lower class (Dobson, 2016). A large proportion of citizens (39.6%) were working full time and 25.3% were retired. Most respondents (83.1%) lived in England, especially in the South and East of England (33%). As there were significant differences between the respondents and population statistics, the sample was weighted to be representative of the population for the gender, age, social grade, working status and home region of respondents. This was done using the most recent population statistics (Office for National Statistics, 2017). The analysis is based on this weighted sample.

For the quantitative analysis, survey data was extracted and analysed using IBM SPSS Statistics 23. Microsoft Excel was used for the design of the displayed figures. The analysis consisted of three key steps: (1) preparing the data, including assignment of missing values and data values, and combination of categories of demographic background variables; (2) exploring basic frequencies for each question; (3) using cross-tabulations with chi-squared tests to explore any significant differences for different types of respondents in relation to gender, age, social class, region and working status. In addition to that, Mann-Whitney U Tests were used for ordinal variables and Kendall's Tau was used to determine correlations between ordinal items. Test results including effect sizes are displayed in brackets. Conventions for Cramer's V depend on the degrees of freedom (*df*). According to Cohen (1992), Cramer's V of .1 is regarded as small, Cramer's V of .3 as medium and Cramer's V of .5 as large, if df=1. For higher degrees of freedom, the required Cramer's V for the interpretation of small, medium and large effect sizes is smaller.

For the qualitative analysis, open responses from 1,958 respondents were coded using Microsoft Excel. This

involved thorough reading of all responses of the open-ended question and generating and validating key themes. These were then used to define categories and the open responses were repeatedly analysed collectively and assigned to one of the categories. Six categories were defined, encompassing scepticism, conditions, range of applications, productivity, inexperience, information flow. These were further categorised into assessed barriers (scepticism, conditions), advantages (productivity, information flow), and experience (range of applications, inexperience) regarding social media use in emergencies. The literature review and the quantitative analysis that was done beforehand helped to increase 'theoretical sensitivity' (Strauss, 1987) and establish the context of the qualitative analysis.

It also needs to be noted that the questionnaire did not define an emergency concept or situation, mainly to find patterns and similarities within individuals' own perceptions towards emergency situations. Situations of emergencies were thus defined by the individuals themselves.

Contrasting prior work focusing on bigger disasters (UN Office for Disaster Risk Reduction, 2016; Whittaker et al., 2015), we choose a broader definition (Haddow et al., 2002) of emergencies, referring not only to academically conceptualised emergencies and disasters but also emergency situations in which only a few individuals may be affected and call upon emergency services' standard procedures for help (e.g. burglary). This allows a glance at individual perceptions of incidents disrupting their everyday lives while otherwise not reaching the categorical threshold of an emergency with collective impact. Communication via social media may prove to be effective in each scenario. Aware that individual incidents differ in scope and individuals may pursue actions via social media differently, citizens may want to contact emergency services or have high expectations towards authorities independent from the type of emergency. We assume that a broad understanding of an emergency takes into consideration that various participants define emergencies based on their own experiences and conventional usage of the term, the common understanding forming the basis of individual action and defining circumstances at which social media may aim. In contrast to other studies focusing, e.g. only on perceptions of directly involved individuals, we defined individuals to use social media during emergencies even when they were not directly involved as primary sources of information as this may show interesting results as well.

4 FINDINGS

In the following, we present our results regarding ordinary social media and smartphone use, social media use in emergencies and the use of emergency applications. At the same time, we report correlations between sociodemographic factors and ordinary social media use, respectively, and the use of social media in crisis situations, potentially yielding both theoretical and practical implications.

4.1 Use of Smartphones and Social Media

The survey confirmed findings from other recent research in the UK (We Are Social, 2016) regarding the use of smartphones and social media usage. Table 1 below sets out the main findings from the UK survey carried out in October 2016.

Activity	Hourly	Daily	At least once a week but less than daily	Less than once a week	Never
Use a smartphone	30%	43%	6%	2%	19%
Use Facebook	11%	48%	12%	7%	21%
Use Twitter	4%	14%	9%	11%	62%
Use other types of SM	5%	19%	19%	18%	39%
Post messages on SM	3%	14%	21%	28%	34%

Table 1: Proportion of regular smartphone and social media users (N=2000)

It shows that over four-in-five adults in the UK currently use a smartphone at least occasionally while 19% never use one. Looking at these 19% more closely, it shows that they are most likely to be older and/or in the lowest social grade of the population. More specifically, those reporting not to use a smartphone are most likely to be:

- aged 75 or older: 49% of this age group do not use a smartphone, compared with 3% of 18-24-year-olds; among those aged 65 to 74, it is 37% (χ^2 (6, N=1999) = 232.97, p <.001, Cramer's V =.34).
- in the lowest social grade (E) of which 32% never use a smartphone; in contrast only 10% of those in the highest social grade (A) do not use one (χ^2 (5, N=2001) = 57.78, p <.001, Cramer's V =.17).

There was no difference depending on gender.

The analysis also shows that a very similar overall proportion of citizens use Facebook as there are smartphone users. But even though there is clearly some overlap of non-Facebook users with those who use a smartphone. Around half of those not using a smartphone still use Facebook. In total, around 9% of citizens neither use a smartphone nor Facebook.

Interestingly, even though young people are far more likely to be Facebook users, relatively high proportions of older people use it too (χ^2 (12, N=2000) = 138.03, p <.001, Cramer's V =.26). While 93% of 18-24-year-olds use it at least sometimes and 76% of those in this age category use it daily, 58% of those aged 75 or above use it occasionally or more and 39% on a daily basis. One other noticeable pattern is that there is virtually no difference between 18-24- and 25-34-year-olds in the proportion that uses Facebook on a daily basis.

The survey also showed that there is a significant difference in the use of Facebook depending on gender (χ^2 (2, N=2001) = 34.13, p <.001, Cramer's V =.13). Thus, 65% of women use Facebook on a daily basis, compared with 53% of men. Similarly, while 82% of women use Facebook at least sometimes, it is only just above three-quarters of men who do so. Adult citizens in social grades ABC1 were also slightly more likely to use Facebook (81%), compared with those in lower social grades C2DE (77%) (χ^2 (1, N=2000) = 4.73, p <.05, Cramer's V =.049). However, this could reflect the fact that 31% of those in the social grades C2DE are retired, compared with 21% of those in ABC1, potentially reflecting the older age group of those in the lower social grades above anything else.

Twitter is used by fewer people than Facebook in the UK. Thus, around one-in-five (18%) use it daily and 38% use it at least occasionally (less than once a week or more often). Once again, Twitter users are most likely to be young citizens: Fifty-three per cent of under 50 years use Twitter at least sometimes, compared with only 22% of those aged 50 or above (χ^2 (2, N=2000) = 224.94, p <.001, Cramer's V =.34). Daily Twitter use is at a peak among 18-24-year-olds (37%) and falls to just one per cent among those aged 75+ (χ^2 (12, N=1999) = 257.09, p <.001, Cramer's V =.36).

Looking at respondents who use Twitter on an hourly basis, the proportion is only relatively high (11%) among both 18-24- and 25-34-year-olds. For all other age groups, it is at three per cent (35-44-year-olds) or below. Another significant difference is that regular Twitter users are most likely to come from social grades ABC1 (χ^2 (2, N=2000) = 51.55, p <.001, Cramer's V =.16): Two-thirds (67%) of those who use Twitter daily are in these social grades. Thus, is that almost twice as many citizens in social grades ABC1 (23%) use Twitter on a daily basis, compared with those in social grades C2DE (13%).

Moreover, men are significantly more likely to use it on a daily basis (22%, including 6% using it on an hourly basis) than women (15%, including 2% using it hourly) (χ^2 (2, N=2000) = 19.30, p <.001, Cramer's V =.098).

4.2 Use of Social Media in Emergencies

While the majority of UK citizens (85%) use some form of social media at least occasionally, considerably fewer citizens have used social media during an emergency. More specifically, around one third of the survey sample (34%) indicated to have used some form of social media in the past to look for or share information during an emergency, such as an accident, power cut, severe weather, flood or earthquake (**¡Error! No se encuentra el origen de la referencia.**). This includes 21% who used it to share information and 13% who used social media to find information only. It is worth noting that those participants that have not used it may not have had the need to do so as they may not have experienced an emergency.

These results are reflected in responses to an open-ended question in the survey, asking participants to provide fuller details about their use of social media in emergencies. This included respondents who stated that they either do not use social media at all or have never used it during an emergency. Others highlighted the way social media was a useful tool to send and receive up-to-date information very quickly:

> *'Social media is often the most effective way of finding out about incidents quickly'.*

> *'It's a very easy and convenient way to reach a lot of people all at once! Information spreads quickly on social media and is more likely to be seen by a large audience. If there was a national or even worldwide emergency, it would be one of the best ways of quickly sharing important information with everyone.'*

Specific uses of social media included looking for information shared by emergency services or news agencies, using it to share or look for transport disruption details, and for sharing information about the emergency, or that you are safe, with friends and family:

> *'When being stranded in Europe due to ash cloud I have shared pictures of queues at airport on Facebook.*

Used Twitter feed for latest information on closures and shared my location with colleagues also trying to get home.'

'It's good to warn friends of things or to let people know you are safe without contacting each one individually.'

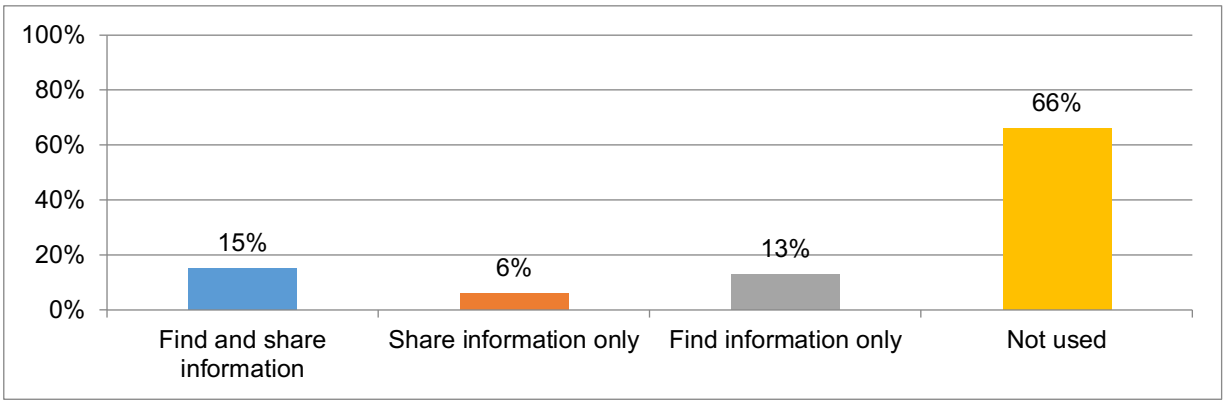

Figure 1: Use of social media (Facebook, Twitter, Instagram etc.) during an emergency (N=2000)

The survey indicated noticeable differences in the characteristics of those who have/would and have/would not used/use social media during an emergency, relative to their age, gender and social grade. In particular, respondents most likely to use it were young people, women and those in social grades ABC1. Figure 2 presents the levels of social media use in emergencies by age of participants, categorised into seven age bands. It shows that those in the youngest age band are most likely to have used it (χ^2 (6, N=1999) = 254.56, p <.001, Cramer's V =.36), although the levels of use are quite similar for those aged 25-34 and 35-44. As Figure 2 shows, there is a noticeable drop in use for those aged 45 or above – suggesting a 'digital divide' between younger and older citizens in the UK.

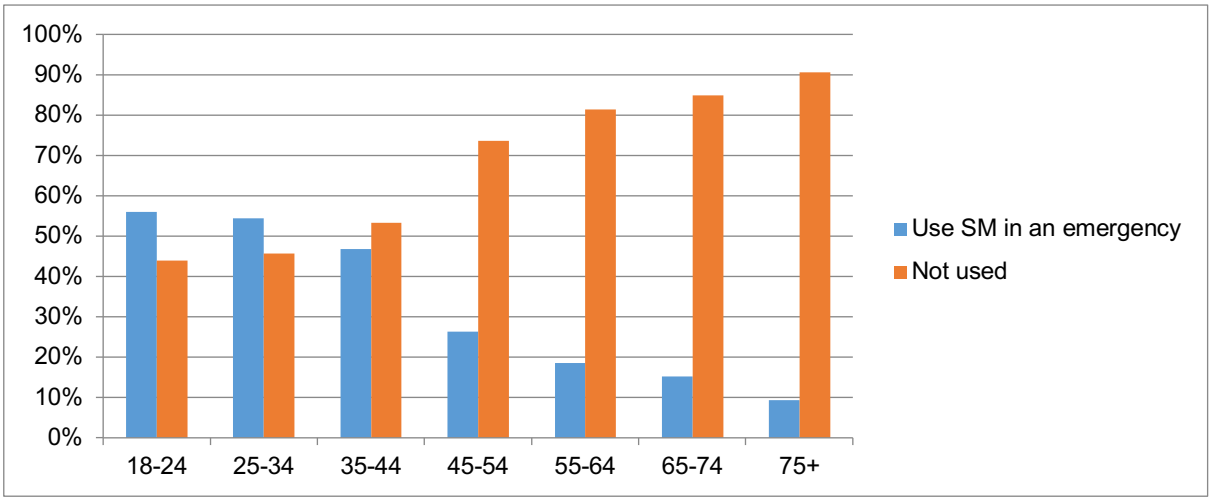

Figure 2: Use of social media in an emergency by age (N=2000)

Analysis of the data also showed that those in the youngest age group are more likely to have used social media to look for information, while those in the 25-34 age group are more likely to have used it to share information.

Age group	Use SM to look for info only	Use SM to share info	Total use
18-24	40%	16%	56%
25-34	19%	36%	54%

Table 2: Ways of using social media in emergencies by age group (N=575)

Women are also significantly more likely to have used social media in an emergency (37%) than men (31%) (χ^2 (1, N=1999) = 7.52, p <.01, Cramer's V =.061). In particular, women are more likely to use social media to share information in an emergency (23%) than men (18%) (χ^2 (2, N=1999) = 8.01 p <.05, Cramer's V =.063), while similar proportions have used it to look for information (14% of women and 13% of men, respectively). Similarly, 38% of those in the social grades ABC1 have used social media in an emergency, compared with 29% of those in

social grades C2DE (χ^2 (1, N=2000) = 18.65, p <.001, Cramer's V =.097).

While a third of respondents in the UK (34%) has used social media in an emergency, two-thirds (66%) have not done so. Asking for reasons behind not using social media in emergencies, responses (see Figure 3) suggest that citizens are mostly concerned about the trustworthiness of information on social media, that information shared on social media is not reliable (60%) and that there are many false rumours on social media (64%). These concerns were reflected in many responses to the open-ended question:

> *'I have never used social media in any emergency and would be hesitant in doing so as you could have anyone turning up and taking advantage of the situation.'*

> *'I wouldn't use social media in an emergency - far too unreliable and prone to rumour'*

Furthermore, people have technical concerns. More than half (62%) state that they are concerned about mobile phones and social media not working properly in a serious emergency and that this would (definitely) put them off using social media. Lack of confidence in using social media was only a reason for around a third (28%) of citizens.

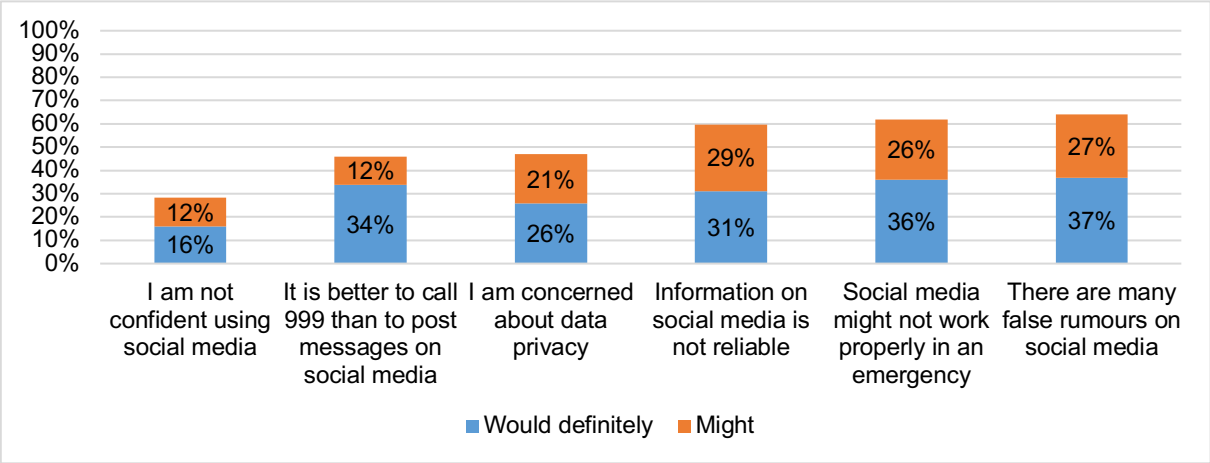

Figure 3: Reasons for not using social media during an emergency (N=2000)

In contrast, several respondents indicated several factors that would make them more likely to use social media in the future to look for or share information. Among these are information accuracy and data security as well as having assured that emergency services are actually known to look for and act on any information shared.

> *'I have never used social media in an emergency. I would need to be reassured about its reliability and that it was monitored.'*

> *'I suppose I might be likely to use it if I found that the emergency services WANTED to be contacted that way and would respond quickly'*

The 432 citizens who have already used social media to share information during an emergency were most likely to have done so to share weather conditions or warnings (43%) and road or traffic conditions (42%). A further 31% have shared their own feelings or emotions about the event (see Figure 4). However, some significant differences were revealed depending once again on gender, age and social class of citizens. The most noticeable of these were that women were significantly more likely to have shared their feelings or emotions via social media (35%) than men (25%; χ^2 (1, N=412) = 4.15, p <.05, Cramer's V =.10), while men were more likely to have shared advice on what to do to stay safe than women (23% versus 15%; χ^2 (1, N=412) = 3.89, p <.05, Cramer's V =.097). Regarding age, 18- to 34-year-olds were more likely to share eyewitness photos than citizens in older age groups (13%; χ^2 (2, N=411) = 7.38, p <.05, Cramer's V =.13). In contrast, those aged 55 or older were more likely to have shared weather conditions or warnings (59%) and road or traffic conditions (58%) than younger citizens (χ^2 (2, N=412) = 10.36, p <.01, Cramer's V =.16 and χ^2 (2, N=413) = 12.42, p <.01, Cramer's V =.17, respectively).

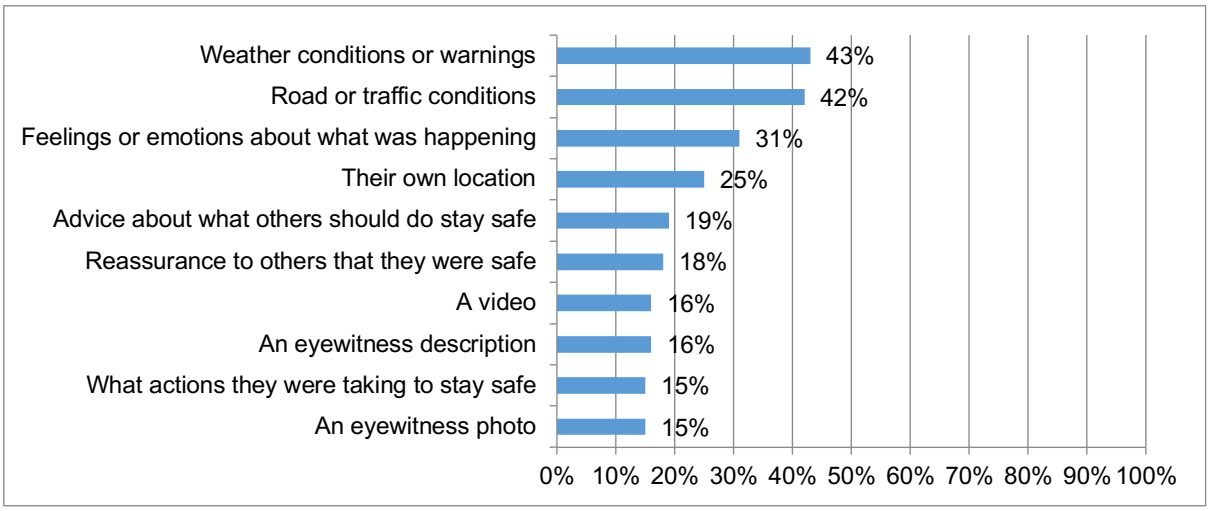

Figure 4: Types of information shared during an emergency (N=432)

Considering that a respectable proportion of respondents (21%) said to have shared information via social media and our research interest of deriving useful practical insights with respect to potentially influencing factors, we asked participants what online responses they expect from emergency services. Figure 5 shows that the majority of UK participants do not expect emergency services to respond to messages posted to them on social media during an emergency or to monitor social media. Thus, only around a third (30%) of citizens agreed or strongly agreed with the statement that they would expect to get a response to such a message within an hour. The main reason for this appears to be that more than 60% of citizens think that emergency services are too busy during an emergency to monitor social media. Indeed, medium correlations were found between thinking that emergency services are too busy and expecting emergency services to monitor social media (r_τ = -.235, p<.001) and expecting emergency services to respond within an hour (r_τ = -.246, p<.001), respectively.

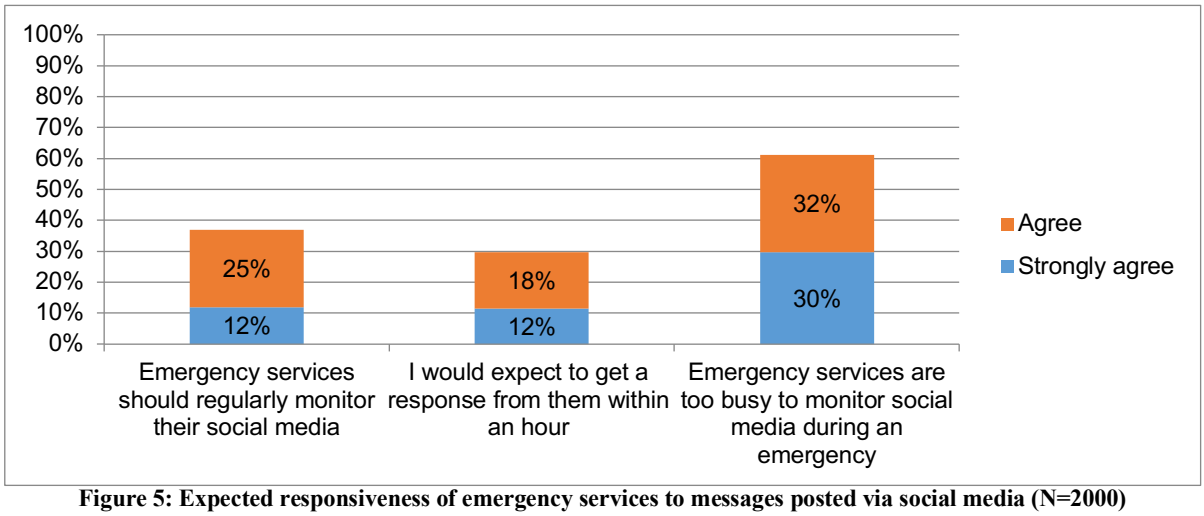

Figure 5: Expected responsiveness of emergency services to messages posted via social media (N=2000)

Despite this overall low expectation of emergency services to monitor their social media accounts and to respond to messages sent via social media, there are subgroups of citizens with higher expectations. Younger people (r_τ=.152, p<.001) and people using smartphones in their daily life (U = 307901.5, p<.001) tend to have higher expectations. Thus, for example, almost half of those aged 18-34 (48%) think that emergency services should regularly monitor their social media, compared with only 27% of those aged 55 or older and 38% of those aged 35-54. Similarly, 41% of smartphone users agreed with this statement, compared with 22% of those at the time of conducting the survey not using a smartphone.

4.3 Use of Emergency Apps

Instead of using common social media platforms, specific smartphone apps are available that could help in a disaster or emergency. Currently, such apps are not widely used in the UK. Indeed, only 7% of survey participants reported to have downloaded such an emergency app. Even when excluding those 376 participants who currently do not use a smartphone, the proportion increases only slightly to 8%. Thus, this group is likely to represent a

unique group of citizens with a particular interest in emergency response or in smartphone applications. When looking at the characteristics of this group, significant relationships were found between having downloaded an emergency app and gender, age, social grade as well as Twitter use. Firstly, 65% of those who have downloaded an emergency app were male (χ^2 (1, N=1913) = 15.15, p <.001, Cramer's V =.089) and 59% were between 25 and 34 years old (χ^2 (6, N=1911) = 116.54, p <.001, Cramer's V =.247) while 23% of the survey sample falls in this age bracket. Secondly, 80% belonged to the social grade ABC1, with only 54% of the survey sample falling in this social grade (χ^2 (1, N=1913) = 38.92, p <.001, Cramer's V =.14). Lastly, 28% of this group of respondents use Twitter hourly while there are only 4% hourly Twitter users in the sample overall (χ^2 (4, N=1913) = 261.46, p <.001, Cramer's V =.37).

Of all citizens that had downloaded an app (n=135), the most downloaded app was a weather app (44%), followed by a first-aid app (42%). A warning or alert app was downloaded by 36% and an emergency call app was only downloaded by 28%. Ten respondents indicated that they had downloaded another app that did not fall into these four broad categories including a power cut notification and a missing child alert, thus, exemplifying the potential diversity of emergency applications use. Although the vast majority of citizens (93%) have not yet downloaded an emergency app, a large proportion of respondents indicated that they were likely to use apps in the future for various reasons. It shows that citizens are generally most likely to use apps to receive information during emergencies rather than to share information (Figure 6). Around 40% thought it was at least quite likely they would use an app to find out information about an emergency while only 21% thought they would use it to contact an emergency service instead of making a 999 call. Perhaps unsurprisingly, those who had downloaded an app in the past were significantly more likely to think that it was very likely they would use an app for all of these purposes in future (U=68535.0, p<.001; U=61724.0, p<.001; U=70002.0, p<.001; U=67244.0, p<.001; U=67244.0, p<.001; U=62576.0, p<.001, respectively).

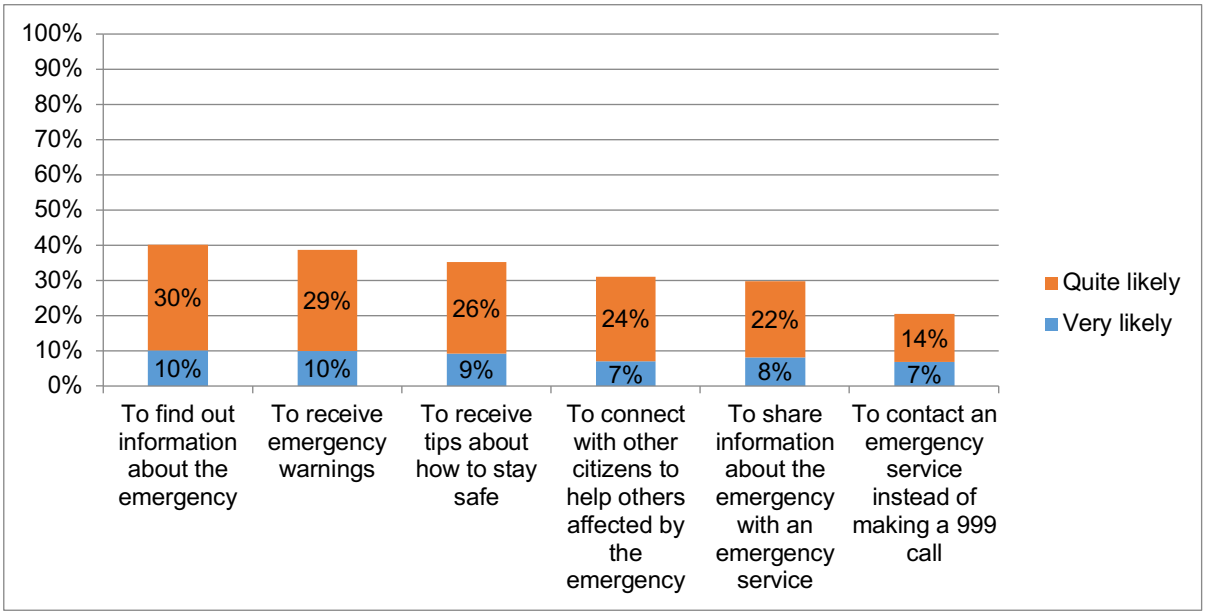

Figure 6: Likelihood of using an app in future for different purposes (N=2000)

The general trend that citizens would use such apps to receive information but not so much to share information was also found within the open question responses. For example:

> *'I would use it for additional advice/guidance but never as an alternative method to contact an emergency service.'*

Respondents further provided suggestions of additional emergency apps that they would use if they were available. Examples include: A 'check in' app which sends out text messages to let friends and family know the person is fine, a real-time time connection with emergency authorities, an app for emergencies at sea or in the mountains to locate the person, an app providing status updates.

5 DISCUSSION AND CONCLUSION

The use of social media in the UK is widespread and growing. Services such as Facebook and Twitter are still used by considerable proportions of citizens among the older generations, even though older people are significantly less likely to use them. The findings of the survey with over half (58%) of those aged 75 or above using Facebook may be surprising to some who believe that social media is predominantly used by adolescents.

Furthermore, research elaborated on potentials of new technologies for safety-critical work or, more specifically, emergency response (Norros et al., 2011). Compared with the general levels of social media usage, much lower proportions of citizens have used social media in an emergency to look for or share information. This could reflect a reluctance to do so given the perceived dangers highlighted in this survey of false rumours circulating on social media during recent crises. Yet, at the same time, it could also reflect a lack of perceived need. In particular, some people may still rely on traditional media or online news sites to provide them with information in such instances, while others may not have been in a situation where they have needed to do so.

Context, i.e. time and place, may influence social media usage as well. Thus, it is worth considering that the recent terrorist attacks carried out in the UK in 2017, including the Westminster attack on 22nd March and the Manchester bombing on 22nd May, which happened after the survey was conducted, may have increased people's use of social media in the UK during emergencies. Indeed, as reports following these attacks showed, social media was used extensively by emergency services and citizens during these events.

At present, only a relatively low proportion, around a third, of citizens in the UK expect emergency services to monitor social media and to respond to messages posted on social media. At the same time, the expectation is much greater among younger citizens and those using social media actively. This suggests that, in the coming years, more and more citizens will expect emergency services to monitor and respond to such messages. If emergency services monitor, respond to messages on social media and citizens perceive this shift in crisis communication, more and more people may start using it as a form of sharing and looking for information in cases of emergency. However, this raises some potential issues. First, as the survey has shown, social media is used the least by older, socio-economically disadvantaged citizens. This could mean that in an emergency, such as a flood or large-scale fire, emergency services are not alerted to the needs of those not using social media. Then, we could envisage a scenario in which emergency services commit increased resources to support citizens in areas with higher proportions of young and affluent social media users to the detriment of those living in areas with a poorer and older age profile. Habitual use of social media is reflected by the younger generation of 'digital natives', most open to share eyewitness pictures and most strongly expecting other entities (like emergency services) to integrate social media into their working procedures.

If organisations take this interpretation into account, social media usage might increase during emergency events. The risk of such increased use of social media during crises is that emergency services could be swamped by the information published form the civilians. Already today, emergencies are accompanied by enormous amounts of social media messages. The Brussels bombing in 2016 (McMahon et al., 2016), for example, prompted a large volume of social media traffic in the hours and days following the events, with over 2 million messages posted on Twitter. Other research has shown that during major events such as terrorist attacks, emergency services are often overwhelmed with information – including calls to emergency helplines or 999 calls – which means it could limit their ability to access or identify additional data from social media (Plotnick et al., 2015). At present, there are some social media analytics tools like AIDR or Dataminr used for event detection (Imran et al., 2014; Miller, 2017). Yet, further effort is necessary to be able to compress streams of data into manageable chunks of information.

By testing for correlations between extraordinary social media behaviour in times of crises and ordinary use, our study sheds light on specific usage patterns regarding certain social media platforms. Ensuring successful crisis communication requires emergency services to monitor and respond on various platforms simultaneously to not discriminate against socially potentially more disadvantaged individuals. At the same time, multimodal communication channels among authorities responsible for social media content, providers of news websites or of TV or radio news could prove to be helpful in spreading information to non-users of smartphones or online social media. Furthermore, our study highlighted differences in the behaviour of men and women in relation to social meda. Here, UK participants' statements reflect rather conventional gender roles with advising male respondents (Janković et al., 2017), indicating the necessity of sensitive communication.

This study has strengthened findings from previous qualitative and quantitative studies of the use and impact of social media during emergencies. In particular, it has highlighted the extent to which the use of social media is widespread among citizens in the UK and that they are increasingly using it to look for and share information during emergencies. There is also a growing trend towards sharing information, photos and videos with others and directly with emergency services – and as the latter become more responsive, this diversification of use is likely to grow. Thus, it can be said that civilians show a growing interest of using social media in any kind of

emergency, while requiring assurance by emergency services.

However, further qualitative and quantitative research is needed to explore the extent to which specific events of emergencies like recent terrorist attacks in the UK and other parts of Europe have changed citizens' attitudes towards using social media or settings in which they would use social media. This includes that there is also a need to further examine ways in which emergency services can deal with additional data in crisis situations and what tools are best suited to help them to do so.

ACKNOWLEDGEMENTS

ABSTRACT

Approaches for effectively filtering useful situational awareness information posted by eyewitnesses of disasters, in real time, are greatly needed. While many studies have focused on filtering textual information, the research on filtering disaster images is more limited. In particular, there are no studies on the applicability of domain adaptation to filter images from an emergent target disaster, when no labeled data is available for the target disaster. To fill in this gap, we propose to apply a domain adaptation approach, called domain adversarial neural networks (DANN), to the task of identifying images that show damage. The DANN approach has VGG-19 as its backbone, and uses the adversarial training to find a transformation that makes the source and target data indistinguishable. Experimental results on several pairs of disasters suggest that the DANN model generally gives similar or better results as compared to the VGG-19 model fine-tuned on the source labeled data.

Keywords

Image classification, disaster damage, domain adaptation, domain adversarial neural networks.

INTRODUCTION

The increased popularity of social media websites has transformed the way in which affected populations communicate with response organizations during and following major disasters. Victims of several recent hurricanes, including Hurricane Harvey, Hurricane Irma and Hurricane Florence, have turned to social media to request help and assistance, as emergency hotlines were sometimes unreachable due to the high volume of calls (Rhodan 2017; MacMillan 2017; Frej 2018). According to Rhodan (2017), a woman and two children were rescued during Hurricane Harvey after the woman posted a desperate message for help on Twitter: 'I have 2 children with me and tge [sic] water is swallowing us up. Please send help.' Similarly, an image posted on Twitter, which showed 'elderly residents sitting in greenish flood water,' raised awareness of a nursing home situation and resulted in urgent help being sent to the nursing home (Rhodan 2017).

*corresponding author

While social media can help increase situational awareness, inform rescue operations, and save lives, its value is highly unexploited by response teams, in part due to the lack of tools that can help filter actionable information from the big data posted during disasters. A recent study (Villegas et al. 2018) reported that during Hurricane Harvey, FEMA missed 46% of the critical damage information posted by affected individuals on Twitter, and thus many areas heavily impacted by the hurricane were missed from the original damage estimates provided by FEMA. Similarly, Kryvasheyeu et al. (2016) used Hurricane Sandy tweets, and Enenkel et al. (2018) used Hurricanes Harvey and Irma filtered, geo-located tweets to show that rapid early damage assessment can be facilitated by social media. Among others, the above-mentioned studies (Kryvasheyeu et al. 2016; Villegas et al. 2018; Enenkel et al. 2018) suggest that tools that can identify critical social media information in real-time are greatly needed, and should be incorporated into the operational decision-making pipelines of response organizations.

To meet these requirements, many studies have focused on the design of machine learning tools to identify relevant, informative, actionable situational awareness information in social media (Vieweg et al. 2010; Sen et al. 2015; Huang and Xiao 2015; Imran et al. 2016). More recently, deep learning approaches have also been proposed in the context of identifying information useful for disaster response on social media (Caragea et al. 2016; Nguyen, Al-Mannai, et al. 2017; Neppalli et al. 2018; Derczynski et al. 2018; Aipe et al. 2018), and have been generally shown to produce better results than the traditional supervised learning approaches. As opposed to research on classifying disaster tweets, research on classifying and retrieving useful information from disaster images is still in its early stage, although recent studies have suggested that useful social awareness information can be found in social media images (Bica et al. 2017; Lagerstrom et al. 2016; Alam, Ofli, et al. 2018b). To advance the state-of-the-art in this area, Alam, Ofli, et al. (2018) and Mouzannar et al. (2018) recently published multi-modal datasets, consisting of both tweet text and images. Furthermore, Mouzannar et al. (2018) developed a deep learning approach to identify damage images in their dataset. Related to this, Nguyen, Ofli, et al. (2017) proposed to classify disaster images according to damage severity using fine-tuned convolutional neural networks, and X. Li et al. (2018) proposed a method based on class activation mapping (CAM) to localize and quantify damage in social media images posted during disasters.

While significant contributions have been made in terms of developing traditional and deep learning models to identify useful situational awareness information in social media, most of the existing approaches are supervised learning approaches, which require labeled data to train accurate models. It is unrealistic to assume that labeled data is readily available in the early hours of a disasters, when help may be most needed. Domain adaptation or transfer learning approaches (Pan and Yang 2010), which make use of labeled data from a prior disaster (called *source*) and unlabeled data from the emergent disaster (called *target*), have been shown to lead to better results as compared to supervised classifiers learned from a prior disaster, when used for target tweet classification (H. Li et al. 2017; Mazloom et al. 2018). Domain adaptation has been used extensively for image classification using deep neural networks (Wang and Deng 2018), including social media image classification by fine-tuning a pre-trained deep neural network, such as VGG-16 or VGG-19 (Simonyan and Zisserman 2014), as in (Nguyen, Ofli, et al. 2017; X. Li et al. 2018). However, domain adaptation from a source disaster to a target disaster has not been explored in the context of classifying social media images posted during and shortly after a disaster. Thus, the goal of this study is to gain insights into the usefulness of transferring knowledge from a source disaster to a target disaster, when classifying images according to damage severity.

We propose to use an approach called Domain-Adversarial Neural Network (DANN) introduced by Ganin et al. (2016). The DANN approach is based on domain-adversarial training, which reduces the shift between the source and target domains, by making the source and target feature representations indiscriminate, while the source feature representation is discriminative for the source classification task. Experimental results on images from several source-target disaster pairs have shown that the DANN approach, which uses source labeled data and unlabeled target data, can improve the classification accuracy obtained with a deep neural network trained only from source labeled data, especially if the two disasters are of different type (e.g., a hurricane and an earthquake).

The contributions of the paper are as follows:

- We have adapted the DANN model by combining it with VGG-19 to benefit from the VGG-19 extensive training.
- We have performed extensive experiments on several pairs of disasters, and studied the ability of the adapted model to transfer information about image damage from a source disaster to a target disaster.
- We have performed visualization of the original and transformed representations of the source versus target images to gain insights into the results of the model.

The rest of this paper is organized as follows: We discuss "RELATED WORK" in the section following the "INTRODUCTION". Details of the domain adversarial neural network are presented in the "BACKGROUND AND APPROACH" section. The experimental setup and results are described in "EXPERIMENTAL SETUP" and "EXPERIMENTAL RESULTS" sections, respectively. Finally, we conclude the paper, discuss the limitations of our work, and also several ideas for future work.

RELATED WORK

Domain adaptation on image data has received much attention in recent years (Gopalan et al. 2011). In particular, approaches based on Convolutional Neural Network (CNN) have been very successful, for example, Siamese networks (Bromley et al. 1993) such as the one proposed in (Long et al. 2015). Approaches based on reconstruction have also become popular. For example, Ghifary et al. (2016) applied image reconstruction on target unlabeled data by using a CNN autoencoder. Together with the reconstruction model, a supervised model was also trained on the source labeled data. The resulting model was used to retrieve information from target data. Ganin et al. (2016) applied adversarial training to adapt data from a source domain to a target domain. The adversarial training was originally used to generate synthetic images (Goodfellow et al. 2014). In domain adaptation, the adversarial training learns a data transformation which makes the source and target data to have similar distributions. Then, the classifier trained on the transformed source data can be used on the target data.

In disaster response, domain adaptation is a desirable approach, as it enables fast reaction when a disaster occurs. Several studies have applied domain adaptation approaches on disaster related text data. For example, H. Li et al. (2017) used the iterative Self-Training (Yarowsky 1995) strategy, with Naive Bayes as a base classifier, to perform domain adaptation for identifying tweets related to a disaster. Domain adversarial training has been applied to disaster tweet classification (Alam, Joty, et al. 2018). Compared to the research on disaster tweet classification, research on disaster image classification and analysis is more limited as of now. Bica et al. (2017) performed a visual analysis of two 2015 Nepal Earthquakes, and found a positive correlation between damage severity and the number of geotagged images posted by eyewitnesses of the earthquakes. Lagerstrom et al. (2016) studied the ability of machine learning approaches to identify Twitter images posted during a bush fire emergency situation, and concluded that the fire images can be identified with high accuracy.

More recently, Alam, Ofli, et al. (2018) and Mouzannar et al. (2018) recently published text and image multi-modal datasets, which have the potential to advance the state-of-the-art in disaster image analysis. Furthermore, Mouzannar et al. (2018) developed a deep learning approach to classify images based on damage. Similarly, Nguyen, Ofli, et al. (2017) used an approach based on CNNs to classify disaster images according to damage severity. Given that damage is a concept quantifiable on a continuous scale, X. Li et al. (2018) used the CAM approach to localize and quantify damage in disaster images. While these studies represent important steps towards disaster images analysis in real time, they assume target labeled data is available. Domain adaptation approaches, while greatly needed, have not been studied until now.

BACKGROUND AND APPROACH

In this section, we introduce some background on image classification, and describe the approach used to perform domain adaptation from a source disaster to a target disaster. Figure 1 shows an overview of the model used, which has the VGG-19 network (Simonyan and Zisserman 2014) as its backbone, and uses the domain-adversarial training (Ganin et al. 2016) to reduce the domain shift.

Adapted VGG-19 Architecture

Convolutional neural networks (CNN) have achieved impressive results in image analysis and computer vision. Many network architectures have been proposed for image classification in recent years, including AlexNet (Krizhevsky et al. 2012), VGG-19 (Simonyan and Zisserman 2014), ResNet (He et al. 2016). ResNet and VGG-19 models have won the ImageNet competition[1], which proves that these models have good performance on image classification. We choose VGG-19 as the backbone for our model given that this network is relatively simpler than ResNet.

As can be seen in Figure 1, VGG-19 consists of 16 convolutional layers and 3 fully connected layers. A convolutional layer can be seen as a feature extractor, as it extracts image fragments (e.g., edge) that are important with respect to the classification task, while ignoring noisy fragments which do not contribute to classification. Each convolutional layer is accompanied by a non-linear ReLU activation. The 5 max pooling layers shown in the figure are used to achieve dimensionality reduction and further filter out noise. The standard VGG-19 has two fully connected layers

[1] http://image-net.org/challenges/LSVRC/

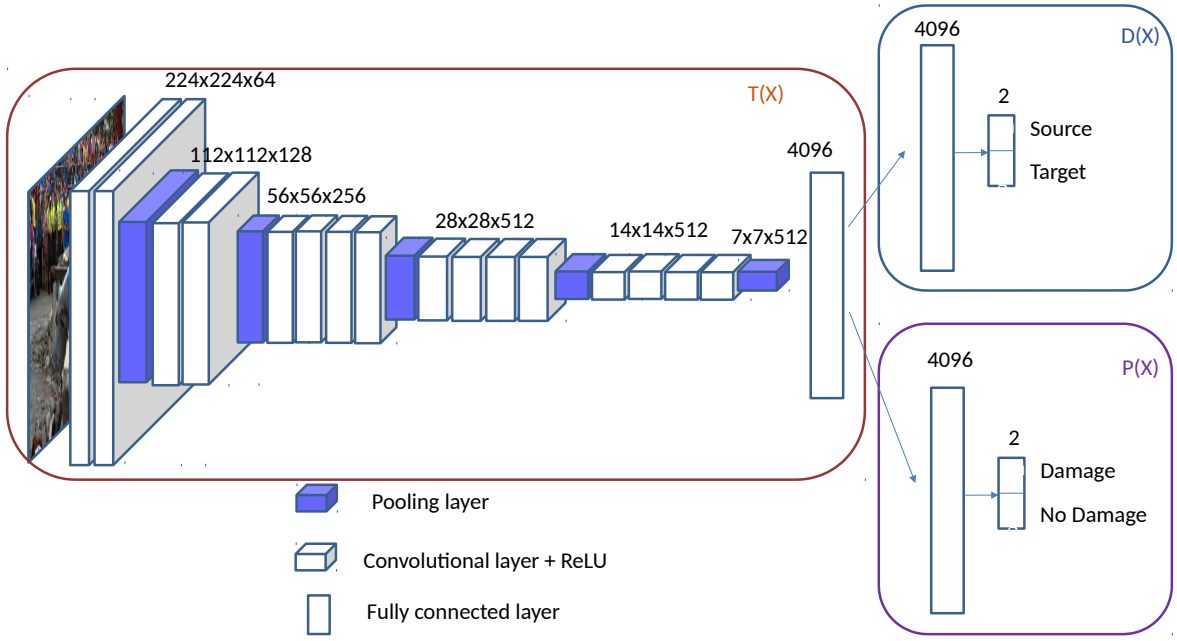

Figure 1. Overview of the Model Architecture.

with dimension 4096, and one softmax layer with dimension 1000. The softmax layer has dimension 1000 because VGG-19 was originally trained for a 1000-class object classification task. However, we aim to adapt VGG-19 to classify disaster images in two classes: *damage* or *no-damage*, and thus, we have changed the dimension of the softmax layer from 1000 dimensions to 2 dimensions. The VGG-19 model includes more then 130 million parameters that need to be learned. It is unfeasible to learn all those parameters from scratch. Instead, we have used the pre-trained VGG-19 model to initialize the parameter values in our network for all, but the last fully connected layer (as that layer has a different dimension), and subsequently fine-tuned all parameters of the model based on our disaster data. Given that the pre-trained VGG-19 model is learned from millions of images, it is known to generalize well to other sets of images in terms of informative features that it extracts. Thus, we can fine-tune it to our specific classification task with a relatively small number of images.

Domain-Adversarial Neural Networks

Domain Adaptation is a machine learning setting, where data from a source domain, X_s, is used to predict a target domain, X_t, under the assumption that the source and target domains have different distributions (a.k.a., domain shift), but share some similar patterns. In unsupervised domain adaptation, the labels of the source domain data, denoted as y_s, are available, while the labels of the target domain data, y_t, are not available. The task is to learn a classifier for the target data, using the labeled source data and the unlabeled target data. A standard approach to domain adaptation is to transform the source and target data representation (a.k.a., feature adaptation), so that the source and target distributions become indistinguishable (Pan and Yang 2010). More precisely, one needs to identify a transfer function, $T(X)$, to transform the original source, X_s, and target, X_t, domain data into $T(X_s)$ and $T(X_t)$ data which have similar distributions. Intuitively, a classifier learned on $T(X_s)$ with labels y_s should presumably have a good predictive performance on $T(X_t)$. Thus, the domain adaptation problem is reduced to finding the transfer function $T(X)$. Inspired by the generative adversarial network (GAN) proposed by Goodfellow et al. (2014), Ganin et al. (2016) designed a Domain-Adversarial Neural Network (DANN), which includes a component that explicitly aims to reduce the shift between a source and a target.

We have adapted the DANN model proposed by Ganin et al. (2016) by combining its adversarial training with the VGG-19 network, to take advantage of the extensive training of VGG-19. The architecture of the adapted DANN network, is shown in Figure 1. As can be seen in Figure 1, our model includes three components: 1) a transfer network, denoted by T, which enables the transfer of information from the source to the target, by reducing the shift between the two domains (in our case, between the two disasters); 2) a domain discriminative network, denoted by D, which identifies if an input image is from the source or from the target domain; 3) a prediction network, denoted by P, which is used to predict if an image is in the *damage* category or in the *no-damage* category. The input for the

transfer network, T, consists of images from either source or target domain. After applying the transformation T to the source or target images, the transformed images are classified as *source* or *target* by the discriminative network D, and classified as *damage* or *no-damage* by the predictor network P. Informally, the idea of the adversarial training is to train a good domain discriminant to separate the source and target domains, and at the same time, train a transfer network to make the two domain look so similar, that even a good discriminant network can not separate them. The predictor network, P, is trained on the transformed source data and then used to classify the transformed target data.

As can be seen in Figure 1, the transfer network, $T(X)$, consists of the first 16 convolutional/pooling layers of VGG-19, together with the first fully connected layer in VGG-19. The domain discriminative network, $D(X)$, and prediction network, $P(X)$, have similar architectures, which are equivalent to the last two fully connected layers of VGG-19. Specifically, $D(X)$ has one fully connected layer with dimension 4096, and one fully connected softmax layer with two dimensions, corresponding to the source (S) and the target (T) domains, respectively. Similarly, $P(X)$ has one fully connected layer with dimension 4096, and one fully connected softmax layer with two dimensions, corresponding to *damage* and *no-damage* categories, respectively.

DANN Model Training

The DANN is trained by minimizing the total loss of the model shown in Figure 1. To define the total loss function, we first define the following cross-entropy loss functions, corresponding to the three sub-networks in our model:

$\mathcal{L}_{prediction} = \min_{P} \mathcal{L}(y_s, P(T(x)))$, where y_s is the true class label of the transform instance x.

$\mathcal{L}_{domain} = \min_{D} \mathcal{L}(TDL, D(T(x)))$, where TDL is the true domain label, i.e., S for *source*, and T for *target*.

$\mathcal{L}_{transfer} = \min_{T} \mathcal{L}(FDL, D(T(x)))$, where FDL is a fake domain label, i.e., S for *target*, and T for *source*.

The total loss is defined as follows: $\mathcal{L}_{total} = \mathcal{L}_{domain} + \mathcal{L}_{transfer} + \mathcal{L}_{prediction}$

Let θ_D denote all the parameters in $D(X)$, θ_T denote all the parameters in $T(X)$, and θ_P denote all the parameters in $P(X)$. At each training step (a pass through the source data), we first compute each loss, $\mathcal{L}_{domain}$, $\mathcal{L}_{transfer}$, and $\mathcal{L}_{prediction}$, and update the parameters accordingly. However, we notice that the discriminant loss function always 'defeats' the transfer loss function. To account for this, we compute the transfer loss function two times in each step, as suggested in (Bang and Shim 2018). Then, the transfer and domain losses become almost equal, which means the transfer function reduced the difference between the two domains to an extent that the discriminant function can not separate the domains. The update rules are shown below:

$$\theta_D \longleftarrow \theta_D - \mu \frac{\partial \mathcal{L}_{domain}}{\partial \theta_D} \quad (1)$$

$$\theta_T \longleftarrow \theta_T - \mu \frac{\partial \mathcal{L}_{transfer}}{\partial \theta_T} \quad (2)$$

$$\theta_T \longleftarrow \theta_T - \mu \frac{\partial \mathcal{L}_{prediction}}{\partial \theta_T} \quad (3)$$

$$\theta_P \longleftarrow \theta_P - \mu \frac{\partial \mathcal{L}_{prediction}}{\partial \theta_P} \quad (4)$$

where μ is the learning rate. We use the stochastic gradient descent (SGD) to optimize the parameters. The pseudocode for training the DANN network using SGD is shown in Algorithm 1. Parameter updates are performed for each batch sampled from source. Corresponding to a batch from source of size m (line 5 in the algorithm), which is used to train the prediction network, the algorithm also creates a batch that has half (i.e., $m/2$) source instances and half target instances (line 6 in the algorithm). The source/target batch is used to train the transfer and domain networks.

EXPERIMENTAL SETUP

In this section, we present the experimental setup, including the dataset used, cross-validation setup, baselines, and implementation details. The experiments conducted in this study were designed to answer the following research questions: (1) How does the DANN model work for adaptation between disasters of the same type (e.g., two earthquakes) versus adaptation between disasters of different types (e.g., an earthquake and a hurricane)? (2) Does the source-target feature adaptation through DANN give better results as compared to the direct source adaptation from VGG-19? (3) How do the results of the DANN model compare to the results of a VGG-19 network adapted based on data from the target domain itself?

Algorithm 1 DANN Training Using SGD

Input: Datasets $S = \{(x_i^s, y_i^s)\}_{i=1}^{n_s}$ (where n_s represents the number of instances in the source S) and $T = \{x_i^t\}_{i=1}^{n_t}$ (where n_t represents the number of instances in the target T)
Output: $\theta_T, \theta_P, \theta_D$

$\theta_T \leftarrow$ pre-trained VGG-19 weights
$\theta_P, \theta_D \leftarrow$ random initial weights

    Update θ_D using Equation (1)
    Compute the loss $\mathcal{L}_{transfer}$
    Update θ_T using Equation (2)
    Compute the loss $\mathcal{L}_{transfer}$
    Update θ_T using Equation (2)
    Compute the loss $\mathcal{L}_{prediction}$
    Update θ_T and θ_P using Equations (3) and (4)

Table 1. Disaster class distribution, together with the total number of labeled images in each disaster.

Class	Nepal Earthquake	Ecuador Earthquake	Ruby Typhoon	Matthew Hurricane
Damage	11,183	933	433	204
No-damage	7,919	791	400	127
Total	19,102	1,724	833	331

Dataset

We used the disaster image dataset published by Nguyen, Alam, et al. (2017) in our experiments. The dataset contains images from four disasters, specifically Nepal Earthquake, Ecuador Earthquake, Ruby Typhoon, and Matthew Hurricane. In the original dataset, there are three damage classes: *severe*, *mild*, and *none*. However, Nguyen, Alam, et al. (2017) suggested that the task of discriminating between *mild* and *severe* damage is very subjective, and there is significant overlap in the dataset between the two classes. Therefore, we combine the classes *severe* and *mild* into one class called *damage*. Our goal is to identify images that include damage and separate them from images that do not show any damage. Table 1 shows the total number of images in each disaster, and also the class distribution for each disaster.

Setup

Given the four disasters in our dataset, we experiment with all possible source/target pairs. Thus, some source/target pairs consist of disasters of the same type (e.g., two earthquakes), while other pairs consist of disasters of different types (e.g., an earthquake and a hurricane). Furthermore, some pairs have smaller amounts of source data, while others have larger amounts of source data. Similarly, some pairs have a smaller amount of target unlabeled data, while other pairs have a larger amount of target unlabeled data. This variety of pairs makes it possible to answer the research questions we have raised.

For each source/target experiment, we randomly split the target data into target unlabeled (80%) and target test (20%). Each DANN model was trained on all source data and the target unlabeled data, and subsequently tested on the test dataset. The results are evaluated using four standard metrics, specifically, accuracy, precision, recall and F1-measure. For cross-validation purposes, we created three different random splits for each source/target pair. The metrics reported represent averages over the three random splits (together with the standard deviation).

Baselines

We compared the DANN model against two baselines: 1) a model that uses only the labeled source data to adapt the pre-trained VGG-19 – this model can generally be seen as a lower bound for domain adaptation; 2) a model that uses the target data as labeled data to adapt the pre-trained VGG-19 – this model can generally be seen as an upper bound for domain adaptation.

Implementation Details

We used TensorFlow's MomentumOptimizer procedure to train the model using the mini-batch stochastic gradient descent on a K80 graphics card. Based on our preliminary experimentation, we set the learning rate to 0.001, and the batch size to 64 images. Furthermore, we used the dropout technique with a rate of 0.5 to prevent overfitting. The code for the VGG-19 model was adapted from https://github.com/machrisaa/tensorflow-vgg.

EXPERIMENTAL RESULTS

The results of the experiments are shown in Table 2 for the DANN model, which was trained on source labeled and target unlabeled data (denoted as DANN-SL-TU), and for the two baselines, VGG-19-SL (VGG-19 adapted using source labeled data), and VGG-19-TL (VGG-19 adapted using target labeled data). The DANN model and the baselines are tested on the same target test data. Each experiment was repeated three times with different target unlabeled/test splits, and the results averaged over the three runs.

Discussion of the Results

To answer our first research question, *How does the DANN model work for adaptation between disasters of the same type versus adaptation between disasters of different types?*, we compare the results of DANN-SL-TU with the results of VGG-19-SL for pairs of similar and different disasters. We consider Matthew Hurricane and Ruby Typhoon to be disasters of the same type, and the same for Ecuador Earthquake and Nepal Earthquake. Disaster pairs consisting of a hurricane/typhoon and an earthquake are considered to be different. As can be seen from Table 2, the results of DANN-SL-TU are similar and sometimes better than the results of VGG-19-SL, for pairs of similar disasters. Furthermore, the DANN-SL-TU results are generally better than the VGG-19-SL results for different disasters. For example, when we use either Ecuador Earthquake or Nepal Earthquake as source, the results for predicting the other earthquake are similar between DANN-SL-TU and VGG-19-SL. However, if we use either disaster as source, and predict Matthew Hurricane or Ruby Typhoon, DANN-SL-TU gives significantly better results. Similarly, when Ruby Typhoon is used as source, the results obtained with DANN-SL-TU for Nepal Earthquake and Ecuador Earthquake are significantly better then the results obtained with VGG-19-SL, while the two models are similar for Matthew Hurricane.

Given the above-mentioned results, the answer to our second question, *Does the source-target feature adaptation through DANN give better results as compared to the direct source adaptation from VGG-19?*, is overall positive, as the DANN-SL-TU model gives similar or better results than VGG-19-SL. However, if we consider the size of the datasets used in our experiments, the results in Table 2 suggest that the DANN-SL-TU approach gives better results if the source labeled data and the target unlabeled data used for training are relatively large (e.g., a few thousands). Furthermore, it can be seen that DANN increased the recall for the damage class in most case, especially when the source and target disasters are of different types. Finally, when comparing DANN-SL-TU with VGG-19-TL to answer our third question, *How do the results of the DANN model compare to the results of a VGG-19 network adapted based on data from the target domain itself?*, we observe that indeed VGG-19-TL acts as an upper bound for the DANN-SL-TU model. While the gap between the two models is significant, the gap between VGG-19-TL and VGG-19-SL is also large, suggesting that the source data distribution is indeed different from the target data distribution, and better domain adaptation models have the potential to bridge the gap.

Figure 2 shows examples of images that are correctly classified or miss-classified by the DANN-SL-TU/VGG-19-SL/VGG-19-TL networks, when Ruby Typhoon is used as target disaster and Ecuador Earthquake is used as source disasters. Specifically, the top row in Figure 2 shows examples of images that are correctly classified as *damage* by DANN-SL-TU and VGG-19-TL, but miss-classified as *no-damage* by VGG-19-SL. As the VGG-19-SL network is trained to recognize earthquake damage, it can fail to recognize rain/flood/wind damage present in typhoon images. As opposed to that, the middle row in Figure 2 shows images that are miss-classified as *damage* by both DANN-SL-TU and VGG-19-TL, but correctly classified as *no-damage* by VGG-19-SL. It seems that the networks that use images from the target typhoon during training may over-learn that water-related or wind-like images are showing damage. Finally, the bottom row in Figure 2 shows images that are miss-classified by both DANN-SL-TU

Table 2. Classification results: average accuracy (Acc.), precision (Prec.), recall (Rec.) and F1-measure (F1) for the damage class (average is taken over three runs), together with the corresponding standard deviation (in parentheses), for DANN-SL-TU (which uses source labeled data and target unlabeled data), VGG-19-SL (adapted using source labeled data), and VGG-19-TL (adapted using target labeled data). Highlighted in bold font are results that are statistically different when comparing VGG-19-SL and DANN-SL-TU using a paired t-test with $p \leq 0.05$.

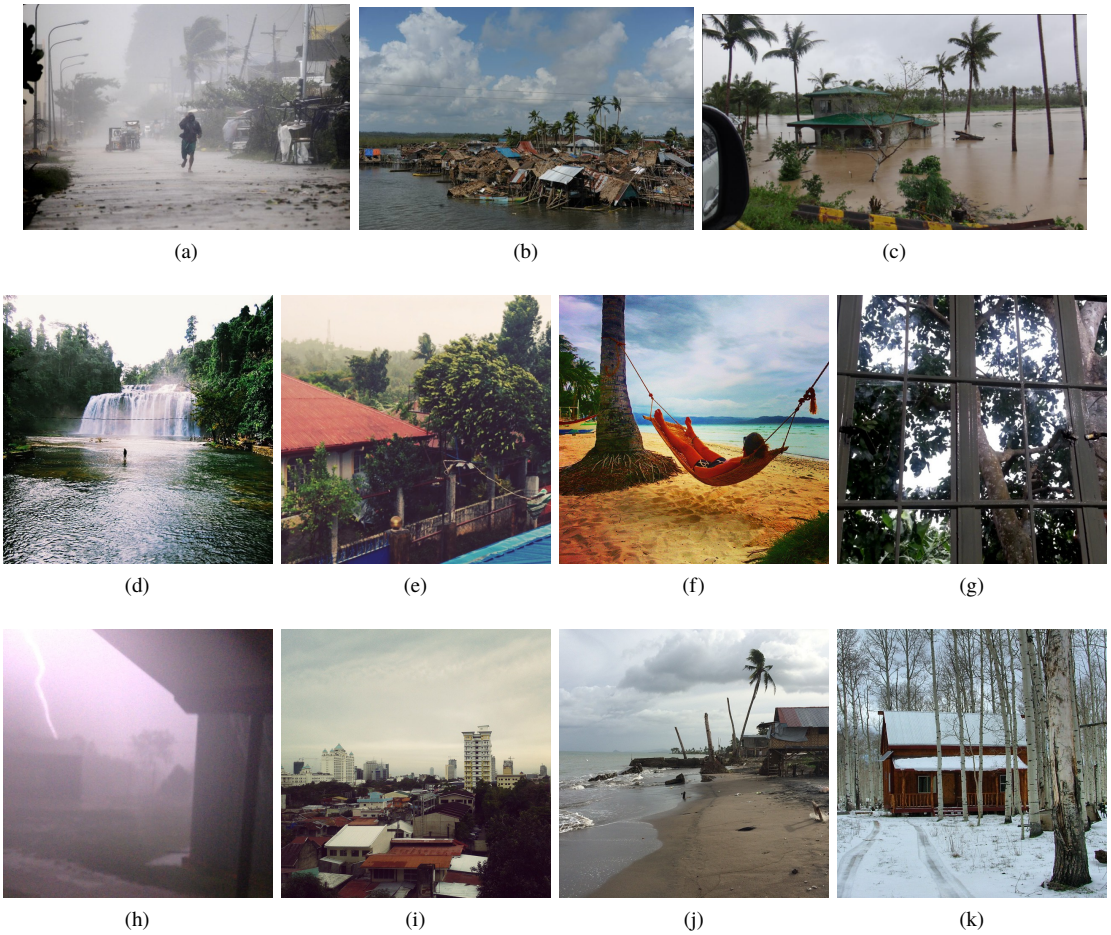

Figure 2. Examples of images that are correctly classified or miss-classified by different networks, when Ruby Typhoon is used as target disaster and Ecuador Earthquake is used as source disaster. (Top) Images that are classified correctly as *damage* by DANN-SL-TU and VGG-19-TL, and miss-classified as *no-damage* by VGG-19-SL. (Middle) Images that are miss-classified as *damage* by DANN-SL-TU and VGG-19-TL, while VGG-19-SL correctly classifies them as *no-damage*. (Bottom) The first two images on the left are miss-classified by both DANN-SL-TU and VGG-19-SL, while VGG-19-TL correctly classifies image (h) as *damage* and image (i) as *no-damage*. The last two images on the right have label *no-damage* and are miss-classified by all networks as *damage*.

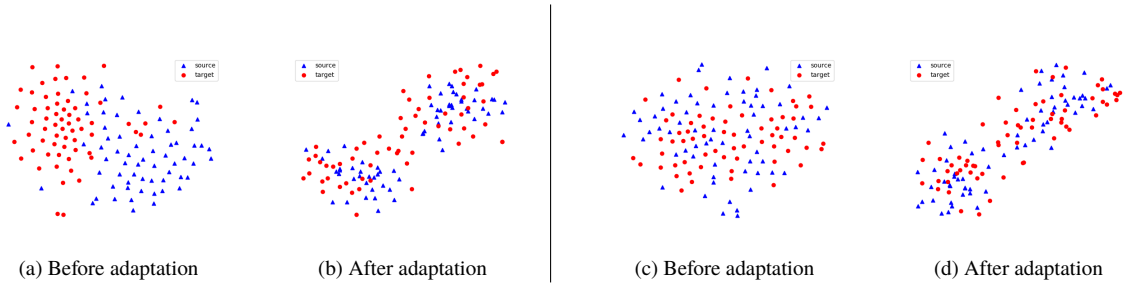
and VGG-19-SL. The first two images in the bottom row are correctly classified by VGG-19-TL as *damage* and *no-damage*, respectively, while the last two images are also miss-classified by VGG-19-TL as *damage*. Together with the quantitative evaluation in Table 2, these examples suggest that more unlabeled images from the target, and ideally more labeled images from the source, can potentially improve the results.

Estimating the Distance between Source and Target Domains before and after Adaptation

To evaluate the difficulty of the domain adaptation tasks in our study, we used the proxy $\mathcal{A}$-distance (Ben-David et al. 2007) to measure the domain shift. We expect domain adaptation to give better results than VGG-19-SL if the source and target domains are different, and similar results if the target and source domains are similar. Table 3 shows the domain pairs used in our experiments and their corresponding domain divergence in terms of the proxy $\mathcal{A}$-distance, before and after feature adaptation. To compute the proxy $\mathcal{A}$-distance, we trained a CNN model to separate the source domain X_S from the target domain X_T using unlabeled data. Then, we calculated the proxy $\mathcal{A}$-distance as $2(1 - 2\epsilon)$, where ϵ is the mis-classification error on test data. A high proxy $\mathcal{A}$-distance means that the two domains are far apart, and benefit from adaptation. A proxy $\mathcal{A}$-distance close to zero means that the two domains have essentially the same distribution. In addition to the proxy $\mathcal{A}$-distance before adaptation, we also calculated the proxy $\mathcal{A}$-distance after adaptation to understand if domains with different distributions are brought closer through adaptation. We should note that the model used to obtain the proxy $\mathcal{A}$-distance between $T(X_S)$ and $T(X_T)$ is equivalent with a two layer perceptron network, based on our model architecture. In practice, we found that sometimes the classification error may be larger than 0.5, which resulted in a negative value for the proxy

Table 3. Proxy $\mathcal{A}$-distance between different domains. In the 'After Adaptation' case, $(A \rightarrow B)$ means that the model was trained with A as source and B as target, while $(B \rightarrow A)$ means that the model was trained with B as source and A as target.

Domain A	Domain B	Before Adaptation	After Adaptation $(A \rightarrow B)$	After Adaptation $(B \rightarrow A)$
Matthew Hurricane	Ruby Typhoon	1.287	0.625	0.141
Ecuador Earthquake	Matthew Hurricane	1.633	0.125	0.141
Ecuador Earthquake	Ruby Typhoon	1.637	0.250	0.219
Nepal Earthquake	Ecuador Earthquake	1.831	0.132	0.091
Nepal Earthquake	Matthew Hurricane	1.951	0.078	0.281
Nepal Earthquake	Ruby Typhoon	1.915	0.112	0.288



(a) Before adaptation (b) After adaptation (c) Before adaptation (d) After adaptation

Figure 3. Two dimensional representation of source (blue) and target (red) using the VGG-19-SL representation of the images (before adaptation), and the DANN-SL-TU transformed representation of the images (after adaptation), for two pairs of disasters. The pair on the left consists of two dissimilar disasters, Ecuador Earthquake (source, blue) and Ruby Typhoon (target, red). The pair on the right consists of two similar disasters, Ecuador Earthquake (source, blue) and Nepal Earthquake (target, red).The two representations are reduced to 2 dimensions using the t-SNE (Van Der Maaten 2014) technique.

$\mathcal{A}$-distance. In such cases, we took the absolute value of the proxy $\mathcal{A}$-distance, as suggested in (Ben-David et al. 2007). From Table 3, we can see that the distance between Matthew Hurricane and Typhoon Ruby is the smallest among all the distances, suggesting that the distributions of the two disasters are similar. Also, considering the pairs which contain Nepal Earthquake, we can see that the smallest distance is obtained for Ecuador Earthquake. Thus, the distances in Table 3 generally are in agreement with the classification results in Table 2. It is also interesting to note that, after domain adaptation, all proxy $\mathcal{A}$-distances become smaller, which means that the distributions of $T(X_S)$ and $T(X_T)$ are more similar as compared to the original distributions of the source and target datasets.

Visual Distribution Analysis

It can be proven that $T(X_S)$ and $T(X_T)$ have similar distributions after the domain adversarial training. Here, we visualize $T(X_S)$ and $T(X_T)$ for some sample source/target pairs to visually analyze the distributions of the transformed source and target data, by comparison with the distribution of the original source and target data.

To perform this visualization, first, we randomly selected 64 images from Ruby Typhoon and 64 images from Ecuador Earthquake, two disasters with relatively high distance. Using the VGG-19 model trained on Ecuador Earthquake, we extracted the weights of the last fully connected layer in the VGG-19 model (this layer has dimension 4096). Next, we used t-SNE (Van Der Maaten 2014) to reduce the dimensionality from 4096 to 2. As a result, each image is represented by a two dimensional vector. We plotted the 128 images using the binary representation in Figure 3 (a), where we used blue triangles for images from Ecuador Earthquake and red dots for images from Ruby Typhoon. Similarly, using the DANN model trained on Ecuador Earthquake as source and Ruby Typhoon as target, we extracted the weights of the first fully connected layer, which represents the output of the transfer function $T(x)$. The graph for the 128 images (from Ecuador Earthquake and Ruby Typhoon) is shown in Figure 3 (b), where the blue triangles represent images from Ecuador Earthquake and the red dots represent images from Ruby Typhoon. As can be seen, the graph in Figure 3 (a) shows a clear boundary between the two domains, while in the graph in Figure 3 (b) the two domains are harder to separate as their distributions overlap significantly. Thus, the visualization of the reduced representations shows that after domain adaptation, the difference between source (Ecuador Earthquake) and target (Ruby Typhoon) has been indeed reduced.

In addition to performing the visualization of the transformed representations for two domains with high distance, we also performed if for two domains with relatively smaller distance. Specifically, we randomly selected 64

images from Nepal Earthquake and 64 images from Ecuador Earthquake. Following the same procedure described above, we plot two graphs in Figure 3 (c) and (d), respectively. In (c), the VGG-19 model was trained on Ecuador Earthquake and in (d), the DANN model was trained on Ecuador Earthquake as source and Nepal Earthquake as target. As can be seen in (c), the distributions of the two domains are indistinguishable even before adaptation, as the two domains have similar distributions in the first place. Thus, in this situation, DANN can not improve much the results of VGG-19, as the domains are already similar.

CONCLUSIONS AND DISCUSSION

In this paper, we studied the application of domain adaptation to identify disaster images that show damage. We adapted the DANN approach by combining it with the VGG-19 model, and thus taking advantage of the available labeled data used to train VGG-19. Experimental results suggest that the domain adaptation approach is especially useful when the source and target disasters are of different types, and thousands of labeled instances are available for the source disaster (a requirement which can be met without much effor or cost).

Given that the proposed approach does not require labeled data from the target domain, it can potentially be used to identify damage images in nearly real time. To do this, one would first use a pre-trained model that identifies images relevant to disasters and filters out non-relevant images. A model like this is already available as part of the AIDR platform (`http://aidr.qcri.org`), as described by Nguyen, Alam, et al. (2017). Subsequently, our approach can be used to identify images that show damage, by first employing the model pre-trained on source data, and gradually adapting it based on unlabeled disaster-relevant target images. The identified damage images could be used to perform fast damage assessment, which in turn can results in faster disaster response. Thus, we envision that our approach, together with relevancy-filtering models, can be incorporated in the routine operations of disaster response and management organization.

We should note that our current models were trained to distinguish between damage and no-damage images. This is a limitation imposed by the data that was available for training, which did not discriminate well between severe and mild damage classes. However, as labeled images for more specific classes of damage become available, our models can be re-trained and adapted to identify such classes. Moreover, one can further analyze images that show damage by localizing and quantifying damage on a continuous scale, as shown in X. Li et al. (2018). Such level of detail can help response teams prioritize their operations based on the severity of the damage, assuming that resources are scarce.

As part of future work, we plan to apply the DANN approach to other disaster image classification problems, for example, specific types of damage including building damage, road damage, bridge damage, human damage, etc. We also plan to study other domain adaptation approaches in the context of image analysis for disaster response. Finally, we aim to study approaches that can help identify image features indicative of damage, or even other features that might be useful for response teams.

ABSTRACT

This paper describes a prototype system that integrates social media analysis into the European Flood Awareness System (EFAS). This integration allows the collection of social media data to be automatically triggered by flood risk warnings determined by a hydro-meteorological model. Then, we adopt a multi-lingual approach to find flood-related messages by employing two state-of-the-art methodologies: language-agnostic word embeddings and language-aligned word embeddings. Both approaches can be used to bootstrap a classifier of social media messages for a new language with little or no labeled data. Finally, we describe a method for selecting relevant and representative messages and displaying them back in the interface of EFAS.

Keywords

Social Media, Disaster Risk Management, Flood Risk

INTRODUCTION

Over millennia humans have developed villages and cities near water bodies, mainly for two reasons: (i) improvements in agricultural yields due to yearly floods in fertile floodplains leaving nutrient-rich silt deposits behind; and (ii) people's desire to live near coastlines and river valleys, often on wetlands and backfilling otherwise natural flood buffers. Due to the closeness of human settlements to rivers and coasts, floods are the natural disasters with the greatest damage potential and the ones that affect the greatest number of people (UN Office for the Coordination of Humanitarian Affairs 2017).

According to recent studies, Global warming is linked to a substantial increase in flood risk over most countries in Central and Western Europe, even if the temperature increases remain close to the lower estimates. For instance, flood peaks with magnitude as it happens once in 100 years, called 'return period', are projected to double in frequency within the next three decades (Alfieri et al. 2015).[1]

[1]The return period of an event is the time span it would take to observe one such event on expectation.

In Europe, the Emergency Response Coordination Centre (ERCC), operating within the European Commission's Civil Protection and Humanitarian Aid Operations department, was set up to support a fast and coordinated response to disasters both inside and outside Europe using resources from the countries participating in the EU Civil Protection Mechanism. This centre monitors hazards and risks, collects and analyzes real-time information on disasters, prepares plans for the deployment of experts, teams and equipment, and in general coordinates the EU's disaster response efforts.

The European Flood Awareness System (EFAS) provides real-time information and forecasts about floods to the ERCC as well as to a series of partners including national and regional hydrological services. EFAS is part of the Copernicus Emergency Management Service (Copernicus EMS), and holds regularly updated flood-related information such as probabilistic medium-range flood forecasts (including short-range flash floods), seasonal forecasts, and impact assessments and early warnings.

Current flood hazard mapping methodologies, such as the one implemented in EFAS, have high scale spatial resolution capacity: 1×1 kilometer resolution globally and 100×100 meter resolution in Europe (Dottori, Salamon, et al. 2016). This combined with state-of-the-art forecasting models provide detailed information about the risk associated with a flood in terms of likelihood, magnitude, timing, and impact (Dottori, Kalas, Salamon, et al. 2017).

Due to nature of floods phenomena and its dynamics, it is important that satellites can monitor the flood extent during the flood peak, therefore early warnings are important to allow sufficient lead time for requesting satellite mappings of the area at risk (Dottori, Kalas, Lorini, et al. 2017).

Over the past decade, social media has emerged as a relevant information source during disasters, prompting researchers from diverse areas to converge on this domain (Castillo 2016; Palen and Anderson 2016). Social media analysis has demonstrated the potential to provide timely, precious information about the spatial (Brouwer et al. 2017; Restrepo-Estrada et al. 2018) and temporal (Vieweg et al. 2014) development of a crisis, as well as supporting the identification of key disaster-related events (Musaev et al. 2015). Although the value of social media analysis in providing timely data and methods for the analysis of natural hazards has been recognized in previous work, comparatively much less attention has been given to how to integrate social media in a seamless, reliable way with tools for disaster forecasting and monitoring.

Since the geographical domain of EFAS products covers an area where population speaks more than 27 languages, we focused on a multi-lingual system. We therefore use representation of words as vectors in order to exploit probabilistic functions to infer similarities between words, know as word embeddings(Pennington et al. 2014).

Our research fills this gap by describing the integration of social media monitoring into a flood monitoring and forecasting platform, enriching hydro-meteorological information with reports from the public.

We developed software for EFAS named Social Media for Flood Risk (SMFR) which provides near-real-time information collected from social media about flood risks and impacts, including examples of messages in social media about it. Figure 1 represents the conceptual schema of SMFR's components, part of which is described in this paper, and their integration.

Our main contributions are:

- We integrate social media data collection into the European Flood Awareness System (EFAS) based on EFAS forecasts. Whenever EFAS rapid risk assessment identifies heightened risk of floods in a certain area, we trigger data collection from social media (in our case, Twitter) respecting API limitations while dealing with the possibility of various events happening at the same time. A similar mechanism is already in use for triggering pre-tasking of satellite image acquisition in Copernicus EMS
- We describe a methodology that requires a minimal amount of manual intervention for each additional language, and demonstrate it with four languages being used to bootstrap a classifier for a fifth language. This methodology is based on Convolutional Neural Networks and its multi-lingual capabilities stem from using either language-agnostic word embeddings, where vectors representing sentences are not dependent on a single language, or multi-lingual word embeddings (Conneau et al. 2017).
- We describe an aggregation and selection module that can select representative messages for an area in which flood risk has been predicted.
- We integrate SMFR into EFAS and demonstrate it during the recent floods affecting Calabria, Italy, in early October 2018. Note that we decided to present only one case for the sake of clarity and conciseness, however SMFR has been tested with additional real cases.

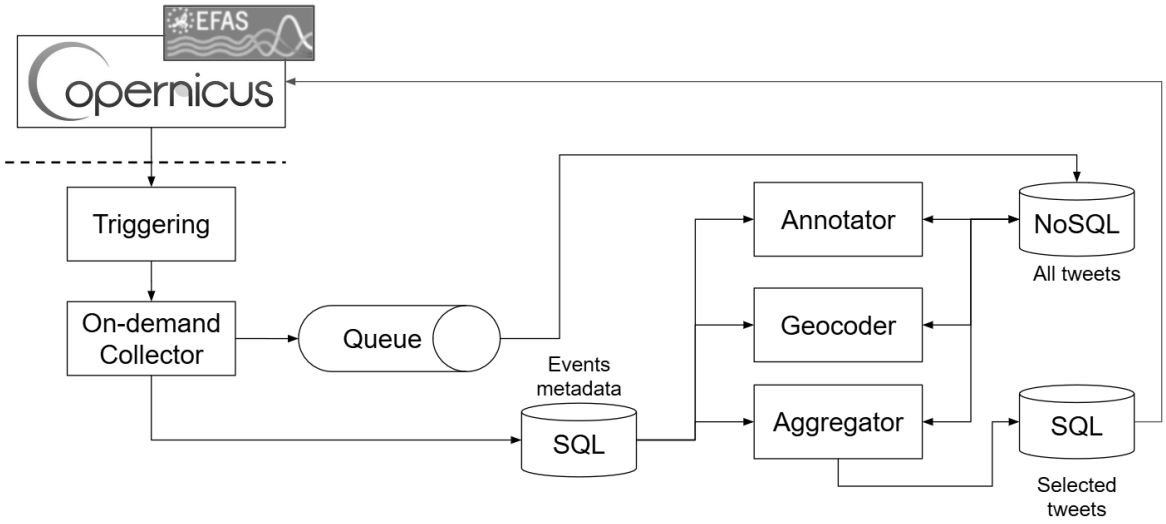

Figure 1. Schema of SMFR components

The remainder of this paper is organized as follows: the next section presents related work; then, three technical sections describe the methods for on-demand data collection, multi-lingual classification, and aggregation and selection. Finally, we present experimental results, including a case study, followed by our conclusions and future work.

RELATED WORK

Background: European Flood Awareness System (EFAS)

EFAS is part of the Copernicus Emergency Management Systems, and serves the ERCC and EU member states' Civil Protection agencies with forecasts of flood risks. It covers the European Union as well as several neighbouring areas that are relevant from the perspective of flood risk and EU policies (e.g. all countries of the Danube river basin). EFAS provides information based on weather forecasts[2] and hydrological ensemble predictions obtained by an hydrological model simulations, therefore subjected to uncertainty. For being exploited at its maximum potential it should offer additional supporting information that could be used for prioritizing resources and interventions. EFAS already includes products that go in that direction. For instance pre-tasking satellite mappings is triggered in advance integrating socio-economic data (population, infrastructures, economic losses fused as impact indicators) with flood magnitude and probability (likelihood)(Dottori, Kalas, Lorini, et al. 2017).

EFAS forecasts have good accuracy level which is constantly monitored[3], but Crisis are only declared, formalised and managed by the local authorities and it's up to them to decide what to do with the data provided. The new layer presented helps in the near real time confirmation of floods for areas where a high flood risk was forecasted. The SMFR layer includes a set of representative tweets and a dot distribution map of social media messages related to floods.

Combining authoritative and non-authoritative data

A recent trend in research on social media on disaster has been to study methodologies for combining non-authoritative and authoritative data in risk assessment. The non-authoritative data are reports generated by the public, typically posts in social media platforms. The authoritative data comes from various sensors including meteorological and hydrological ones as well as physical models for creating forecasts with this data. In previous work, these data have been combined in various ways.

Musaev et al. (2015) describe the LITMUS platform, which collects and filters messages about landslides from various social media platforms and geo-locates them to merge reported events with data from physical sensors referring to the same location.

[2]EFAS inputs are based on the Ensemble Prediction System from the European Center for Medium Range Weather Forecast (ECMWF) which consists of 51 ensemble member.

[3]publicly available at https://www.efas.eu/validation-and-skill-scores

Brouwer et al. (2017) use social media combined with authoritative data to define probabilistic and deterministic flood-extent maps. Information gathered from the public is used to make inferences about rainfall, contributing to interpolate coarse-grained data at a the same resolution as a Local Drainage Direction (LDD) map, in order to determine water levels for different cells.

Restrepo-Estrada et al. (2018) use a transformation function for creating a proxy variable for rainfall by analyzing keywords-filtered geo-located social media messages and rainfall measurements from authoritative sources. The proxy variable is incorporated in a hydrological model for stream-flow estimation.

Our work differs from the previous ones in important ways. First, we do not filter social media posts by flood-related keywords, but rather according to the location of a possible flood based on forecasts from the EFAS system. Second, we aggregate data using a geocode standard for referencing the subdivisions of countries for statistical purposes, known as Nomenclature of Territorial Units for Statistics(EC 2016). Its granularity is identified by levels, the higher the level, the higher the granularity. In our work we used level 2 (NUTS-2) as the main subdivision. Third, we cover a large area by automatically processing content in several languages. The goal of our system is to confirm and bring more detail to the outcomes of an hydrological model.

Multi-lingual classification of social media postings

SMFR is designed to work across multiple languages. The main processing that we do to messages is to determine whether they are relevant to flood risks/impacts or not. This is done through supervised classification, which requires labeled data. However, to work across multiple languages in practice requires to be able to classify messages in languages for which we may not have labeled data yet.

Past research addressed cross-lingual bootstrapping of classifiers for natural disasters detection on twitter (Middleton et al. 2013) relying on automatic translation to use available models. Previous works, such as Li et al. (2018) has shown how an approach based on *word embeddings* works better than a simpler method based on bag-of-words when generalization is critical, including our case which requires generalizing across languages. Khare et al. (2018) built a statistical-semantic classification model with semantics extracted from BabelNet and DBpedia and compared relevancy classifiers with datasets translated into a single language, as well as with cross-lingual datasets. They have shown how adding semantics increases cross-lingual classification accuracy.

Our work, in contrast, does not require semantic resources, we only leverage on word embeddings for multi-lingual modelling as demonstrated by Luong et al. (2015). Indeed, we present and demonstrate two different ways in which word embeddings can be used to perform multi-lingual classification: using language-agnostic word embeddings learnt from a multi-lingual corpus (Pennington et al. 2014), and using multi-lingual word embeddings that are aligned across languages (Conneau et al. 2017). In both cases, we can use labeled data in a set of known languages to bootstrap a classifier for a new language for which no labels are available.

ON-DEMAND DATA COLLECTION

The data collection should ideally achieve high recall, capturing a large fraction of the relevant information, while at the same time having high precision, avoiding irrelevant information. Both goals usually enter into conflict and trade-offs are necessary. Previous research has described extensively how data collection from Twitter is done (see, e.g., Imran, Castillo, Diaz, et al. 2015), in this section we focus on the specific aspects of our system, which performs *on-demand data collection*.

The key element of our data collection is its triggering mechanism which is done dynamically according to flood forecasts. EFAS runs two simulations per day, identifying NUTS-2 areas (typically regions or provinces) where there is a high probability of floods impacts in the following 48 hours as shown in figure 2.

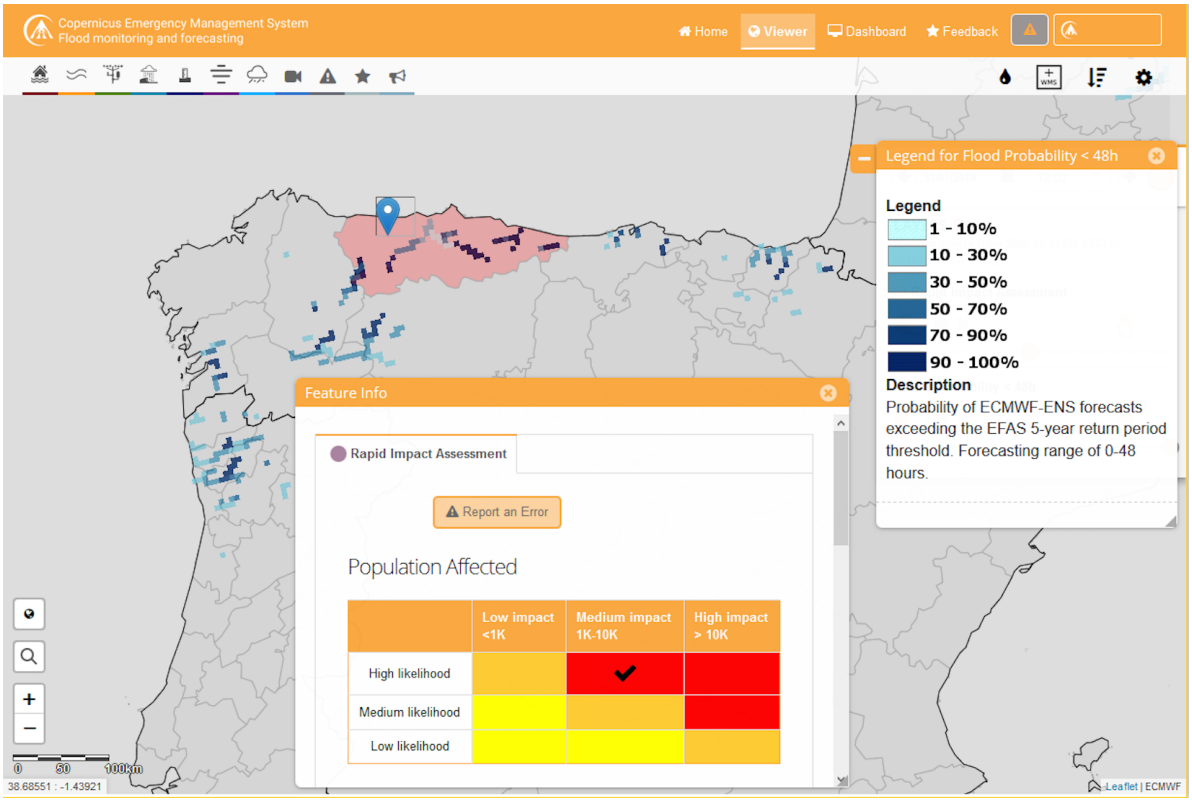

Figure 2. Screenshot of EFAS web interface with the layers identifying areas where there is high probability of floods in the following 48 hours and rapid impact assessment

Once the list of NUTS-2 areas is received, the system extracts their coordinates and the names of all cities in the area that have more than a certain number of inhabitants. The coordinates are used for filtering the Tweets by location while the names of cities, in english and local language, translate into a series of 'OR' filters by keywords. In our current configuration, we set this threshold empirically to 80,000 inhabitants, which tends to capture a handful of cities for each event. A lower threshold is possible as long as it does not generate a large number of city names that exceeds Twitter's API limitations.

Given the limitations in Twitter's API, we use a single connection against Twitter's public streamer at any given time. Additionally, the public streamer limits queries to up to 400 keywords (each of less than 60 bytes) and up to 25 location rectangles.[4] A *query builder* component groups several active events in order to update a single request respecting these limitations, while keeping information about the single possible event identified by EFAS. Each collection is kept active for two days after the expected peak time. If the peak time estimation is updated by a new EFAS simulation, the collection's expiration time is extended. Given that we have a single query, SMFR has to separate the incoming stream into different events according to locations and keywords. If a message belongs to overlapping regions or contains names of cities in different events, the message is copied to all the matching events.

Figure 3 depicts how rapid risk assessment leads to the definition of a series of keywords (city names) and locations (rectangles containing NUTS-2 areas) for filtering information from Twitter's public streamer. The areas in yellow and red in the figure are identified as having high risk of flood by EFAS. Then, the system determines names of cities in each area and bounding boxes surrounding each area. We have heuristics that merge neighboring areas and de-prioritize smaller cities if their quantity exceeds Twitter's limitations, but in practice these are rarely triggered.

[4] https://developer.twitter.com/en/docs/tweets/filter-realtime/overview accessed November 2018.

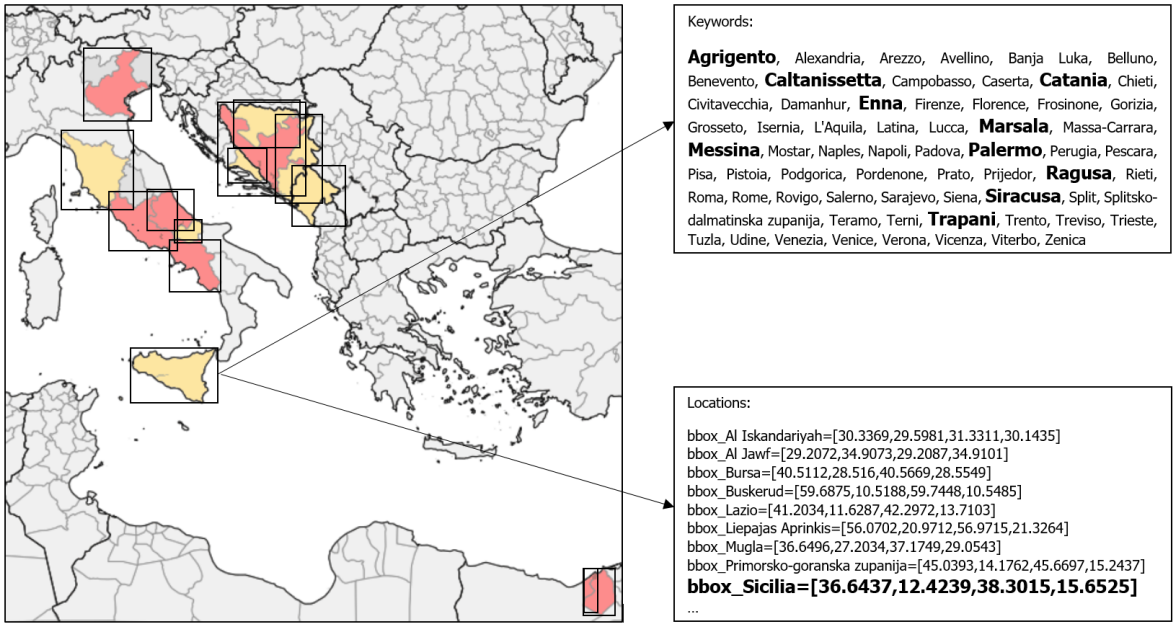

Figure 3. Example depicting areas in which EFAS forecasts high risk, which appear in yellow and red color. Each area defines a set of keywords, which are names of cities, and locations, which are bounding boxes (rectangles). These keywords and locations are used to gather information from Twitter.

MULTI-LINGUAL CLASSIFICATION

The setting used was supervised binary classification. The positive class comprised all messages indicating that "a flood has just happened or is about to happen" while the negative class included all other messages.

Training data was labeled using crowdsourcing platform GetHybrid (https://gethybrid.io/). The amount of labeled data comprises over 7,000 annotated messages, each one annotated by three annotators independently. Four training datasets were created, containing labeled tweets in German, English, Spanish, and French. Each language includes between 1,200 and 2,300 annotated messages, as shown in Table 1 (column "TL" for Total Labeled) in the section describing the experiments. This amount of data is typical in automatic classification tasks (Imran, Castillo, Diaz, et al. 2015).

Convolutional Neural Networks

We tested a number of learning algorithms, including Support Vector Machines (Joachims 1999), which have been shown to be effective for a number of general text classification tasks, and Random Forests, which have been shown to be effective specifically for classifying crisis-related Twitter messages (Imran, Castillo, Lucas, et al. 2014). In both cases, we represented messages as bag of word unigrams and bigrams, and the performance was better than simpler methods such as a naïve Bayes classifier or a decision tree.

A comparatively newer approach for text classification that has proven to be quite effective is the use of Convolutional Neural Networks (CNN). These have been employed for a number of tasks including sentiment analysis (Severyn and Moschitti 2015).

There are four main operations in every Convolutional Neural Network:(i) Convolution; (ii) Non Linearity, Rectified Linear Unit (ReLU); (iii) Pooling or Sub Sampling;(iv) Classification (Fully Connected Layer). The primary purpose of (i) Convolution is to extract features from the input using a filter smaller in size than the original input. The second (ii) operation ReLU replaces all negative values in the feature map by zero. The (iii) Pooling operation , max pooling in our case, reduces dimensionality by taking the largest element from the rectified feature map within a neighborhood. The (iv) Classification operations, after a series of iteration of the (ii) and (iii) then uses the higher-level features identified to deter a class using several fully connected perceptrons layers.

A Support Vector Machine (SVM) is a classifier defined by a separation hyperplane. Input of the algorithm is the labeled training data, while its output is an optimal hyperplane which places new data into distinct classes.

Random forest classifiers infer a series of decision trees from randomly selected subset of the labeled data. The results are then passed through different decision trees to finally classify the test data.

The specific architecture we used is described in the next section; using it, we performed various experiments using 10-20 epochs of training (passes over the entire training set in randomised order).

The results were similar in performance to the SVM and Random Forests. However, manual error analysis showed that qualitatively these errors were different. While in the case of SVM and Random Forests a misclassification, such as a false positive, is usually the result of a word marking flood relevance (e.g., "flood") used in a completely different context (e.g., "my timeline is flooded with messages"), in the case of the neural network we used a misclassification was often semantically related to floods, such as a message referring to the effects of other natural disasters. The lesson learned from these experiments was that neural networks are better in this problem at capturing semantic characteristics that are relevant for our task of distinguishing flood-related messages.

Neural Network Architecture

Current implementations of convolutional neural networks for text processing tasks tend to have a similar architecture. They consist of an input layer, a word embedding layer, a series of convolutional and max pooling layers, a dense layer, and an output layer (Liao 2016).

The input layer holds a padded sequence of words with a maximum length $S = 100$ words, which is more than sufficient for tweets considering their maximum length is 280 characters.

The word embedding layer converts every word into a low-dimensional vector, typically in the order of a few hundred dimensions (e.g., $D = 200$ or $D = 300$). We used two sources of pre-trained word embeddings, as described in the next section. For each pre-trained word embedding, we considered two configurations-ups: one in which the parameters of the pre-trained word embedding were fixed, i.e., not modifiable while training the neural network, and one in which they were part of the optimization process, i.e., modifiable while training. In our experiments, best results were obtained when these parameters were fixed, probably because the amount of flood-specific data that we are using for training is small in comparison with the corpora used to create these word embeddings. The results we report on this paper use fixed word embeddings.

The convolution layers collect several word embeddings representing adjacent words and “summarize” them into a single vector. The main parameter for the convolutions is the width C, which is how many adjacent words to take into account. In the text "flood warning due to heavy rain" using $C = 5$, there are two possible convolutions: “flood warning due to heavy” and “warning due to heavy rain.” The parameter C is determined considering what is the effect of the context on the meaning of a word, and $C = 5$ is a typical value. We did not observe any increase in performance with a larger value of C, while a smaller value of C may lose contextual information.

The max pooling layer collect a series of m disjoint convolutions as input, and generate a vector of dimension $d < D$ as output. The max pooling step operates differently from the convolution layers in the sense that the windows it uses are disjoint, i.e., non-overlapping. The purpose of this layer is to reduce the dimensionality of the network for computational purposes and to reduce the chances of overfitting. In our case we used $m = 5$ and $d = 128$, which are typical parameters used in text classification.

The final layer is a densely-connected (complete) layer. All the neurons in the last max pooling layer are connected to all the neurons in this dense layer, and all the neurons in this dense layer are connected to the two output neurons. One of the two output neurons should activate when the example is positive (i.e., a message indicating that a flood has just happened or is about to happen), and the other output neuron should activate when the example is negative (i.e., the message does not indicate that a flood has just happened or is about to happen).

Word Embeddings for Multi-Lingual Classification

The usage of word embeddings allows to incorporate multi-lingual capabilities in two ways: by using language-agnostic word embeddings and by using language-aligned word embeddings.

Our source of language-agnostic word embeddings is GloVe (Pennington et al. 2014), which are vectors of dimensionality 200 obtained from a large corpus of tweets containing 27×10^9 tokens (1.2 million of them unique). While these word embeddings were not developed for multi-lingual tasks, they do incorporate any word present on a tweet in a language-agnostic manner.

Our source of language-aligned word embeddings is MUSE (Conneau et al. 2017), which are vectors of dimensionality 300 obtained from various snapshots of Wikipedia in various languages. For each language, vectors for the 200,000

most frequent tokens are provided, and these vectors have been *aligned* across languages using parallel lists of tens of thousands of words. In the resulting embeddings, two words with the same meaning in different languages are mapped to similar vectors.

In our experiments, presented on the next section, both pre-trained sets of vectors allow to transfer an automatic classifier learnt with labeled data from one language (or a set of languages) into another language with no new labeled data ("cold start") or with a limited amount of labeled data ("warm start").

AGGREGATION AND SELECTION

In our integration with EFAS, flood risk is established by an hydro-meteorological model and our task is to add complementary information that brings a better understanding of the situation on the ground. Relevant messages are mapped to NUTS-2 areas (Nomenclature of Territorial Units for Statistics, Level 2) either by using explicit coordinates which are rarely present in tweets, or more often, via a text-based geocoder. Geocoding deals with messages that do not include explicit geographical coordinates, but mention a place name such as landmark or city. Geocoding uses a Named Entity Recognition tagger to obtain possible locations in a text considering the syntax of the message. It uses a gazetteer in a large database of place names with their corresponding geographical coordinates, and finally it uses a neural networks to infer the correct country and correct gazetteer entry for those places. We used a library named Mordecai (Halterman 2017) which extracts place names from a piece of text, resolve them to the correct place, and return their coordinates and structured geographic information.

Messages are aggregated at the level of an event, but also at the level of each NUTS-2 area. In both cases, one key operation is to select a representative sub-set of messages. We do this operation by using the following efficient heuristic based on de-duplication and text centrality:

1. Select up to 5,000 tweets having at least a 90% probability of being flood-related; if there are more than 5,000 tweets, select the ones with the highest probability
2. Compute similarities between these tweets
   (a) Consider only pairs having probabilities of being flood-related that differ at most by 0.0001, exploiting the fact that near-duplicate tweets will be given the same probability by the neural network
   (b) Compute edit distance and use it to compute normalized similarity: $1 - \ell(m_1, m_2)/(|m_1| + |m_2|)$ where $\ell(m_1, m_2)$ is the edit distance between the two messages and $|m_1| + |m_2|$ the sum of their lengths.
   (c) If the normalized similarity is greater than 0.8, use the timestamps of the tweets to mark the newer tweet as a duplicate of the older tweet
3. Sort all unique tweets by their *multiplicity*, i.e., by the number of duplicates they have, and keep the top 100
4. For these tweets, compute all pair-wise similarities using the same formula as above, and add the similarities for every tweet; this is the *centrality* of the tweet.

Step 1 of the heuristic has the goal of removing messages that are irrelevant. Step 2 removes near-duplicates which are redundant, but keeps track of how many near-duplicates a tweet has, for the purposes of using redundancy as a signal of importance. Step 3 applies a well-known lexical centrality heuristic (Erkan and Radev 2004), in which a salient message is one that has content in common with many other messages.

Figure 4 shows a first deployment of SMFR on EFAS web interface, it describes how the areas and their most relevant tweets are presented to EFAS users. The NUTS-2 area can be grey (low activity), orange (medium activity) or red (high activity) according to the ratio between numbers of annotated tweets. The triggering that lead to the creation of the collection depicted can be seen in figure 2

EXPERIMENTAL RESULTS

We describe two types of experimental results. First, we perform experiments to test the performance of the multilingual-classifier, comparing it with a mono-lingual classifier. Second, we show a real example of an actual flood event, describing the performance of the on-demand collector, of a multi-lingual classifier that does not use labeled data from the target language, and of the aggregation and selection method.

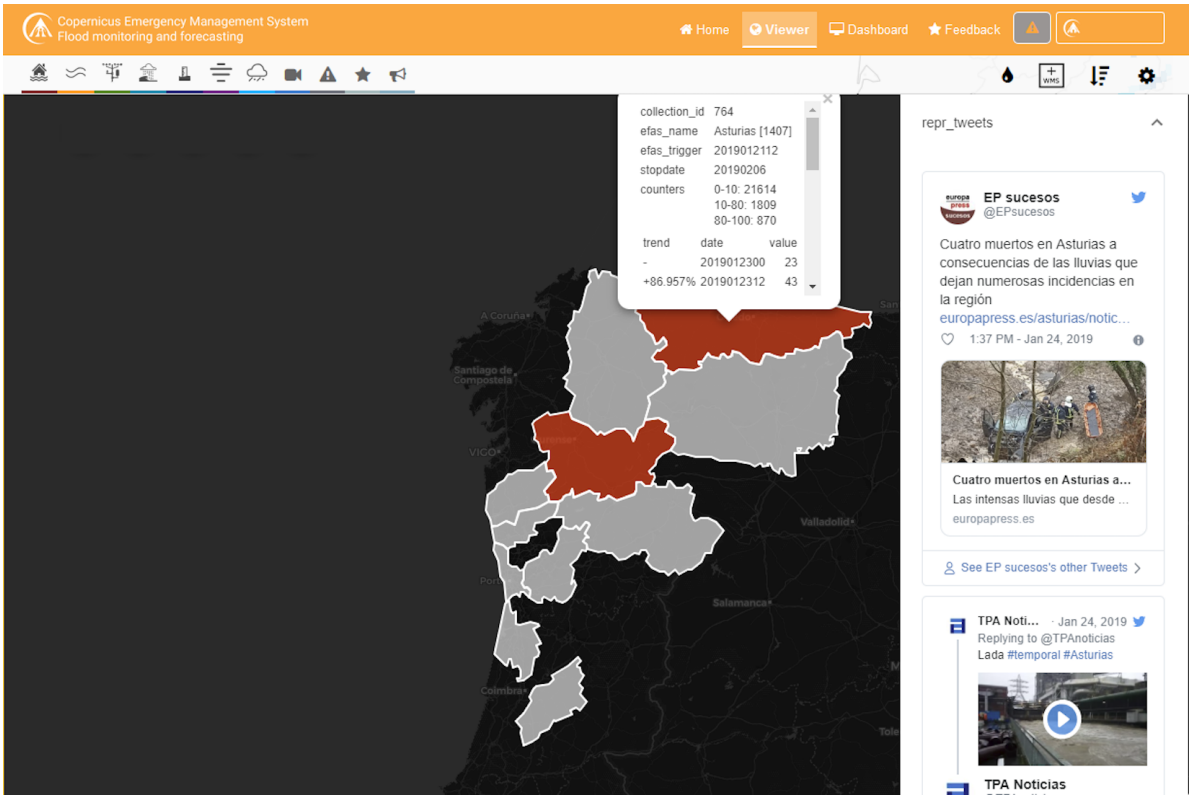

Figure 4. Screenshot of EFAS web interface with the layer identifying areas where there is high tweet activity and their most representative tweets on the right side. The basemap has been darkened for better visualization

Multi-Lingual Classifier

The multi-lingual classifier provides a solution for bootstrapping classifiers in new languages based on labeled data for other languages. The aim of the experiments is to compare the classifiers trained with and without labeled data for a specific target language. Performing this evaluation, nevertheless, requires having labeled data to measure effectiveness parameters.

For these experiments we use four labeled sets of flood-related tweets in German (DE), English (EN), Spanish (ES) and French (FR). These were labeled by crowdsourcing workers via crowdsourcing as previously described; the question the annotators had to answer was "is this message indicating that a flood is happening or about to happen?" Hence, positive examples are the ones that are related to flood risk and impact, and negative examples are the ones that are not.

For each language and word-embedding source we performed three experiments: mono-lingual, cold-start, and warm-start. We used two thirds of the labeled data for training the classifiers and the remaining third for testing. We keep the testing portion fixed across experiments.

In the *mono-lingual* experiment we simply use labeled data in one language to predict the label for messages in the same language. In the *cold-start* experiment we train a classifier for a new language using only labeled data for other languages; for instance for automatically labeling tweets in Spanish, we use a classifier trained on labeled data for English, German, and French. In the *warm-start* experiment we use a set-up similar to the one of the cold-start experiment, but we add a limited number of messages (300) labeled in the target language. Each experiment is done once using GloVe embeddings and once using MUSE embeddings. We report precision, recall, and F-measure for each experimental setup in Table 1.

Table 1 reports values for Precision (P) , Recall (R) and F-measure. We also include the total number of tweets manually labeled by crowdsourcing workers (TL) and its percentage of positive (Pos.) tweets. Collections for German, English, Spanish, and French consider tweets posted during floods happening in the last two years in Germany, the UK, Spain and Mexico, and France respectively. Hence, the number of labeled tweets and the percentage of positive examples differ across languages.

All the results show the same pattern: the mono-lingual classifier performs best, as expected; the cold-start classifier (which does not use any labeled data in the target language) suffers from a loss mostly of precision, but also of recall;

Table 1. Classification results for four languages (German, English, Spanish, and French). TL indicates the total number of labeled messages, while Pos. indicates the percentage of those who were labeled as flood-related. P, R, and F indicate Precision, Recall, and F-Measure respectively. We report the performance of a mono-lingual classifier, of a cross-language classifier with "cold start" (uses no training data in the target language), and of a cross-language classifier with "warm start" (uses 300 labeled items in the target language).

			Glove embeddings									MUSE embeddings								
			mono-lingual			cold-start			warm-start			mono-lingual			cold-start			warm-start		
	TL	Pos.	P	R	F	P	R	F	P	R	F	P	R	F	P	R	F	P	R	F
DE	2356	46%	0.95	0.82	0.87	0.59	0.85	0.70	0.93	0.8	0.86	0.88	0.85	0.87	0.54	0.82	0.65	0.89	0.80	0.84
EN	1999	20%	0.79	0.63	0.70	0.59	0.49	0.54	0.67	0.51	0.58	0.64	0.68	0.66	0.33	0.50	0.40	0.58	0.28	0.38
ES	1592	48%	0.80	0.78	0.79	0.61	0.75	0.67	0.71	0.83	0.77	0.70	0.84	0.77	0.62	0.69	0.65	0.68	0.89	0.77
FR	1248	40%	0.74	0.72	0.73	0.50	0.46	0.48	0.62	0.77	0.69	0.69	0.75	0.72	0.44	0.86	0.58	0.59	0.72	0.65

and the warm-start classifier (which involves annotating a small number of tweets in the target language) has better performance than the cold-start classifier both in terms of precision and recall. Indeed, the warm-start classifier often achieves an F-measure that is comparable to the one of the mono-lingual classifier. Regarding the choice of word embeddings, results suggest that the performance using GloVe or MUSE embeddings are comparable.

In general, considering the combination of the information from the classification with the known locations from the EFAS forecasts, the classification performance is sufficient to extract representative tweets from an event and to map approximately the affected locations, as we demonstrate next.

Case Study: Calabria Floods in October 2018

In early October 2018, floods affected the region of Calabria in southern Italy. At least 2 people died in flash flooding after severe weather which peaked on October 5th. A mother and her seven year old son, who were swept away by flood waters in their car, were found in a river near Lamezia Terme, between the towns of San Pietro a Maida and San Pietro Lametino in Calabria. Other areas of Calabria were also hit by flooding and landslides.

Several families were forced to evacuate their homes and people were rescued after they climbed onto the rooftops of houses to escape the flooding.[5] Italian news agency ANSA, stated that the Ponte delle Grazie bridge on provincial highway 19 in the area collapsed during the storms (Redazione ANSA 2018). Vigili del Fuoco, Italy's National Firefighters Corps, reported major flooding in Ciro Marina, Petilia de Policastro, Strongoli, Cotronei and Isola di Capo Rizzuto. As shown in Figure 5 (a) more than 300 mm of rain fell in 3 days (Schiaroli 2018).

EFAS forecasted a potential flood in the Calabria NUTS-2 area on the 4th of October with a predicted peak time of the event for the following day. As planned, SMFR triggered a collection with a duration of 2 days that was later extended for an additional day due to persistence of the signal from EFAS forecasts. We analyzed the collection once it was stopped, at midnight on the 7th of October, after collecting 14,347 tweets.

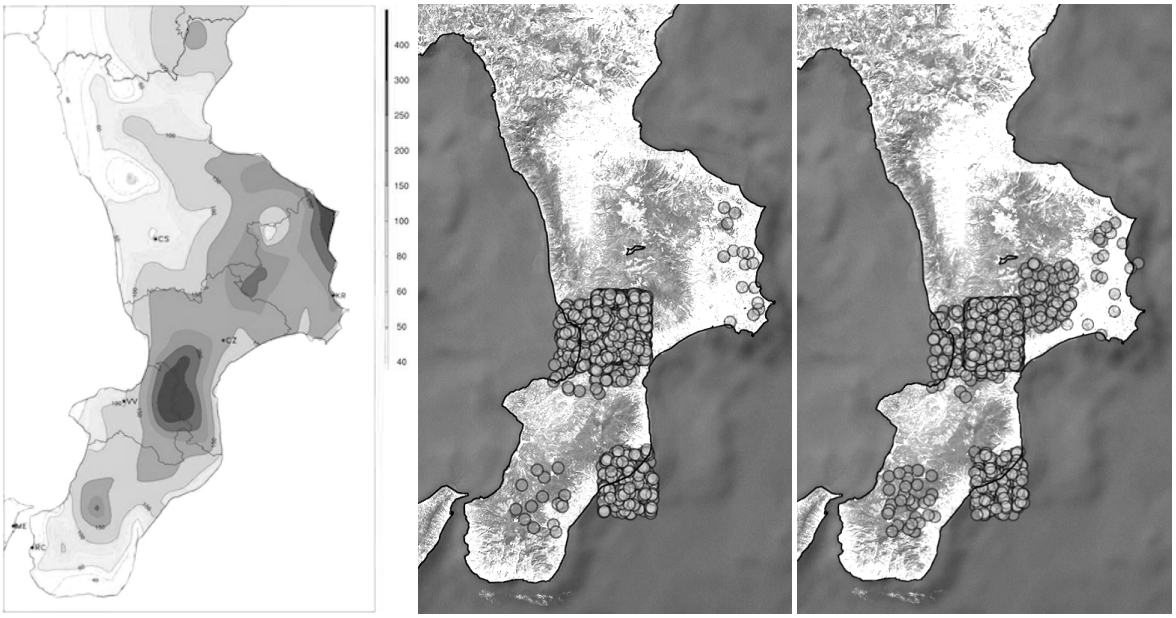
In order to confirm what emerged from experiments in the previous section, we trained two classifiers for messages in Italian, the first (cold-start) using only labeled data in German, English, Spanish, and French, and the second (warm-start) adding 300 manually labeled tweets in Italian from the collected dataset. For brevity we present results obtained using the GloVe embeddings (results using MUSE embeddings are similar).

In Figures 5 (b) and (c) we depict the position of geo-located tweets annotated by the cold-start and warm-start classifier respectively. Tweets have been filtered using a relevance to flood (label predicted) greater or equal to 0.8. We include the tweets geolocated within the bounding box used for triggering the collection, resulting in 2,847 tweets for the cold-start scenario against 3,857 for the warm-start scenario. For visualization purposes, tweets geo-located to the exact same location are randomly scattered by a small amount in the map.

Figure 5 confirms the results from the experiments, in the sense that both cold-start and warm-start classifiers are able to classify relevant tweets, with an advantage for the warm-start classifier in the sense that it identifies more relevant tweets and has better coverage of the areas affected by heavy rainfall. This suggests that the cold-start method can provide a first approximation for identifying an ongoing event, while the warm-start method yields more precise and relevant tweets.

Finally, Table 2 shows samples of tweets that have been selected as the most representative for this event, following the heuristic described previously, and taking as input the tweets found relevant using the cold-start and warm-start methods. We can see that in the cold-start scenario the most representative tweets are relevant to the event considered. However, the warm-start scenario gives more informative messages. While tweets selected by the cold-start classifier

[5]Data provided by floodlist.com, which is a EU-supported project providing reports on past floods.



(a) Rainfall (b) Tweets, cold start (c) Tweets, warm start

Figure 5. Comparison of (a) rainfall, (b) tweets located by cold-start model, and (c) tweets located by warm-start model. Data from floods in Calabria, Italy, 2-5 October 2018. Tweets falling in the same location are randomly scattered for visualization purposes.

are relevant, they mostly just confirm the event as reported in the news; in constrast, the tweets selected in the warm-start case identify a message from the Italian Prime minister as the most representative ("I follow with concern the evolution of events ...") and include information about damages and casualties due to the flood.

Table 2. Representative tweets selected by cold-start and warm-start. Conf. is the confidence of the classifier. Mult. the multiplicity (number of near-duplicates of the tweet). Cent. is the centrality (number of closely related but not duplicate tweets).

CONCLUSIONS AND FUTURE WORK

We have described how to integrate social media into the European Flood Awareness System (EFAS) to provide valuable signals augmenting flood risk information provided by this platform, by finding potentially relevant and representative messages from flood-affected areas in the languages spoken in those areas. Our work provides a solution and methodology for integrating flood modeling and evidence from the ground in real-time for several countries, potentially providing information from local witnesses or local media to first responders. This unique combination of hydrological simulation forecasting and an automatic, immediate monitoring of the extent of the event through social media without necessity to manually translating information, allows to shorten the response time, which is extremely precious in the very early stages of a flood. Moreover, during the development of an event, collected messages could be valuable to international rescue coordinators such as ERCC because they provide insights about the local response, about whether alerts that have been issued by authorities, and about some of the concerns that those affected by a flood or a flood alert may have. The research also highlighted the need for high-recall data collection in which data in multiple languages is captured, and provided a methodology for dealing with a new language, by bootstrapping a classifier with similar languages for which labeled data is available, using either language-agnostic or language-aligned word embeddings. Additionally, it was clear during the development of the project that naturally occurring data (i.e., actual messages posted during a flood in a particular country) are necessary to build an accurate classifier and aggregator.

Limitations. Due to the nature of EFAS and its geographical domain (pan-European) we focused on language spoken in the region, therefore we only tested the methodology proposed for indoeuropean languages. The performance with other languages remains to be studied.

At the time of writing, the described system is still in testing phase. After a period of internal evaluation, SMFR will become operational and its results will be disseminated among EFAS Partners.

Future Work

As future research activities, one can envision a global system comprising dozens of languages used to augment the Global Flood Awareness System (GloFAS; http://www.globalfloods.eu/). One can also envision further steps in the direction of using social media as a data source that can feed into a predictive model, using it not only for confirming known flood risks, but also for detecting new ones, particularly in areas where digital devices are prevalent but meteorological stations and other physical sensors are scarce in comparison.

Reproducibility. Datasets and code for the experiments described on this paper will be available for research purposes at https://bitbucket.org/lorinivalerio/iscram_2019/.

ACKNOWLEDGMENTS

This job has been funded by an Exploratory Research grant made available by the Joint Research Centre of the European Commission. ABSTRACT

We address the problem of making sense of rumour evolution during crises and emergencies. We study how understanding and capturing emerging rumours can benefit decision makers during such event. To this end, we propose a two-step framework for detecting rumours during crises. In the first step, we introduce an algorithm to identify noteworthy sub-events in real time. In the second step, we introduce a graph-based text ranking method for summarising newsworthy sub-events while events unfold. We use temporal and content-based features to achieve the effective and real-time response and management of crises situations. These features can improve efficiency in the detection of key rumours in the context of a real-world application. The effectiveness of our method is evaluated over large-scale Twitter data related to real-world crises. The results show that our framework can efficiently and effectively capture key rumours circulated during natural and human-made disasters.

Keywords

Rumours, large-scale data, event summarisation, sub-event detection, social media analysis

INTRODUCTION

Nowadays social media platforms are main sources of a variety of information with rapidly growing rates of user engagement and global mobile social media usage. According to the Global Digital Report 2018, 3.196 billion users are using social media. Along with the growth of social media, its role during emergencies and crises has become prominent (Andrews et al. 2016; Arif et al. 2017; Castillo 2016; Imran et al. 2015; Rudra et al. 2018; Zeng et al. 2016). For instance, emergency services can remotely identify areas affected by crises situations based on social media users' posts reporting what they are seeing and hearing (Yin et al. 2012) or find victims seeking help (Zubiaga et al. 2018a). Emergency responders can then make adequate decisions such as the allocation of resources and police. The enormous and continuing growth of user activities on social media is accompanied by the real-time acquisition of a substantial amount of user-generated data with an unprecedented volume and variety and different levels of veracity. As the speed of event evolution is very fast, the existence of such information in the real-time stream of social media content poses a challenge to decision makers, in particular, in time-sensitive situations such as natural disasters and terrorist attacks. It is impossible for humans to manually inspect rapidly changing and noisy messages in a timely manner. In addition, citizens can be confused by unfounded or conflicting rumours regardless of whether they were generated purposely or unintentionally.

Research areas using social media that have been in the limelight recently are *automated rumour and fake news detection* (Helmstetter and Paulheim 2018; Kwon et al. 2017; Shu et al. 2017, 2018; Wong et al. 2018) and *fact-checking* (Boididou et al. 2018; Vosoughi et al. 2017). Social media are origins of rumors and where they spread among a large number of people (Ma et al. 2018). Despite the growing interest in rumours and fake news on social media and several attempts to make sense of them in both academia and industry, the utilisation of rumours for emergency response poses several challenges (Andrews et al. 2016; Starbird et al. 2016). In this study, we aim at partially filling this gap by studying how to identify rumours appearing during crises without manually examining a large number of messages. Our framework comprises of real-time key sub-event detection and summarisation. Summaries obtained by our method can include both rumours and non-rumours. According to our experiments, most summaries contain informative details related to emergencies and reflect what draws the public's attention.

Our system can help practitioners identify not only newsworthy events but rumours to debunk or verify without examining an entire stream of messages.

In this paper, we address the problem of the early and semi-automatic identification of *rumours* on social media during crises. To this end, we first analyse rumours during emergency situations. We adopt the definition of rumour proposed by (DiFonzo and Bordia 2007): "an unverified and instrumentally relevant information statement in circulation that arises in contexts of ambiguity, danger or potential threat, and that functions to help people make sense and manage risk". We refer to (Olteanu et al. 2015) to categorise rumours by type. We claim that some information types such as 'donations and volunteer', 'caution and advice', and 'sympathy and emotional support' can contribute to situational awareness but cannot be considered as rumours. Our scope of rumour during crises include a) affected individuals, infrastructure, and utilities, b) the location of the event, c) other useful information (e.g. details about suspects and weapons). We use Twitter as a representative social media.

To help decision makers and journalists identify breaking news or understand unfolding situations as early as possible, we pose the following research question: "Which moments in event evolution are worth being paid attention to from the perspective of emergency responders?" To address the question, we introduce "noteworthy moment detection" into the framework of rumour studies. Several studies have studied bursts in the popularity of events on social media (Hu et al. 2017; Keneshloo et al. 2016; Kong et al. 2015; Matsubara et al. 2012; Wang et al. 2016). The main focus of such studies is often a 'peak'. However, a peak indicates that a rumour has already become popular (i.e. a large amount of information regarding the rumour is available). This phenomenon makes it difficult for professional analysts to take action to deal with the rumour in a timely manner. We emphasize the importance of capturing bursts of user activity along with peaks, and collectively refer to both types of events as *noteworthy moments.* The identification of such moments in rumour evolution without domain knowledge is often challenging and tricky as a boundary between noteworthy and normal moments may not be obvious to a lay person. Noteworthy sub-events are not necessarily equivalent to novelties concerning their content (i.e. topics) as considered in the area of first story detection, but they are considered to be novel in temporal context.

Having identified noteworthy sub-events, our proposed framework generates summaries of a high volume of messages. There are commonly two approaches for event summarisation. One is generating a whole new text which contains important information. The other is extracting representative messages that have high scores. In this work, we choose the latter approach. Several studies on crisis management via social media have proposed sub-event summarisation methods (Kedzie et al. 2015; Nguyen et al. 2015; Rudra et al. 2015, 2016, 2018). The state-of-the-art work on event summarisation usually focuses on achieving higher Recall-Oriented Understudy for Gisting Evaluation (ROUGE) scores (Lin 2004). ROUGE is a metric which evaluates the quality of a summary by comparing overlapping n-grams between the summary and gold standard references. Our framework also consists of two steps: noteworthy moment detection and sub-event summarisation. What differentiates our study from the state-of-the-art work is that we undertake an extensive analysis of rumours that emerge and evolve during crises. We believe that understanding rumour evolution during crises can benefit both the improvement of situational awareness during crises and diverse realms of rumour studies. Attempts to understand differences between true information and false rumours have been extensively studied in the community of rumour studies. Crisis management via social media can benefit from findings of rumour studies. Meanwhile, examples of crises and emergencies can be useful resources for rumour studies.

The main contributions of our work are summarised as follows:

1. We propose a semi-automatic framework for the early detection and summarisation of key sub-events. Our framework can identify potential rumours that draw people's attention before their popularity reaches a peak. Our framework makes it possible for decision makers to understand developing situations quickly and to take action proactively. This can lead to the minimization of the extent of the damage.
2. We demonstrate that our framework can work with events with different types of language and different sizes. We conduct experiments over real-world datasets that mainly consist of English, Italian and Russian tweets.
3. We evaluate our framework's effectiveness quantitatively and qualitatively by comparing different methods for key sub-event detection.
4. Our framework generates readable and meaningful summaries that cover a wide range of information so that end users who do not have background knowledge on models can easily understand unfolding events.

REQUIREMENTS AND SYSTEM DESIGN

- **Early detection**: A system must be able to capture informative reports in the early stages of event evolution. This makes it possible for decision makers to be prepared for potential hazards in the near future.

- **Real-time detection**: The speed of the dissemination of information during crisis is very fast. A system must be able to process a stream of posts in real time so that decision makers can plan urgent and planned remedial actions in a timely manner.
- **Scalability**: Rumours during crises and emergencies are usually unexpected, sudden, and unusual. One major drawback of using a threshold to identify key moments such as emerging patterns and spikes in event evolution is that system performance is highly dependent on data sizes.
- **Generalisation**: A system must be transferrable to events from different domains and with different characteristics (e.g., language, burstiness, and geolocation).

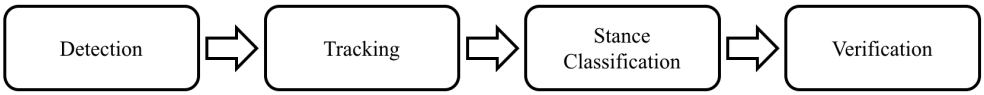

Figure 1. Architecture for rumour studies.

Figure 1 shows a commonly used architecture in rumour studies (Zubiaga et al. 2018b). Systems for rumour detection perform binary classification to decide whether a piece of information (e.g. a single tweet) is a rumour or non-rumour. In general, tweets during crises can be collected using a set of keywords related to an event or geolocation. For example, relevant keywords such as 'bostonexplosion', 'bostonbombing', 'bostonblast', and 'prayforboston' can be identified at the early stage of the Boston marathon bombings. In particular, the hashtag starting with 'prayfor' is very popular worldwide and usually appears when tragic events take place. Due to this data collection procedure, there can be lots of irrelevant or uninformative posts in a stream. Therefore, we argue that it is impractical to apply a rumour detection system to a raw stream of posts. Our framework will bridge the gap between real-time data collection and the automatic detection of breaking news and rumours.

We further discuss why 'peaks' are not appropriate signals for key moments detection. Let us think about the task of determining whether the time window marked in square in Figure 2a is noteworthy or not. This task may become less challenging if we observe the next time window. For example, we can confirm that the time window marked in square is a key moment without doubt in Figure 2b because it is a 'peak'. On the other hand, it is still challenging to decide whether the target window is noteworthy or not in Figure 2c. The target lies on the increasing line of the graph. However, the amount of increase is not significant compared to that between the time windows marked in square and star. By looking at this simple example, we can draw two conclusions. Firstly, it is impossible to identify a peak without observing future instances. This means the detection of peaks in event evolution cannot be done in real time. This is why several studies on key moment detection employ retrospective approaches for detecting peaks. Secondly, the term 'noteworthy moment' can be considered an anomaly of interest to analysts or domain experts. As several studies on anomaly analysis point out, it is subjective to judge whether a point in the evolution of an event can be considered to be noteworthy or not (Aggarwal 2015). The distinction between noteworthy and non-noteworthy moments could be regulated based on the interest of analysts.

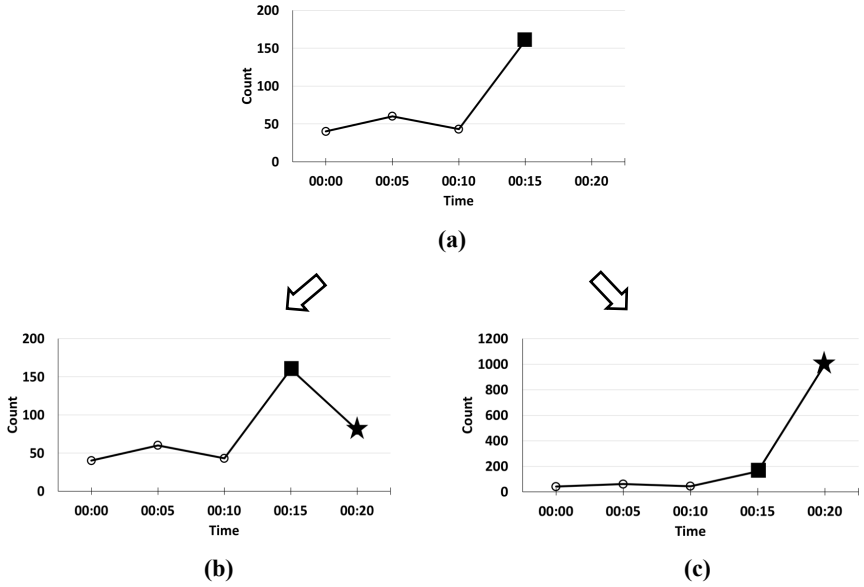

Figure 2. Examples of event evolution.

Previous studies on key sub-event detection utilize thresholds. Specifically, their methods recognize sub-events the volume of messages of which exceeds a certain threshold. A drawback of most existing methods based on thresholds is that they tend to capture a large number of instances in periods of persistent decline. However, we observe that these instances are generally spurious anomalies in the context of content novelty. We are interested in detecting newly emerging or developing stories rather than already seen sub-events with a high volume of messages. Our observation shows that the same topic can be actively discussed even after its popularity reaches a peak for several reasons such as the time difference between locations of users. Instances located in a persistently falling line are not of interest because they are likely to be duplicates of key sub-events in the past. We will further investigate this argument using real-world datasets. We design our architecture for *event-level* studies of crises in the real world. We aim to aid tweet-level rumour studies by reducing data granularity. We propose our method as a pre-processing step for rumour detection in crises and emergencies. The output of our framework can be used as *candidates* for the construction of annotated data for rumour detection. The state-of-the-art work on rumour detection annotated only highly retweeted tweets (Ma et al. 2017; Zubiaga et al. 2016b; a). This data sampling may lead to biased results for rumour detection as some minor but important sub-events do not get a high number of reactions (Meladianos et al. 2015). The fine-grained detection, tracking, stance classification, and verification of rumours are beyond the scope of this paper.

NOTEWORTHY MOMENT DETECTION

We propose a rule-based algorithm for detecting noteworthy moments in quasi real-time. Our method identifies key moments by solely using the left-hand side of any instances (i.e. time window) of a time series. Table 1 describes features associated with the number of tweets. We use the Boston marathon bombings to empirically choose our parameters. Specifically, we visualise key moments detected using different combinations of parameter values and select a set of parameters which satisfies best our hypothesis: noteworthy moments lie in increasing lines in even evolution graphs. We set α for EWM_MEAN to 0.3, S for DIFF_RMEAN to 3, and λ for ψ to 0.01. Recall that it is subjective to judge whether a point in the evolution of an event can be considered to be noteworthy or not. Therefore, the used parameter values are rules of thumb. Even so, our experiments show that they are scalable and generalize well to datasets with different sizes and from different types of crises.

Table 1. Features extracted from the tweets within the i^{th} time window.

Name	Description	Mathematical Equation
COUNT	The number of tweets	c_i
EWM_MEAN	Exponentially weighted average of COUNT	$s_i = \begin{cases} c_i & i = 1 \\ (1-\alpha) * s_{i-1} + \alpha * c_i & i = 2, \dots, N \end{cases}$, where $0 < \alpha \leq 1$
DIFF	Difference between s_i and s_{i-1}	$d_i = \begin{cases} 0 & i = 1 \\ s_i - s_{i-1} & i = 2, \dots, N \end{cases}$
DIFF_RMEAN	Rolling mean of d with a window size of S	$z_i = \begin{cases} 0 & i = 1 \\ \frac{\sum_{k=1}^{\min\{S, i-1\}} d_{i-k}}{\min\{S, i-1\}} & i = 2, \dots, N \end{cases}$
STDEV	Sample standard deviation of 4 time windows	$std_i = \begin{cases} 0 & i = 1 \\ \sqrt{\frac{\sum_{k=0}^{\min\{3, i-1\}} (s_{i-k} - \bar{s})^2}{\min\{i, 4\} - 1}} & i = 2, \dots, N \end{cases}$, where $\bar{s}$ is the mean of s_i.
θ	A combination of EWM_MEAN and STDEV	$\theta_i = \begin{cases} 0 & i = 1 \\ s_{i-1} + std_i & i = 2, \dots, N \end{cases}$
ψ	A combination of DIFF and DIFF_RMEAN	$\psi_i = \begin{cases} 0 & i = 1 \\ \lambda * z_{i-1} + (1-\lambda) * d_i & i = 2, \dots, N \end{cases}$

We formulate noteworthy sub-event detection into a binary classification task. Algorithm 1 describes the rule-based procedure of identifying noteworthy moments using the above features. In order to simulate a real-time scenario, we assume that a time series consists of N time windows. Given the N instances with the features, the algorithm assigns binary labels to time windows based on a set of conditions. A label is 1 if a window is noteworthy and is 0 otherwise. Some existing studies define thresholds for the absolute number of messages of each time window (Gillani et al. 2017; Shamma et al. 2009; Zubiaga et al. 2012). Others define thresholds for differences in the number of messages over several time windows (Nichols et al. 2012; Peng et al. 2018). Our algorithm overcomes several limitations that existing methods for key sub-event detection have. Firstly, results of the state-of-the-art approaches for sub-event detection are highly dependent on the total number of tweets posted during event evolution. This poses a challenge because the performance of a detection method can be poor if an inappropriate threshold is chosen. To overcome this, we adjust thresholds in the early stages of event evolution (LINE 3-7). As rules of thumb, we set H to 24 for instantaneous events and to 36 for progressive events. In other words, for instantaneous events, thresholds are adjusted during the first 24 time windows regardless of resampling window size. Using a larger value of H indicates our algorithm needs a longer time to learn event evolution. In general, it takes longer to draw people's attention in the case of progressive events as interesting sub-events develop slower than they do in instantaneous events. Secondly, our algorithm considers both the absolute volume (LINE 10-14) and differences in the number of messages (LINE 15-17) to detect noteworthy sub-events. Consequently, detected sub-events have a significant number of messages to be considered anomalous. Data instances lying in decreasing lines in time series plots are filtered out. We implement our method via Python.

Algorithm 1. Algorithm for the real-time and automatic detection of noteworthy moments.

Algorithm 1. Noteworthy sub-event detection

Input: N time series with features
Output: Binary labels

```
1: for i=1 to N do  // Iterate N time windows
2:     // Calculate thresholds
3:     H = constant
4:     while i < H do
5:         AVG = mean(COUNT)  // the mean of COUNT up to the i^th time window
6:         THRESHOLD = min(AVG, 100)
7:         DIFF_THRESHOLD = max(θ)  // the maximum θ up to the i^th time window
8:     if i == 0 then  LABEL ← 0
9:     else
10:        if (COUNT > THRESHOLD) and (COUNT >10) then
11:            if PREVIOUS LABEL == 1 then

15:            elif (PREVIOUS LABEL == 0) and (EWM_MEAN > θ) then
16:                if ψ > DIFF_THRESHOLD then  LABEL ← 1
17:                else  LABEL ← 0
18:            else  LABEL ← 0
19:        else  LABEL ← 0
```

EVENT SUMMARISATION

Given detected noteworthy moments, we extract representative tweets that can summarise unfolding events within each key moment. One simple approach to extract summaries are to assign scores to words in each tweet using a frequency or term frequency-inverse document frequency. However, this approach generally produces poor results. We use an unsupervised graph-based ranking algorithm for text called TextRank (Mihalcea and Tarau 2004). We decide to use TextRank for two reasons. One reason is that it is fully unsupervised. The performance of supervised text ranking models is highly dependent on training data. On the other hand, it is capable of extracting summaries solely based on the text itself. This is particularly important for crises as they are usually unseen and evolve unexpectedly. Another reason is that TextRank can be adapted to short text, which is suitable for tweets. We implement the TextRank using an open source software in Python (Barrios et al. 2016). However, the representation of the graphs of words in their implementation favours long tweets. To avoid this limitation, we follow the representation proposed by (Meladianos et al. 2015). Let a 'document' refer to a set of tweets

published within a time window. Given a document, we firstly generate a graph G whose vertices (V) are words and edges (E) are co-occurrence relation. If two words w_i and w_j co-occur in a tweet, an edge between two vertices V_i and V_j is created. Next, a weight $w_{ij} = \frac{1}{p-1}$ is added to the edge, where p is the number of unique terms in the tweet. If vertices already exist in a graph, the edge weight is accumulated. By repeating this procedure for the document, the algorithm returns scores for words in the document. Given the word scores, the method calculates scores for each tweet in the document by adding up the scores of words appearing in each tweet. Finally, we sort tweets in reverse order and use the top-K tweets as extractive summaries of each key sub-event. We use 10 for K in our experiments. Using a higher number for K may help users discover more sub-events. However, it is not viable for humans to read and annotate all available tweets due to the large volume of tweets during breaking events and time constraints (Zubiaga et al. 2016b; a).

EXPERIMENTS

Datasets

We use two publicly available datasets. A summary is shown in Table 2.

Twitter Event 2012-2016 (Zubiaga 2018) : This data consists of over 147 million tweets about 30 real-world events that took place between 2012 and 2016. The tweets were collected using Twitter's streaming API with keywords and hashtags related to each event. We select three human-made crises: Boston marathon bombings (2013), Ferguson unrest (2014), and Sydney siege (2014). We refer to this data as 'Event1216' hereinafter.

CrisisLexT26 (Olteanu et al. 2014): This data includes tweets regarding 26 hazardous events that unfolded between 2012 and 2013. It is designed to enable decision makers and citizens to understand unfolding disaster situations and obtain information of interest from social media. We select two natural disasters: Northern Italy earthquakes (2012) and Russian meteor (2013). The data size is small, but we decide to use this to show the scalability and generalization of our framework. We refer to this data as 'CrisisLex' hereinafter.

In Table 2, we define the development type of the Ferguson unrest as 'Mixed'. The initial shooting was instantaneous, but the developments were progressive. Table 3 shows the keywords used by the authors of the datasets when retrieving tweets. Some keywords such as 'ferguson' are too general. It is time-consuming to examine the entire set of collected messages as it contains a large number of non-rumours. Therefore, we can appreciate the importance of the detection of noteworthy moments in studying rumours during crises and emergencies. We carry out *event-level* analysis of tweets posted during crises in the real world. Specifically, we are interested in discovering what stories attract the public's attention and candidates for rumours to be debunked and verified by human experts while events unfold. There exists a trade-off between identifying key sub-events in real-time and manually examining candidates for key sub-events. It is not viable to identify key sub-events for every second as large-scale and noisy messages are generated at a rapid pace in social media (Atefeh and Khreich 2015). To tackle the trade-off, we employ a sliding window as previous studies on sub-event detection proposed. We use a 1-minute window for the Boston marathon bombings and a 5-minute window for the others. We use different window sizes for two reasons. One is to show that our method is versatile as it can work for different window sizes. The other is to embody different characteristics of event evolution. For example, sub-events such as affected individuals and details regarding suspects change very rapidly and situations tend to be chaotic and dynamic during the Boston marathon bombings. It is crucial to minimise delays in key sub-event detection by using a shorter window. During the Sydney siege, situations are less likely to require instant emergency responses as a gunman was holding hostages at a café for several hours. It is reasonable to use a longer window.

Table 2. Description of datasets.

Dataset	Event	Year	Country	Start	End	Domain	Development	Tweet Count
Event1216	Boston marathon bombings	2013	US	Apr 15	Apr 15	Bombings	Instantaneous	1,753,836
	Ferguson unrest	2014	US	Aug 9	Aug 25	Shooting/Riots	Mixed	4,183,421
	Sydney siege	2014	US	Dec 14	Dec 17	Hostage taking	Instantaneous	1,292,948
CrisisLex	Northern Italy earthquakes	2012	Italy	May 18	May 31	Earthquake	Instantaneous	4,231
	Russian meteor	2013	Russia	Feb 14	Feb 15	Meteorite	Instantaneous	4,498

Table 3. Keywords used to collect tweets (Olteanu et al. 2014; Zubiaga 2018)

Dataset	Event	Keywords
Event1216	Boston marathon bombings	boston, marathon, #prayforboston
	Ferguson unrest	ferguson
	Sydney siege	#sydneysiege, sydney, gunman, lindt, martin place
CrisisLex	Northern Italy earthquakes	earthquake italy, quake italy, #modena, #sanfelice, San Felice, modena terremoto, #terremoto, #norditalia, modena earthquake, modena quake, terremoto italia
	Russian meteor	#RussianMeteor, #Chelyabinsk, #челябинск, #метеорит, #meteor, #meteorite, russia meteor, russian meteor

Baselines

We compare our method with two baselines which exploit thresholds to identify key sub-events. We reproduce the baselines via Python.

Moving-threshold burst detection (Hsieh et al. 2012): Given the resampled time series, it computes the mean μ and standard deviation σ of the number of tweets observed up to the current time t_i. Then, the threshold at the t_i is defined by $\alpha * (\mu + \beta * \sigma)$. The parameters α and β are set between 0.7 and 1.0, and between 1.5 and 2.0, respectively. However, the authors did not specify default values for their parameters. If the number of tweets at t_i is greater than the threshold, the method annotates the instance at t_i as a key moment.

Outlier-based sub-event detection (Zubiaga et al. 2012): Given the resampled time series, it identifies the instance at t_i as an event of interest if the tweeting rate at t_i is higher than 90% of previously seen tweeting rates.

RESULTS AND EVALUATION

Quantitative Evaluation

Table 4. The results of noteworthy moment detection.

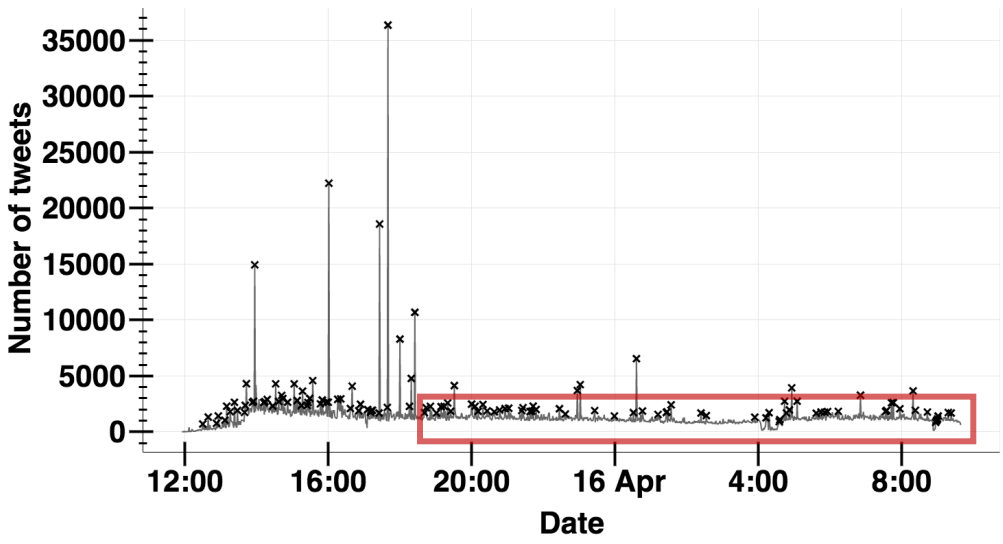
		Our method		Zubiaga		Hsieh	
Event	**# of windows**	**# of key moments**	**% of key moments**	**# of key moments**	**% of key moments**	**# of key moments**	**% of key moments**
Boston bombings	1,305	125	9.6	1,299	99.5	40 - 95	3.1 – 7.3
Ferguson unrest	4,651	603	13.0	4,093	88.0	341 - 646	7.3 – 13.9
Sydney siege	708	11	1.6	688	97.2	13 - 42	1.8 – 5.9
Italy earthquakes	3,585	40	1.1	13	0.4	126 -180	3.5 – 5.0
Russian meteor	337	29	8.6	191	56.7	20 - 50	5.9 – 14.8

Table 4 compares the number and percentage of detected noteworthy moments. (Hsieh et al. 2012) can detect different numbers of sub-events by adjusting parameters. The authors did not propose default values for their parameters. For a fair comparison, we randomly and uniformly draw parameter values from the ranges proposed in the original work. We perform the random sampling 100 times for each event. In Table 4, we show the minimum and maximum number of detected key moments. We find that the higher α and β are, the smaller number of windows are detected. For our method, we set H in Algorithm 1 to 36 the Ferguson unrest and to 24 for the others. We find that the number of detected sub-events depends not only on the total number of tweets but on burstiness. For example, the Sydney siege exhibits huge bursts (i.e. spikes) separated by long periods of inactivity. Small fluctuations between large spikes tend to be considered less noteworthy. On the other hand, the evolution of the Boston marathon bombings displays more bursty behaviour, and therefore relatively small bursts are identified as noteworthy moments. As can be seen in Table 4, Zubiaga's method performs poorly. In particular, their method cannot generalise to datasets with different characteristics. It identifies most of the time windows as key moments for the Event1216. It is not beneficial to perform sub-event detection if an algorithm recognises most time windows as key sub-events. In addition, previous study on sub-detection also showed that Zubiaga's method detect a large number of spurious outliers (Meladianos et al. 2015). On the contrary, it captures about 0.4% of the

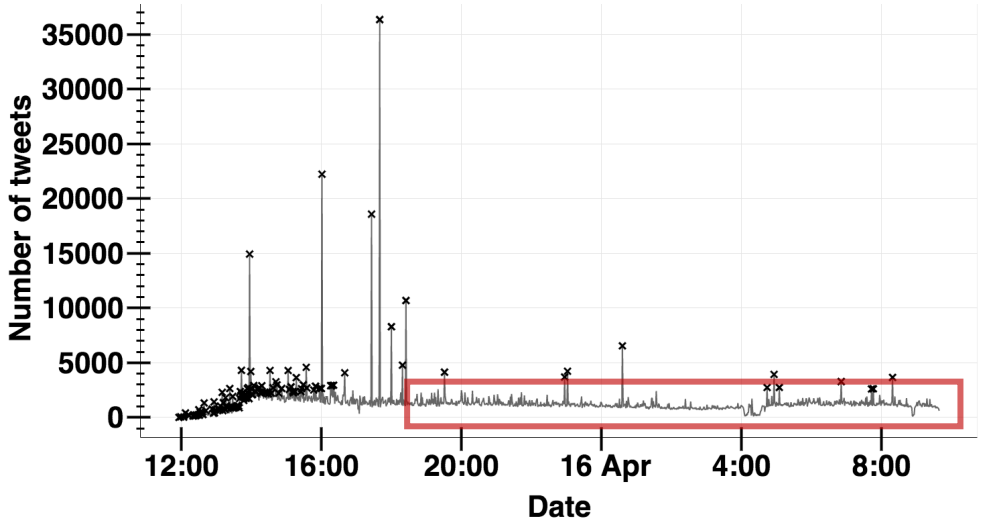
time windows for the Northern Italy earthquakes. Hsieh's method detects a reasonable number of windows. Therefore, we further compare the results in the qualitative evaluation.

Qualitative Evaluation

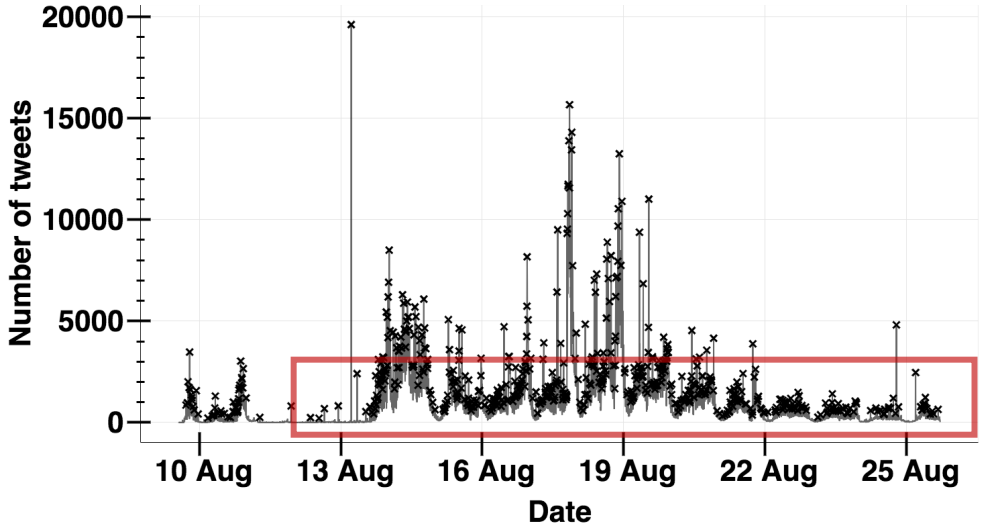
Not only the number of tweets but the distribution of key moments does matter. Here we compare the results obtained by our method and Hsieh's method. The major limitation of their method is their threshold is not adaptive to abrupt and extreme changes in event evolution. Recall that their threshold is based on the mean and standard deviation of the number of messages of preceding time windows. If there exist time windows the volume of messages of which is high in the past, their threshold tends to stay high afterwards. The evolution patterns of events on social media exhibit bursts of intense activity separated by long periods of inactivity or low-frequency periods (Barabási 2005). Taken all together, their method becomes less capable of detecting key sub-events with the relatively low number of messages as an event unfolds. We explain this phenomenon in detail with two real-world examples. Figure 3a and 3b show detected key sub-events for the Boston marathon bombings. For a fair comparison, we experimented with Hsieh's parameters outside the proposed ranges so that the number of sub-events detected by our method is similar to that detected by their method. Figure 3a shows detected key moments when $\alpha = 0.661$ and $\beta = 1.45$. One observation we can make is the results obtained by our method more evenly spread across the entire event evolution than those obtained by their method does. This means that our method is capable of detecting key moments in various phases of event evolution. Hsieh's method tends to detect more instances in the early stages of event evolution than our method does. However, their method only identifies spikes after 16:15 on 15 April. As we have already addressed previously, focusing on peaks in event evolution can prohibit the early detection of rumours. Figure 3c and 3d show detected key moments for the Ferguson unrest. It is clearly shown that a large number of instances are not detected in the red box in Figure 3d. This indicates that our method is better at early detection than Hsieh's method is. Figure 4a and 4b illustrate this observation more clearly. Hsieh's method detects not only instances on increasing lines but also those on decreasing lines. Figure 5 shows a part of Figure 3d. We can observe that all time windows, the number of messages of which is above a certain value are detected as key sub-events. We further investigate why these data examples are likely to be false anomalies in the following section.



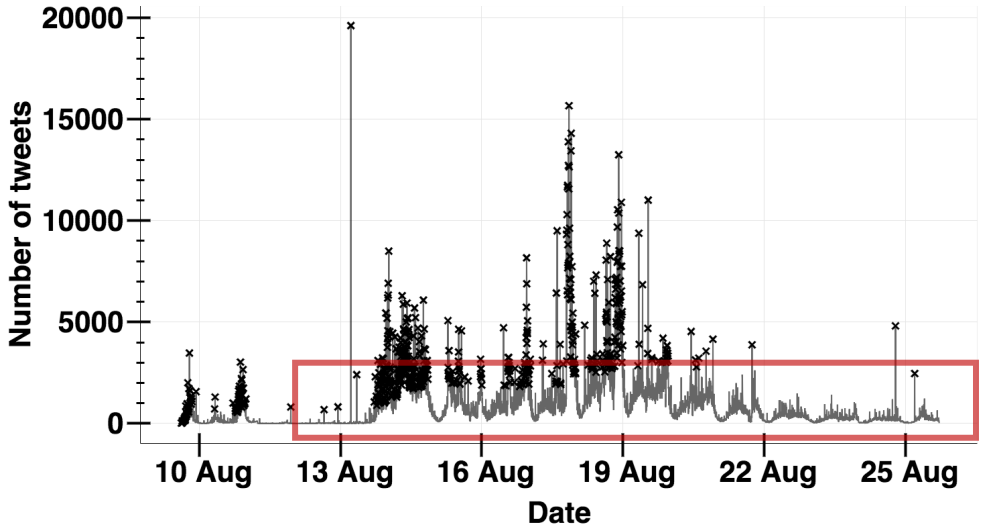
(a) 125 time windows are detected via our method.



(b) 129 time windows are detected via Hsieh's method



(c) 603 time windows are detected via our method



(d) 599 time windows are detected via Hsieh et al.'s method

Figure 3. Visual comparison of the results obtained by our method (a, c) and Hsieh's method (b, d). Detected key moments are marked with ×. (a) and (b) show the Boston marathon bombings. (c) and (d) show the Ferguson unrest.

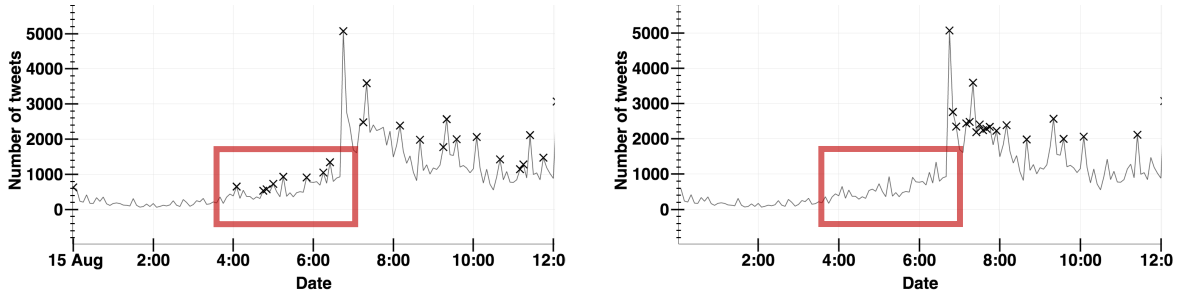


Figure 4. Partial plots of the Ferguson unrest. Detected noteworthy moments are marked with ×. (a) the results of our method (b) the results of Hsieh's method

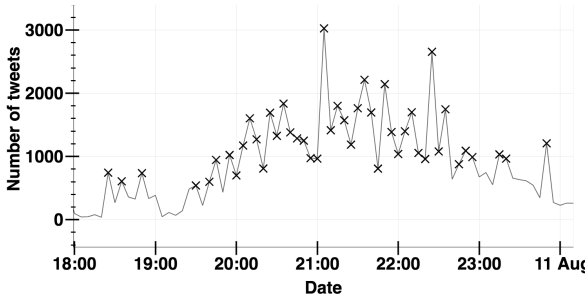

Figure 5. An example showing that Hsieh's method detects both increasing and fading patterns in event evolution.

Rumours During Crises

We apply the event summarisation method to the detected noteworthy moments. We then manually investigate the top 10 representative tweets of each key sub-event. Here, we show some examples of rumours appeared in the noteworthy moments detected by our method and their types. Note that there are more than 10 rumours as the given examples are found across an entire event rather than from one specific key moment. Rumours are classified into four categories: a) affected individuals, infrastructure, and utilities, b) the location of an event, c) other useful information (e.g. details about suspects and weapons). We present some rumours found in the detected noteworthy moments for two different datasets. As can be seen in the following tables, several informative and useful sub-events can be captured by focusing on noteworthy moments rather than the whole sequence. We find that several rumours spread during the Boston marathon bombings and Sydney siege. In particular, several posts related to a certain sub-event but with different entities (e.g. numbers) circulated. For the Boston marathon bombings, for instance, people reported different numbers and locations of explosive devices and whether a victim is an 8-year-old boy or girl. For the Sydney siege, different numbers of hostages and injured people were reported. There were also lots of details related to suspects.

- Boston marathon bombings

Type	Rumour	Type	Rumour
b	Two explosions near finish line	a	8-year-old girl or boy?
b	The 1st explosion reported on Boylston Street	a	An 8-year old girl is not one of the victims, an 8-year-old boy is dead
c	2 explosive devices are found	a	An 8-year-old girl died while running for her best friend
c	2 more explosive devices are found	a	An 8-year old girl/boy died while running for the Sandy Hook kids
c	Boston bombings are a "False Flag" operation	a	An 8-year-old boy killed has been identified as Martin Richard
a	8-year-old child died	a	The killed boy was waiting for his dad to finish his marathon
a	8-year-old boy/girl died	a	Mom and sister of the 8-year-old boy who was killed are injured
a	8-year-old girl died	b	The third explosion at the JFK library (unknown connection)
c	4 explosive devices	c	A fire broke out at the JFK library. Not an explosion
c	No one is in custody	c	Pressure cooker bombs were placed in black duffel bags
c	The third explosion has been reported	c	The third device is found

- Sydney siege

Type	Rumour	Type	Rumour
b, c	A gunman is taking hostages at a café in Martin Place.	c	The hostage taker is named as Man Haron Monis
b, c	An ISIS flag is being displayed on the window of a café	c	Man Haron Monis fled from Iran to Australia in 1996
a	2 killed and 3 seriously injured	a	6 more escaped and 11 in total have escaped
c	Hostages are being forced to hold an ISIS flag	c	Gunman is reportedly killed
b, c	Two gunmen inside the café under siege	a	2 dead (no information regarding the gunman's death)
a	Up to 20 hostages are being held	a, c	3 dead including the gunman (2 hostages and gunman dead)
a, b	Opera house has been evacuated	c	Prime Minister Abbott says Man Monis held a gun license
c	Sydney airspace closed	c	Shots fired
c	Gunman wants to talk to the Prime Minister	a, c	An Islamic extremist took 17 people hostages today
c	5 possible bombs in the city	c	Gunman wants ISIS flags
a	40-50 hostages being held	c	The gunman is carrying 2 bombs
b, c	Gunman says he has 4 bombs/devices around Sydney.	a	2 more hostages escape, 5 now have escaped.
a, c	2 dead including the gunman	c	The gunman is a lone wolf/self-styled.
c	Man Haron Monis is an Iranian cleric on bail for 40 sexual offences and accessory to the murder of his ex-wife.	a	Tori Johnson was the Lindt Cafe manager and tried to take the gun away from the man
a	Hostages who died are named as Tori Johnson, 34 & Katrina Dawson, 38	c	The flag at the window of the café is not an ISIS flag.

A hypothesis of our study is that newsworthy stories and rumours can be detected from time windows lying in increasing lines in even evolution graphs. We further study when rumours are detected for the first time using summaries obtained via our framework. The experimental results confirm our hypothesis. Table 5 shows whether some key rumours appear in noteworthy moments (i.e. increasing lines and peaks) or decaying lines for the first time. Most of the key rumours are detected at noteworthy moments, and therefore, we prove that our hypothesis is acceptable.

Table 5. Table shows whether key rumours detected from our summaries appear in noteworthy moments or time windows lying in decreasing lines in event evolution.

Timestamp	Rumour	Time window type
11:59 Apr 15	Two explosions near finish line	Noteworthy
12:24 Apr 15	The 1st explosion reported on Boylston Street	Decaying
13:28 Apr 15	Boston bombings are a “False Flag" operation	Noteworthy
22:24 Apr 15	An 8-year-old boy killed has been identified as Martin Richard	Noteworthy
19:49 Apr 15	The killed boy was waiting for his dad to finish his marathon.	Noteworthy
12:44 Apr 15	The third device has been found.	Noteworthy
12:42 Apr 15	Police tell people to stay away from the JFK library	Noteworthy
14:27 Apr 15	A fire broke out at the JFK library. Not an explosion.	Noteworthy
14:12 Apr 15	A 20-year-old Saudi Arabian man is in custody.	Noteworthy
09:03 Apr 16	Bombs are made from pressure cookers.	Noteworthy
09:23 Apr 16	Pressure cooker bombs were placed in black duffel bags.	Noteworthy

CONCLUSION AND FUTURE RESEARCH

In this paper, we have proposed a two-step framework to aid rumour detection during crises in real time. There have been several attempts to verify rumours in various domains in the community of rumour studies. However, rumours during crises are new, and therefore there is no *evidence* to debunk or verify claims when crises are unfolding. It is very challenging to develop an automatic system which is capable of verifying such rumours. Rumour detection during crises, however, can be automated and provide useful information for managers and the public. Therefore, our research aims at helping emergency responders and citizens detect emerging and developing rumours without examining an enormous number of messages. The first part of our framework detects *noteworthy moments* that draw the public’s attention during crises. We view noteworthy moments or key sub-events as outliers of interest to decision makers and other stakeholders. The performance of sub-event detection methods based on

thresholds is highly dependent on characteristics of data such as the total number of tweets and burstiness. To overcome this limitation, we incorporate several rules which take into account the absolute volume of messages and differences in the number of messages. Our rule-based sub-event detection system can be adaptive to abrupt and extreme changes in event evolution on social media. Our system can work in real time. This will enable decision makers to plan appropriate actions as early as possible. The second part extracts summaries that represent detected key moments. We employ an unsupervised graph-based text ranking algorithm called TextRank to assign scores to messages. We conducted experiments over large-scale and real-world crises datasets. We show the generalization and scalability of our method by using the datasets with different languages and characteristics such as bursty patterns and the total number of messages. The experimental results show that our method can perform the early detection of informative reports and rumours spreading during different types of crises in a real-time scenario. A common role of social media in crisis management is to improve situational awareness by analysing early reports of events. We have found that there exist several rumours during crises and their contents evolve over time. This behaviour of rumours has been extensively studied in the community of rumour studies. The application of different realms of rumour studies such as rumour tracking and stance classification can benefit emergency responders in real time. For example, decision makers will be able to distinguish rumours that are likely to be false from facts in the initial stages of rumour evolution. They can then take action to debunk and verify rumours in a timely manner. This can lead to the minimization of disaster-related losses. In conclusion, this paper aims to benefit emergency management by mining rumours evolving during crises. We have shown what rumours evolve during crises. Our experiments with real-world examples show that key rumours and informative reports can be detected from *noteworthy moments*. Our research can bridge the gap between the state-of-the-art work on rumours on social media and real-world needs for crisis management.

Future research will delve into how to fully automate rumour detection during crises. Our current system is semi-automatic. It produces summaries of detected noteworthy sub-events. However, these summaries can include rumours and non-rumours. Humans still need to judge whether each summary tweet is a rumour or non-rumour. We will further investigate characteristics of rumours during crises so that a system can distinguish rumours from non-rumours without a manual inspection.

ACKNOWLEDGEMENT

We thank Vitaveska Lanfranchi for helpful comments and discussions on an early draft of this paper. This project was partially funded by the European Commission as part of the Seta European Project (contract no. 688082), Horizon 2020 framework.

ABSTRACT

People use diverse sources of information, e.g., newspapers, TV, Internet news, social media, and face-to-face conversations, to make sense of crises. We apply uses and gratifications theory (UGT) and structural equation modeling to illustrate how using internet-based information sources since the political uprisings in Egypt influence perceptions of information satisfaction. Consistent with expectations we find that content and process gratifications constructs combine to explain information satisfaction, while social gratifications do not significantly influence satisfaction in the context of a crisis. This suggests that UGT is useful for evaluating the use of information technology in a context where information is limited in quantity and reliability.

Keywords

Uses and gratifications theory; information sources; Internet; social media; structural equation modeling

INTRODUCTION

The popular uprisings that brought down governments in Tunisia, Egypt, and Libya, along with protests in other countries, became known as the 'Arab spring'. Political uprisings such as these are crises both for citizens and governments. Uses and gratifications theory (UGT) describes how information consumers use media to meet their information needs. UGT has been widely applied over time and more recently to assess the Internet (Stafford, Stafford et al., 2004), social media (Ku, Chu et al., 2013), and political information (Kaye and Johnson, 2002; Kaye and Johnson, 2004). UGT describes both how (through use of the different communication media and information

technology) and why (to achieve some purpose or need, i.e., gratification) a consumer pays attention to an information source.

Jamal and Melkote (2008) suggest that social gratifications are likely less relevant in crises than in normal non-crisis situations. They propose that process gratifications and content gratifications will dominate perceptions in the crisis context. Using partial least squares based structural equation modeling (PLS-SEM) we show that the expectations for traditional UGT constructs of content and process gratifications hold in our context of political uprisings, explaining a substantial amount of variance in our information satisfaction construct ($R^2 = .30$) and having significant positive influences on information satisfaction. Social gratifications has an inverse effect on satisfaction, rather than the expected positive effect hypothesized from prior Internet and social media research.

In the following section we provide background on the situation and expand on how the theory is relevant in the contexts of political uprisings. This is followed by sections for our hypotheses and research model, research methodology, presentation of measurement model, and results for our two structural models, discussion of the implications and limitations of our study, and summary conclusions.

BACKGROUND AND THEORY

Massive protests occurred in Egypt between January 25 and February 11, 2011 leading to the end of the Presidency of Hosni Mubarak. The government restricted cell phone access in Cairo and Alexandria during demonstrations, and cut off Internet access completely for several days (Singel, 2011), clearly attempting to limit the peoples' abilities to obtain and share information by restricting access to information sources. This is similar to the network disruptions that happen when communications infrastructure is destroyed in natural disasters, however in political uprisings technical disruptions are often a tool that governments use to suppress and control information. The resulting lack of information increases peoples' concerns about the accuracy and reliability of information they receive, ultimately driving their perceptions of information satisfaction.

Information sources in Egypt

There were many television stations, newspapers, and other information sources throughout Egypt at the time of the uprising. Internet adoption in Egypt was 43% in 2012 based on 2013 data from the International Telecommunications Union World Internet statistics (http://www.Internetworldstats.com/stats5.htm). Cell phones were a primary form of communication with an 87% adoption rate. The Internet also had diffused throughout Egypt's 86.9 million population, with Facebook reaching 14.5% of the population in 2012.

Young people (15-29 years old) were a large portion of the Egyptian population (about 33%) in 2012. These young people also were the largest group of Internet users, and users of social media in Egypt at the time (Mourtada and Salem, 2011). Muhtaseb and Frey (2008) apply UGT to Arab Americans' use of the Internet, finding that information-seeking was the most important motive for using the Internet followed by convenience, entertainment, to pass-time, and interpersonal motives including social enhancement. This suggests that our sample is likely primed to using the Internet prior to the emergence of a crisis, implying that they will turn to this resource when in need of information.

While the uprising impacted all of society, it is likely that the dissemination of information through the Internet and social media likely occurred disproportionately through this group (Kavanaugh et al., 2013). They pass along this information through face-to-face and cell phone interactions with older family members and friends. Thus, it is important to understand their perceptions of the information they receive to inform how information sources can be used effectively in the context of crisis situations.

Uses and Gratifications Theory

Uses and gratifications theory has a long history in the study of mass communication (Katz and Lazarsfeld, 1955, Katz et al., 1973). UGT argues that people use media and technology to fulfill specific needs, such as seeking information. Gratifications have been associated with specific media selection and use including: information-seeking, social interaction, relaxation, entertainment, passing time, and companionship (Katz, 1987). Our study draws on research applying UGT to Internet use, social media, and political information.

Stafford et al. (2004) identify a SEM model consisting of three constructs including content gratifications, process

gratifications, and social gratifications of the Internet. Content and process gratifications are defined as: "Content gratifications concern the messages carried by the medium, and process gratifications concern actual use of the medium itself," (Stafford et al., 2004, pg. 267). They include social gratifications due to the nature of communication over the Internet. They then test the measurement model, finding a good fit of their indicators with these constructs in the context of Internet use and confirming the relevance of the social gratifications construct.

We adopt the content, process, and social gratifications construct naming of Stafford et al. (2004) because they find a good fit for these constructs for modeling uses of the Internet. Perceptions of information accuracy and reliability are consistent with their content gratifications construct, while web browsing and surfing are part of their process gratifications construct. Finally, their social gratifications construct includes interactions with friends and other people using technology. These three constructs are consistent with our interest in how information is obtained related to crisis contexts, in this case a political uprising.

UGT applied to the Internet, Social Media, Political information

Permalee and Perkins (2012) applied a qualitative methodology to show that participants used their social network to trigger information-seeking activities on the Internet. Searchers focused on obtaining additional details on topics seen in traditional broadcast media and perceptions of media credibility triggered searches representing ideological diversity and politically diverse opinion.

Ji and Fu (2013) investigate how UGT influences affinity for the Internet and types of Internet content. They find that the affinities for the types of content are correlated and relate positively to social gratifications. Lin (2002) studies gratifications of online services and traditional broadcast media using regression analysis to find that information seeking and the interaction experiences are significant, predicting 39% of the likelihood of media use.

In a content analysis Pentina and Tarafdar (2014) find that social media contribute to and reduce information overload. Social media reduce information overload by providing a filtering of information socially curated by the network based on what others think is relevant. Yet, social media contributes to information overload by increasing the number of messages that must be processed, which implies an association between social and process gratifications. Whiting and Williams (2013) also use UGT to perform a qualitative study of social media. They find an emphasis on entertainment rather than information sharing and information seeking gratifications. Smock et al. (2011) describe a uses and gratifications approach to understanding SNS features using Facebook. They find information sharing and keeping in touch with friends and family motivations drive use of different features and use of Facebook overall. Cheung et al. (2011) include UGT constructs along with social influence and social presence in a SEM model to predict intention to use social media (R^2=0.28). Finding process and social gratifications significant, as well as social presence. However, they do not find content gratifications to be significant.

In a study of the adoption of social media, Pai & Arnott (2013) describe browsing, receiving instant responses, uploading pictures, and customizing as the primary uses of social media. They find that the highest gratifications for users is a sense of belonging, followed by hedonism, self-esteem, and reciprocity. Lee and Ma (2012) study news sharing in social media using UGT. Finding several hypotheses relating information seeking, socializing, and status seeking, along with prior sharing experience, significant for the intention to share news.

UGT has been applied to political information and understanding political activities in many studies. Findings from these studies indicate all UGT constructs contribute to motivations for using (Kaye & Johnson, 2002) and trust (Kaye & Johnson, 2004) in political information. Neubaum et al. (2014) examine sharing of emotions to find that active participation is associated with positive experiences such as feeling better, while passive usage was perceived as less beneficial. Macafee (2013) investigates the use of traditional and social media for political engagement. They find that only frequency of Facebook use is significant for explaining engagement; while TV, Print, and Internet news were not significant. Chung, et al. (2012) compare traditional and technological factors for determining online news credibility. They find that traditional factors of trustworthiness and expertise are the only significant factors driving use of online news sites of established news sources, e.g., New York Times and USA Today. While technology factors, e.g., hypertextuality, are significant for search sites including Google and Yahoo.

In summary, many studies that apply UGT to the Internet, social media, and political news use constructs consistent with the content, process, and social gratifications constructs. Our study applies these constructs in a model to assess their influence on information satisfaction in a crisis context.

RESEARCH MODEL AND HYPOTHESES

We use the construct names identified by Stafford et al. (2004) because they also make sense in our crisis context. Most importantly the process gratifications construct is measured by similar indicators as constructs named information-seeking or entertainment in other studies. Information-seeking is consistent with what we believe occurs related to crises, entertainment is not. Conceptually, browsing the Internet as an entertaining activity, is replaced by browsing the Internet to understand what is happening related to the crisis.

We extend their model by adding the information satisfaction construct used in prior research (Bailey and Pearson 1983, McKinney, Yoon et al. 2002, Wixom and Todd 2005) and hypotheses that relate each type of gratifications to this dependent variable. We define information satisfaction as a 2nd order formative construct consisting of dimensions of information availability and information influence dimensions. Table 1 presents our construct definitions (items for constructs are available upon request).

Information is always constrained in crisis. Sometimes these constraints are due to widespread damage to infrastructure, while in political situations governments may deliberately restrict or disable the Internet and other communications networks. Information availability refers to being able to access the information wanted and needed; higher perceptions of availability are indications of higher satisfaction with the information received. Information influence is our second dimension of information satisfaction. We expect that when people believe that their information was important for influencing their thinking about the crisis, they will also be more satisfied with that information.

Table 1: Construct Definitions: Content, Process, and Social Gratifications, and Information Satisfaction

Panel A: Uses and Gratifications Constructs	
Content	The degree to which the information/messages the participant obtained since the crises was accurate and reliable.
Process Gratifications deriving from the use of the Internet	
Internet Frequency	The frequency with which participants use the Internet for getting information about the crisis. Including how many hours per day, frequency of using video, social media, and Internet news sites.
Information Activities	The number of activities used to get information on the crises. Including the number of actions performed with cell phones, the social media features used, and types of Internet sites visited.
Social Gratifications deriving from the Internet as a social environment	
Sharing Internet	The degree to which the participant shares (receives) information obtained from the Internet with (from) their family and friends.
Sharing Frequency	The frequency with which the participant shares information obtained from all sources with their family and friends.
Panel B: Information Satisfaction Constructs	
Information Influence	The degree the information they obtained was important for influencing their thinking about political events.
Information Availability	The degree to which the participant was able to obtain all the information they needed and wanted.

Content Gratifications

Our first UGT hypothesis is that higher levels of information content gratifications lead to higher levels of information satisfaction. Information related to a crisis is hard to find and interpreting the information appropriately is difficult. Content gratifications in a non-crisis/normal situation is related to the areas identified by Stafford et al. (2004) including, education, learning, research, and knowledge. In crises, the focus is on information related to the issues in the situation, be it natural or man-made, and the other dimensions become less relevant. For example, using

the Internet for education and learning not related to the crisis is less important for those in such situations than information related to crisis response and management. A primary characteristic of the actual message is the perception that the information contained within it is accurate and reliable. When the content of the information is felt to be more accurate and reliable, information satisfaction should be higher, as should perceptions of information availability and the influence of the information. Thus, we propose Hypothesis H1:

H1: Content gratifications has a positive influence on information satisfaction.

Process Gratifications

We define Process Gratifications as a 2nd order formative construct consisting of dimensions of information seeking activities and the frequency of engaging in these activities. Process Gratifications in non-crisis situations are related to activities of using the Internet including searching, surfing, and using web sites (Stafford et al., 2004). In crises the process of obtaining information related to the issues in the situation is often complicated by compromises in network capabilities and other disruptions. Gratifications derived from the process are related to pursuing various activities frequently enough to feel the process is sufficient for obtaining the available information. That is, participants will engage in additional processes or perform more effective processes more frequently in crises, not solely for the experience of the process, but to have the feeling that the process provided the information that can be obtained. When people in the situation feel better about their processes for obtaining information and having the information that is available, their information satisfaction should be higher.

We also expect that more frequent exposure to information, even the same or erroneous information, will influence perception that the information is important and that it should influence thinking about the crisis. In addition, when the information obtained from frequent repetitive access of the Internet related to a crisis doesn't change or changes immaterially, perceptions that participants have the information available should emerge.

So, both the information activities and Internet frequency dimensions of process gratifications should influence the dimensions of information satisfaction. Thus, we propose Hypothesis H2:

H2: Process gratifications has a positive influence on information satisfaction.

Social Gratifications

Our third UGT hypothesis is that higher levels of social gratifications will lead to higher levels of information satisfaction. Social gratifications is defined as using the Internet to share information with others consisting of two dimensions. Sharing information from the Internet is an important aspect of our research due to the demographics of Egypt, with the younger people more likely having access to the Internet. We also expect that receiving and sending information from the Internet to and from family and friends increases connectedness and perceptions of information satisfaction. Higher levels of sharing should increase perceptions of having the information wanted, as sharing informs discussions of the information which should lead to assessment of information that is missing or needed. Further, we expect sharing to initiate interactions vetting the shared information, which should increase perceptions of the influence of that information.

Similarly, sharing information more frequently increases perceptions of the influence of that information and perceptions that you have the information that is available. More frequent interactions that include evaluations of the shared information should increase perceptions the information is important. Despite suggestions that social gratifications may not be as relevant in the context of crises, we follow the preponderance of UGT research on the Internet and social media use that indicates social gratifications likely influence information satisfaction in a positive manner. Thus, we propose Hypothesis H3:

H3: Social Gratifications has a positive influence on information satisfaction.

Social Gratifications influence on Process Gratification

Further we expect that obtaining Social Gratifications likely impacts Process Gratification. This is due to the need to have more and different processes for socially oriented information sharing activities beyond the normal process for information seeking. One result of the Arab spring was the perception that social media was influential in the process of the uprisings and their aftermath. The shut-down of the Internet during the uprising implies authorities were attempting to control information and limit sharing. This leads to an exploratory hypotheses relevant to UGT.

The hypothesis is that higher levels of social gratifications will lead to higher levels of process gratification. Sharing frequency involves social media, video sharing, and other activities that involve the Internet, clearly implying a relationship with Internet frequency. That is, more sharing activities will mean more online activity that could lead to other Internet sites. Similarly, more frequent sharing likely increases the number of Internet activities engaged.

Sharing information from the Internet also likely influences Internet frequency, since, to be shared, information must first be obtained from the Internet. A desire to share information from the Internet also may lead to more Internet activities. Thus, we propose Hypothesis H4:

H4: Social Gratifications has a positive influence on process gratification.

These four hypotheses are derived from the results of UGT studies of the Internet, social media, and political information discussed above. Figure 1 presents our research model.

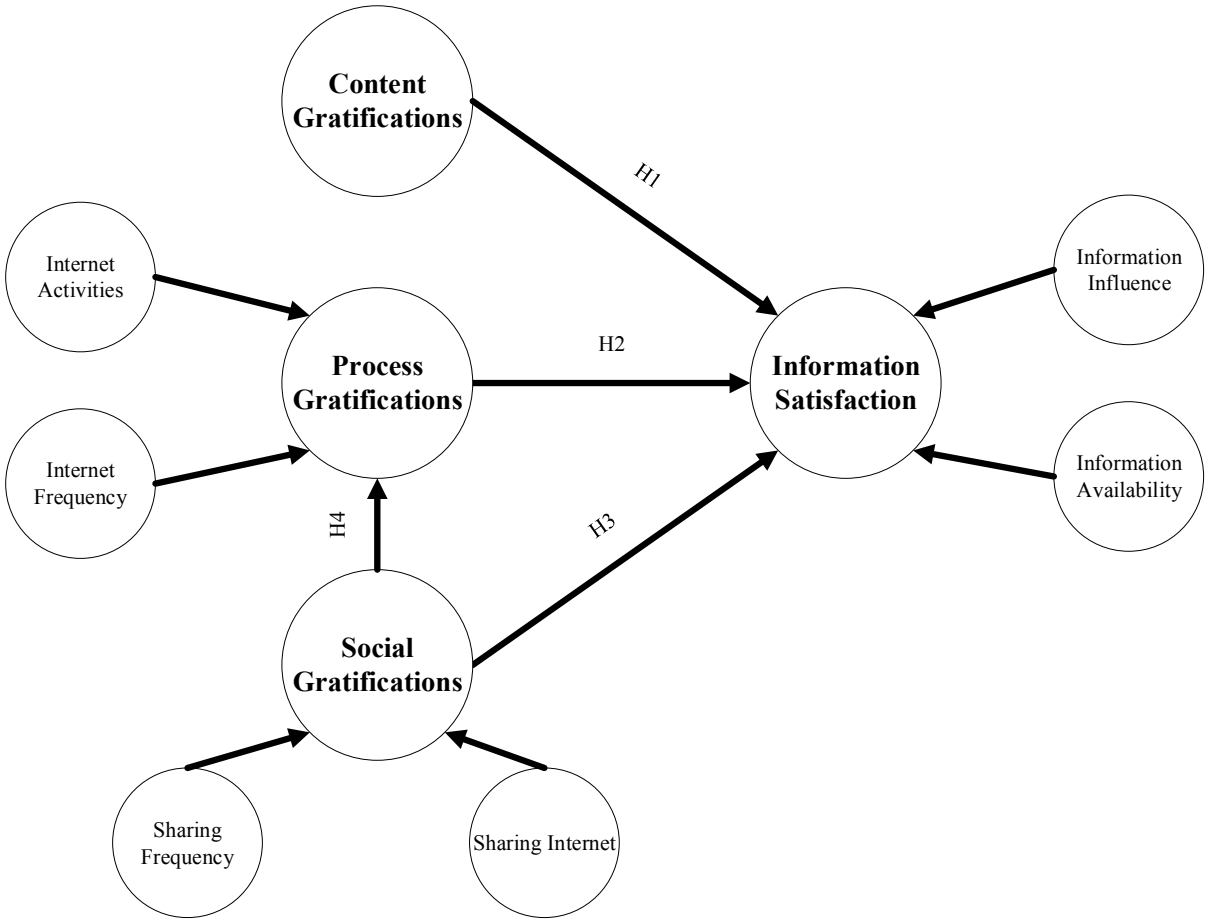

Figure 1: Information Uses and Gratifications in Crisis Research model.

METHOD

We adapted the survey from items used on previous studies applying UGT to investigate the use of the Internet and social media in particular (Kraut et al., 2002). Then we sent via email an invitation to participate in the survey for extra course credit or equivalent assignments to 500 students at a large university in Egypt. Students completed our online survey, which was transcribed into Arabic.

Our procedures for the web-based survey were consistent with the guidelines recommended by Punter, et al. (Punter, Ciolkowski, Freimut, & John, 2003) and (Singer & Vinson, 2002) for online software engineering surveys. Web-based surveys are less costly, more convenient, and provide more control than postal surveys (Couper, 2000). Moreover, web-based surveys have been shown to be similar to postal surveys in terms of the quality of data gathered (Bachmann, Elfrink, & Vanazza, 1996; Coderre, Mathieu, & St-Laurent, 2005), and the number of items answered (Bachmann et al., 1996; Coderre et al., 2005); also they are useful for reducing social desirability bias (Whitley, 2002).

Consistent with the recommendations of Bryant et al. (2004), we included controls to account for internal validity threats such as increased dropout rates and multiple submissions from the same participant. We encouraged participation in the study by describing the intent of the survey to the participants (Lazar & Preece, 1999). To control for the internal validity threat of multiple submissions from the same participant, participants were asked to provide their e-mail addresses; there were no duplicates received. To reduce item non-response, participants had to answer all questions in one section of the survey before proceeding to the next section.

RESULTS

The elections for the unicameral legislature held from November 2011-January 2012 were intended to resolve the crisis. However, the results of these elections were ruled to be illegitimate on June 14th 2012 by the Egyptian Supreme Court. We collected data in April and May 2012, between the election and the contentious ruling by the court. Thus, the resolution of the uprising had not yet occurred during the time our data was collected, even though it was 14 months after the initial uprising.

The survey was sent to 500 potential participants; a total of 204 participants attempted the survey and 170 students completed it, for a 34% response rate. There were more female (56%) than male respondents; most (89%) were single and lived in the city near the university or in nearby towns. Most (73%) had been using the Internet for 7 or more years, with 19% using the Internet for more than 10 years. Most (85%) were 19-21 years old and eligible to vote in Egypt.

We use partial least squares structural equation modeling (PLS-SEM) to test our research model. PLS-SEM is appropriate for our context because it is recommended for exploratory research, such as our unique application of UGT in crisis situations (Gopal, Bostrom, & Chin, 1992). The PLS-SEM measurement and structural models were assessed using smart PLS version 2.0 beta (Ringle, Wende, & Will, 2005).

Measurement Properties of Constructs

We first evaluated the measurement reliability and validity of the 1st order reflective constructs in our model. We assessed the scale reliabilities, along with convergent and discriminant validity of these constructs. Table 3 lists the descriptive statistics and scale measurement properties for these constructs. Scale reliability was assessed via composite reliability and Cronbach's alpha (Fornell & Larcker, 1981). As shown in Table 2, composite reliabilities are all well above the recommended 0.70 level, and Cronbach's alphas for the process and social gratifications constructs exceed the traditional 0.70 cutoff, while content and information influence exceed recommendations of .60 for exploratory research (Agarwal & Karahanna, 2000; Nunnally & Bernstein, 1994; Staples & Seddon, 2004). Although Information Availability at .58 is below the desired level, we maintain it due to high composite reliability (Hair et al., 2013).

Table 2: Construct means, standard deviations, and measures of internal consistency

Construct	# Items	Mean	Std. Dev.	AVE	Composite Reliability	Cron.'s Alpha[a]
Content Gratifications	3	2.88	0.58	0.58	0.85	0.76
Internet Frequency	4	6.00	2.96	0.65	0.88	0.81
Information Activities	3	4.19	1.45	0.62	0.83	0.70
Sharing Internet	2	2.88	1.58	0.95	0.97	0.94
Sharing Frequency	6	4.74	1.88	0.53	0.87	0.82
Information Influence	3	2.16	0.59	0.61	0.82	0.68
Information Availability	2	2.38	0.52	0.70	0.82	0.58

[a] Hair et al. (2014) and Ringle et al. (2005) indicate that Cronbach's alpha is not necessary for component based SEM implemented in PLS.

To determine convergent validity, all item loadings (outer loadings) should be greater than 0.70 (Agarwal & Karahanna, 2000) (Bassellier & Benbasat, 2004). We evaluated the cross loadings factor matrix from smart PLS (Ringle et al., 2005). Most of the items have loadings above the recommended 0.70 (Agarwal & Karahanna, 2000) (Bassellier & Benbasat, 2004). Seven items are below 0.70, yet above 0.60. Only one item, "the number of hours on the Internet per day (0.467), had a loading below 0.60 (text for indicators available from authors upon request). We retained this item due to the high scale reliability for the frequency of Internet use construct and content validity of the item. All items loaded more highly on their hypothesized construct when compared to any other construct. The t-statistics for all other item loadings are greater than 2.58, $p < .01$ (Gefen et al., 2000).

A further test of convergent validity is to determine if constructs have an average variance extracted (AVE) greater than or equal to 0.50, indicating at least 50% of the indicator variables' variance is determined by the latent variable (Chin, 1998). Our 1st order reflective constructs meet this requirement, as shown in Table 2.

We also used an AVE test to establish both discriminant and convergent validity of these constructs (Fornell & Larcker, 1981; Netemeyer, Johnston, & Burton, 1990). The diagonal elements of the matrix in Table 3 contain the square root of the AVE estimates for each construct; the off-diagonal elements are the correlations between constructs. Validity is achieved if the AVE estimates for both constructs are greater than the correlation of the two constructs. The diagonal elements are all larger than their corresponding correlation coefficients, indicating that these constructs all demonstrate convergent validity and discriminant validity (D. Gefen, D. Straub, & M. Boudreau, 2000).

Table 3: Construct correlations and square-root of AVE values on diagonal.

	Info Activities	Content	Internet Frequency	Info Influence	Sharing Internet	Info. Availability	Sharing Freq.
Info Activities	**0.790**						
Content	0.134	**0.837**					
Internet Freq.	0.723	0.119	**0.809**				
Info Influence	0.302	0.217	0.245	**0.779**			
Sharing Internet	0.313	0.075	0.455	-0.124	**0.973**		
Info Availability	0.314	0.418	0.281	0.199	0.196	**0.838**	
Sharing Freq	0.449	0.179	0.368	0.368	0.013	0.059	**0.727**

We conducted a power analysis to ensure our ability to find the hypothesized effects if present. Hair et al. (2013) recommend Cohen's (Cohen, 1988) 80% likelihood for detecting effects approach for determining the sample size needed when using PLS-SEM, while others recommend at least 10 times the largest number of paths affecting a dependent construct in the model (Chin, 1998). Our sample, comprised of 170 observations, is consistent with detecting R^2 values of 0.10 at a 0.05 level of significance for a model with a maximum of 3 paths influencing any one dependent construct (Hair et al., 2013, p. 21), thereby ensuring an adequate level of power.

Results for Structural Models

The second step in PLS-SEM analysis determines which of the hypothesized relationships in the model are significant, and the relative strengths of the significant influences. We first evaluate the highly parsimonious UGT model developed above, then decompose the formative endogenous satisfaction construct as recommended by Cadogan and Lee (Cadogan & Lee, 2013).

We evaluated the structural models for effects on information satisfaction using coefficient of determination (R^2) values and in terms of the significance and relative values of the path coefficients (Kishore & McLean, 2007) (D. Gefen, D. Straub, & M.-C. Boudreau, 2000). The following subsections present the results for the initial and decomposed structural models.

Initial Structural Model

Figure 2 shows the R^2 values, path coefficients, and their significance levels calculated by SmartPLS 2.0 beta (Ringle et al., 2005) for the initial structural model that tests the fundamental propositions of UGT. The model explains 30% of the variance in information satisfaction, indicating a weak yet significant level of explanation (Hair et al., 2013). In addition, the social gratifications construct significantly influences the process gratifications construct, explaining 33% of its variance.

The path coefficient for the relationship showing the effect of the content construct on information satisfaction is significant (0.392, $t = 6.056$, $p < 0.01$), as shown in Figure 2, supporting H1. Hypothesis H2 relating influence of process gratifications on information satisfaction also is supported (0.404, $t = 4.806$, $p < 0.01$). The influence of social gratifications on information satisfaction was marginally significant (-0.109, $t = 1.296$, $p < 0.10$), however the sign of the coefficient is negative rather than positive as hypothesized, thus H3 is not supported.

We investigated whether process gratifications is mediating the influence of social gratifications as described by Hair et al. (2013), pg. 224. After removing process gratifications from the model the path coefficient from social gratifications to information satisfaction is not significant, thus process gratifications is not mediating social gratification. Thus, hypothesis H4 is supported as social gratifications does have a substantive influence on process gratifications (0.578, $t = 12.309$, $p < 0.01$).

Support for three of four hypotheses and explaining 30% of the variance in information satisfaction indicates that UGT is applicable for understanding information use in crises, such as the uprisings and subsequent events in Egypt. In addition, the social gratifications influence on information satisfaction hypothesis that is not supported, was previously suggested to not be relevant in the crisis context (Jamal & Melkote, 2008).

This result suggests one way the use of information in a crisis context is different than in non-crisis contexts where UGT was developed.

In the past our analyses may have ended with this highly parsimonious and UGT congruent result. However, recent measurement research (Cadogan & Lee, 2013; Rigdon, 2014) suggests that dependent variables consisting of higher order endogenous formative constructs can provide potentially misleading results. Since our primary dependent endogenous variable information satisfaction is formative, we decided to evaluate a second model where it is replaced with its 1st order dimensions of information availability and information influence.

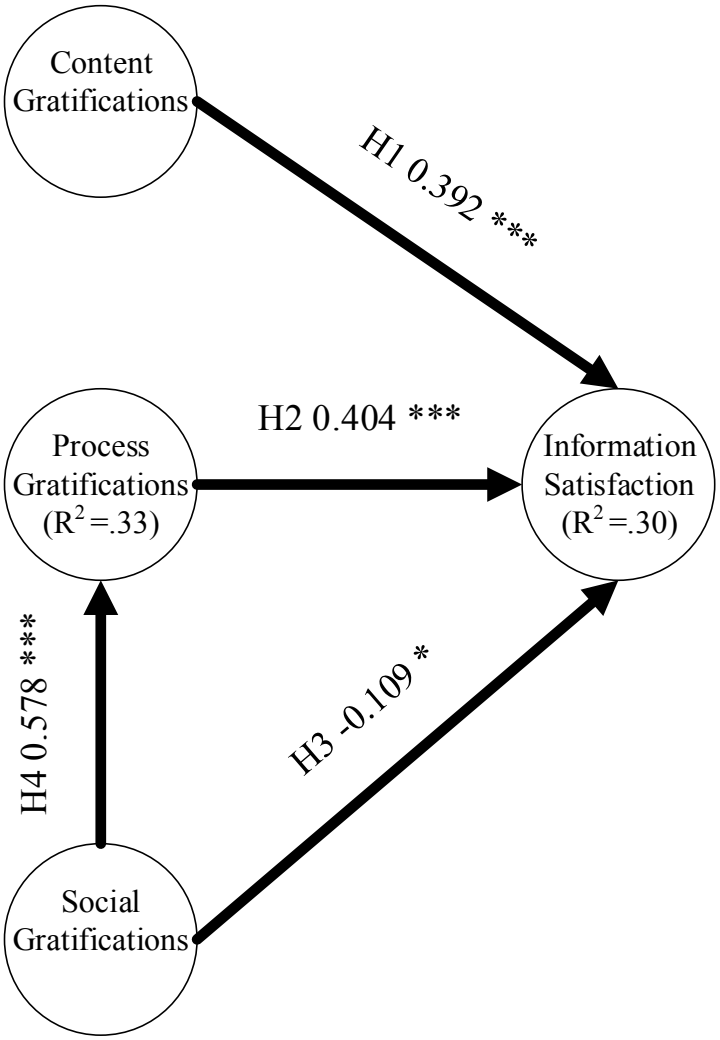

Figure 2: Information Uses and Gratifications in Crisis structural model

Dimensions of Information Satisfaction Structural Model

Evaluating the dimensions of Information Satisfaction means replacing one formative construct with two reflective constructs of information availability and information influence. Each of these constructs has the same paths predicting them as did the higher order information satisfaction construct. The individual dimensions are not as well explained in this model, with information availability having $R^2 = 0.24$ and influence of information having $R^2 = 0.12$; recall that information satisfaction in the initial model has $R^2 = 0.30$. The social gratifications construct also significantly influences the process gratifications construct in this model, explaining 32% of its variance. Figure 3 shows the revised model.

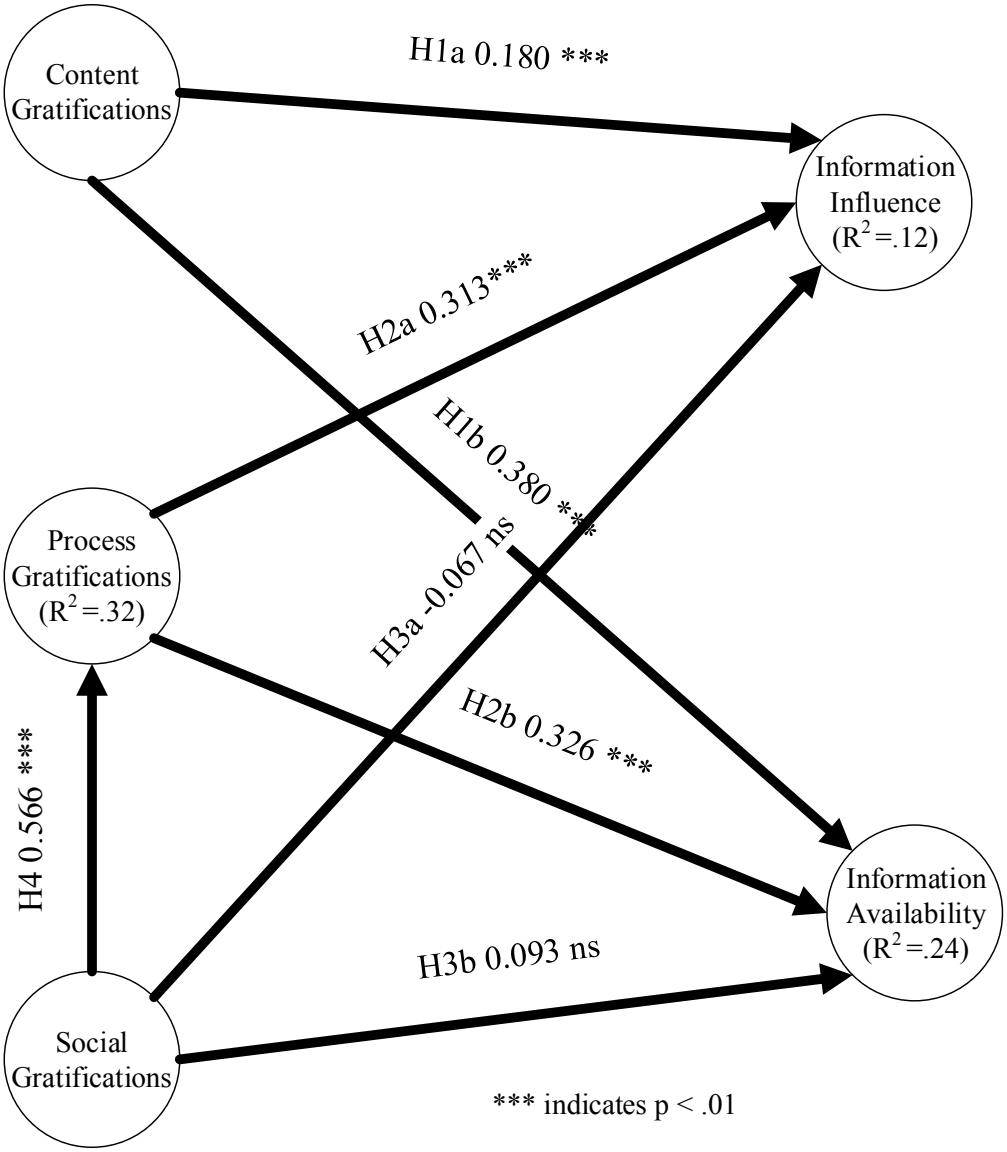

Figure 3: Structural model of dimensions of information satisfaction.

The path coefficients in the decomposed model are consistent with those in the initial model. Content gratifications is a significant contributor to both dimensions of information satisfaction, impacting information influence, i.e., H1a, (0.180, t = 2.673, p < 0.01) and information availability, i.e., H1b, (0.380, t = 5.421, p < 0.01). Process gratifications significantly impacts information influence, i.e., H2a (0.313, t = 4.112, p < .01) and information availability, i.e., H2b, (0.326, t = 4.167, p < 0.01), with nearly equivalent coefficients. Hypothesis H4, that social gratifications influence process gratifications is the same as in the prior model and significant (0.566, t = 10.574, p < 0.01). Thus, hypotheses H1, H2, and H4 are again supported.

Social Gratifications do not significantly impact information influence, i.e., H3a, (-0.067, t=0.416, p ns) or information availability, i.e., H3b (-0.093, t=1.062, p ns), thus not supporting these sub-hypotheses. This suggests again that the crisis context somehow limits the potential for Social Gratifications to lead to Information Satisfaction. These results confirm that the UGT model of information satisfaction in crisis situations is supported overall at two levels of abstraction.

DISCUSSION

In summary, our results suggest several observations. First, higher perceptions of the accuracy and reliability of the information, i.e., content gratifications, are associated with perceptions of higher information satisfaction. Further, content gratifications significantly effect the information availability and the influence of the information dimensions of information satisfaction. Content gratifications has the largest effect of any construct on information availability, and a stronger influence on information availability than on the influence of the information. Indicating perceptions of information availability will increase if the accuracy and reliability of the information obtained can be increased. Specifically recognizing the variability in the accuracy and reliability of information and explicitly considering how to evaluate it may facilitate users' perceptions of knowing when sufficient information is available. Accuracy and reliability also affect the influence of the information, such that more accurate and reliable information will be more important for influencing thinking. We expect the source, e.g., government or independent TV stations, of the information will be one aspect of the information that will be used to judge accuracy and reliability.

Second, process gratifications is predictive of information satisfaction, positively impacting information availability and how influential the information is perceived and the largest impact of any construct on the influence of information. Process gratifications consists two dimensions including the number of information activities engaged and the frequency of those activities. We examined another model (figure not included) where the process gratifications construct was decomposed into its dimensions, finding similar R^2 values for information availability (R^2=0.24) and the influence of information(R^2=0.13). The dimension of internet activities has path coefficients of (0.212, t = 2.473, p < .01) for information availability and (0.281, t = 2.925, p < .01) for the influence of information, while the frequency of internet activities has path coefficients of (0.145, t = 1.686, p < .10), for information availability and (0.061, t = 0.510, p ns), for the influence of information. This suggests that users pay relatively more attention to the number of varying search activities they pursue, rather than the frequency of searching. By increasing the variety of search activities people cast a wider net and should increase perceptions of both information availability and the influence of the information. Participating in different activities has the potential for confirming or contradicting information originating from multiple sources. Finding the same or similar information from multiple activities, i.e., confirming, may indicate that the information available has been obtained, while finding differing information, i.e., contradicting, may imply that more information is available or needed. Similar effects may apply to the influence of the information, with contradicting information suggesting lower influence and confirming information suggesting higher influence. The frequency of activities does not significantly affect the influence of information, perhaps this is due to finding the same information from the same activities, i.e., confirming, is not as satisfying as confirming across activities. In addition, the more frequently the same information is found reduces the amount of different information obtained, i.e., the potential for finding contradicting information is lower. Overall it seems doing the same things more frequently may not provide much marginal satisfaction.

Third, social gratifications were speculated to not be influential in a crisis context (Jamal and Melkote, 2008); our results support this previous speculation. Our finding a negative path coefficient for hypothesis H3 implies that more frequent sharing and more sharing with friends and family of information obtained through the Internet reduces satisfaction with that information. This seems a fundamental disconnect with the widespread use of the Internet for social purposes and is inconsistent with prior UGT research on why people use the Internet and the social gratifications they receive. To understand this in more detail, we examined another model (figure not included) where the social gratifications construct was decomposed into its dimensions, finding a similar R^2 value for information availability (R^2=0.24) and a higher value for influence of information (R^2=0.21). The dimension of sharing activities has path coefficients of (0.028, t = 0.404, p ns) for information availability and (-0.272, t = 4.279, p < .01) for the influence of information, while the frequency of sharing has path coefficients of (-0.160, t = 2.420, p < .01), for information availability and (0.148, t = 1.660, p < .10), for the influence of information. Thus, the subdimensions of social gratifications have inverse effects on different subdimensions of information satisfaction that in the higher order model combine for an overall inverse impact on satisfaction. Higher sharing activity information with friends and family drives lower the influence of information, while the more frequent activities reduces perceptions of information availability.

Our results are consistent with many prior UGT studies related to using the Internet (Ku et al., 2013; Lee & Ma, 2012; Parmelee & Perkins, 2012; Stafford et al., 2004), social media (Ku et al., 2013; Lee & Ma, 2012; Lenhart & Madden, 2007; Macafee, 2013), and political information (Barbara K Kaye & Johnson, 2002; Barbara K. Kaye &

Johnson, 2004; Lariscy et al., 2011; Parmelee & Perkins, 2012). Specifically, we support the theory by finding the constructs valid and reliable in data from another context. Further, we confirm primary hypotheses relating gratifications to information satisfaction, while uncovering a situation where social gratifications are not as influential as expected.

The limitations of our study involve our opportunity sample and our web-based survey methodology. We have attempted to control for the vulnerabilities of the web-based survey as described in the methods section and believe that many of those concerns have been controlled. Our sample makes generalizing beyond young people and college students difficult, however they experienced the uprising and are likely representative of the users of the Internet and social media in Egypt. Further, we feel it is important to understand the perceptions of the young adults given their large proportion of the population in Egypt and many of the other countries involved in the Arab Spring. Our data were collected well after the original uprising, yet it was during the time when the 1st cameral election was invalidated by the supreme court. Which we believe is part of the extended crisis that resulted from the uprising.

CONCLUSION

Uses and gratifications theory can be applied to the use of information sources related to crises. Individuals searching for information related to crisis should 1) identify the information they want and how they'll know it is accurate; and 2) maximize the number of different activities for information-seeking rather than focusing on frequency of a few activities; and 3) beware of potential for information sharing activities to reduce their information satisfaction. Why the impact of social gratifications on information satisfaction hypothesized by UGT seems to be suppressed in the context of this crisis is a topic for future research.

Appendix 1: Indicators of model constructs.

Code	Content Gratifications Items
CON1[a]	Overall, information I was able to get was accurate since the uprising (March 2011 - March 2012). (six point scale strongly disagree to strongly agree)
CON2[a]	The news and information about events I received was reliable since the uprising (March 2011 - March 2012).
CON3[a]	The information I was able to get was not reliable since the uprising (March 2011 - March 2012). (reversed)
	Process Gratification: Internet Activities
PGIA1	What Internet sites did you visit? (check all that apply, ***number checked***) (Facebook pages on the uprising (e.g., we are all Khaled Saed), Twitter - a person you follow, Twitter - an organization you follow, Newspaper websites (e.g., Al Masry Alyoum, Al Youm Al Sabea, etc.), Television News channel websites, News websites (e.g., Masarawy), Other)
PGIA2	Since the uprising (March 2011 - March 2012), which of the following features did you use on Social Networking Sites? (check all that apply, ***number checked***) (Post comments, Post pictures or videos, Physically show others your site, Join groups, Read others' posts, Look at the site information of others, Update my status, Other)
PGIA3	Since the uprising (March 2011 - March 2012), which of the following activities did you do on a cell phone? (check all that apply, ***number checked***) (Make or receive phone calls, Send or receive a text message, Take a picture, Take a video, Send a picture or video to another person, Send a picture or video to an organization, Look at a picture or video from another person, Browse the Internet, Other)
	Process Gratification: Internet Frequency
PGIF1	On a typical day since the uprising (Mar.2011 - Mar. 2012), about how many hours a day were you using the Internet? Include time spent on instant messaging, email, browsing the Internet, and on social networking sites, for work and personal reasons. (***number of hours***)
PGIF2[b]	How often since the uprising (March 2011 - March 2012) were you looking at video or photo sharing websites, e.g., YouTube or Flickr?
PGIF3[b]	How often since the uprising (March 2011 - March 2012) were you using Social Networking sites, e.g., Facebook?
PGIF4[b]	How often since the uprising (March 2011 - March 2012) were you using the Internet?

[a] Measured on: strongly disagree to strongly agree.

[b] Measured on a scale of: almost never, < once per month, about once per month, several times per month, about once per week, serveral times per week, about once per day, several times per day.

Social Gratification	
Code	**Social Gratification: Sharing Activities**
SGSA1[a]	I shared information that I obtained from the Internet (including Facebook, Youtube, Twitter, etc.) with other family members and friends?
SGSA2[a]	Other family members and friends shared information with me that they obtained from the Internet (including Facebook, YouTube or Twitter)?
	Social Gratification: Sharing Frequency
SGSF1[b]	How often did you use email to communicate (share information) with any of your friends and family?
SGSF2[b]	How often did you use a cell phone text message to communicate (share information) with any of your friends and family?
SGSF3[b]	How often did you use a cell phone voice calls to communicate (share information) with any of your friends and family?
SGSF4[b]	How often did you use instant messaging to communicate (share information) with any of your friends and family?
SGSF5[b]	How often did you use a social networking site to communicate (share information) with any of your friends and family?
SGSF6[b]	How often did you use an Internet communication service, e.g., Skype, to communicate (share information) with any of your friends and family?
Information Satisfaction	
	Information Satisfaction: Influence
ISII1[c]	How important has been the information you received from social networking sites, e.g., Facebook, as an influence on your thinking about these events.
ISII2[c]	How important has been the information you received from Internet video sharing sites, e.g., Youtube, as an influence on your thinking about these events.
ISII3[c]	How important has been the information you received from Internet news sites, e.g., Newspaper websites, TV channel websites, Facebook news pages, or News websites (Masarwy), as an influence on your thinking about these events.
	Information Satisfaction: Information Availability
ISIA1[a]	I was not able to get the information I needed since the uprising (March 2011 - March 2012). (reversed)
ISIA2[a]	I was able to get the information I wanted since the uprising (March 2011 - March 2012).

[c] Measured on a four point scale: not at all important, not too important, somewhat important, very important.

TREC Incident Streams: Finding Actionable Information on Social Media

ABSTRACT

The Text Retrieval Conference (TREC) Incident Streams track is a new initiative that aims to mature social media-based emergency response technology. This initiative advances the state of the art in this area through an evaluation challenge, which attracts researchers and developers from across the globe. The 2018 edition of the track provides a standardized evaluation methodology, an ontology of emergency-relevant social media information types, proposes a scale for information criticality, and releases a dataset containing fifteen test events and approximately 20,000 labeled tweets. Analysis of this dataset reveals a significant amount of actionable information on social media during emergencies (> 10%). While this data is valuable for emergency response efforts, analysis of the 39 state-of-the-art systems demonstrate a performance gap in identifying this data. We therefore find the current state-of-the-art is insufficient for emergency responders' requirements, particularly for rare actionable information for which there is little prior training data available.

Keywords

Emergency Management, Crisis Informatics, Real-time, Twitter, Categorization

INTRODUCTION

Mass adoption of mobile devices paired with wide-spread use of social media platforms has created new ways for the public to contact response services (Castillo 2016). Research has shown that 69% of people expect responders to answer calls for help made from these additional channels (O'Dell 2011). In response, emergency and civil protection services are increasingly looking for ways to monitor these channels, answer questions, provide advice, respond to aid requests, and report other useful information to the Incident Commander (FEMA 2013). Monitoring these social media channels is a nontrivial task, however, given the volume of information posted on these platforms and the need to categorise, cross-reference and verify the information contained therein (Castillo 2016).

The combined issues of data volume and public expectation demonstrate a clear need for computer-supported tools to assist response officers. To this end, researchers have invested significant effort into models for categorizing social media content, such as for finding affected people (Imran, Elbassuoni, et al. 2013), analysing infrastructure damage (Truelove et al. 2015) or identifying eyewitness accounts (Olteanu, Castillo, et al. 2014; Diakopoulos et al. 2012). Additionally, a number of platforms such as AIDR (Imran, Castillo, et al. 2014), CrisisTracker (Rogstadius et al. 2013), Twitcident (Abel et al. 2012) and EPIC Analyse (Barrenechea et al. 2015) have been developed.

These technologies have had limited impact on emergency management practice, primarily due to questions of data quality (Hiltz et al. 2014), insufficient trained staff (Plotnick et al. 2015), fear of commitment to social media

*corresponding author

§https://www.nist.gov/ and https://www.nist.gov/people/ian-soboroff

as a primary communication channel (Tapia et al. 2013), and incompatibility with organizational policy (Reuter, Heger, et al. 2013). Indeed, a recent study of ISCRAM papers concluded this research has had "a relatively small contribution to actual technology and industry" (Reuter, Backfried, et al. 2018).

While questions of training, commitment, and policy are organizational in nature, we argue the research community can solve *data quality* issues through: 1) standardizing social media analytics tasks; 2) standardizing datasets used to evaluate these tasks; and 3) focusing research efforts on advancing technical readiness and deployability. In particular, by defining a small number of standard social media analytic tasks that are well aligned with the needs of emergency response officers, it becomes feasible to construct datasets with sufficient size and robustness to confidently quantify tool accuracy (and hence resultant data quality). Then, by bringing together international researchers to work on those tasks and datasets, we can incrementally raise the quality of our solutions to a level where potential end users will be willing to use those solutions.

In this paper, we describe the new Incident Streams (TREC-IS) initiative, aimed at achieving this standardization. This initiative is part of the Text REtrieval Conference (TREC)[1] and sponsored by the Public Safety Communications Research program at the US National Institute of Standards and Technology (NIST, US). TREC-IS aims to develop test collections and evaluation methodologies for automatic and semi-automatic filtering approaches that identify and categorize information and aid-requests made on social media during crises. The end goals are: to advance the technology readiness level (TRL) of current social media crisis monitoring solutions; better support social media monitoring by emergency response officers and other stakeholders; and bring together researchers from across the globe to work on this problem by providing an annual evaluation challenge in which they can participate.

This paper's contributions include:

1. Providing the primary overview for the 2018 edition of the track, detailing track design and motivating why core design decisions were made.
2. Providing an analysis of the distribution of information posted on social media during emergency situations, contrasting general information types against actionable information based on labelling efforts undertaken during the track.
3. Giving a high-level examination of systems that participated in the 2018 edition, highlighting state-of-the-art performance for this task and what the challenges are moving forward.

RELATED DATA CHALLENGES AND INITIATIVES

TREC-IS builds upon expertise from previous evaluation initiatives and data challenges and is part of the long-running TREC conference. TREC is a combined conference and evaluation campaign that encourages research into information retrieval technologies on large test collections. Sponsored by NIST, TREC has run annually for over 25 years and consists of a set tracks, where a track is an area of focus in which particular retrieval tasks are defined. Tracks act as incubators for new research areas, in which the first run of a track often concretizes the problem, and a track creates the necessary infrastructure (test collections, evaluation methodology, etc.) to support research on its task. The tracks also demonstrate the robustness of core retrieval technology in that the same techniques are frequently appropriate for a variety of tasks. Finally, tracks make TREC attractive to a broader community by providing tasks that match the research interests of more groups. TREC has been highly influential in the information retrieval domain, resulting in foundational research into search engines (Robertson et al. 1995) and information extraction from social media (Lin, Roegiest, et al. 2016). TREC-IS is a new TREC track[2] started in 2018 and is designed to unite academia and industry around research into automatically processing social media streams during emergency situations and categorizing information and aid requests made on social media for emergency service operators.

TREC-IS also builds on lessons learned from the Exploitation of Social Media for Emergency Relief and Preparedness (SMERP) workshop (Ghosh et al. 2017), which itself was inspired by the TREC Microblog track (Lin, Efron, et al. 2014). The 2017 SMERP workshop examined two challenges: 1) text retrieval for disaster-related queries on Twitter, 2) text summarization of tweets during a disaster event. For the text retrieval task, the challenge defined four information needs: 'what resources are available'; 'what resources are required'; 'what infrastructure damage, restoration and casualties are reported'; and 'what are the rescue activities of various NGOs / government organizations'. We integrated two main lessons from that data challenge: First, the information needs defined by

[1] https://trec.nist.gov/
[2] http://trecis.org

the SMERP challenge was quite broad, making it difficult to map an information need to an activity that might be performed by a response officer. We therefore developed our own information ontology, which we present in more detail later. Second, due to the small number of information needs and only the single event examined during the SMERP challenge, participating systems' generalizability was unclear. Hence, for TREC-IS, we opted for a larger pool of events across six different event types.

INCIDENT STREAMS TASK

2018 was the first year of the track and focused on how to produce a series of curated feeds of social media posts, where each feed corresponds to a particular type of information request, aid request, or report. Each post in these feeds was also given a criticality score, indicating how critical it was that a user be shown that post. This task is referred to as *classifying tweets by information type (high-level)*, which we define below.

Use-case: Enhanced Situational Awareness

As identified by FEMA (FEMA 2013), social media streams can support several valuable use-cases before, during and after emergency events, including: building situational awareness; understanding issues/needs/concerns from the public and survivors; and saving lives through rapid communication. To situate TREC-IS in this space, we first needed to define the use-case the track would satisfy, which would provide a better understanding of how social media could address problems a real user may have (Whipkey and Verity 2015). Based on discussions with officers from civil protection and resilience agencies, we opted for targeting increased *situational awareness*, a use-case that these stakeholders a) believed social media was suitable for and b) currently lacked the means to effectively tackle. Linking this use-case to existing information flow taxonomies during crisis scenarios (Reuter, Marx, et al. 2012), our task involves enhancing the 'citizen to authority' information flow, thereby improving the authority's situational awareness. Specifically, we consider our end-users to be public safety officers in the central command and control centre during an emergency. These users might be responsible for identifying actionable information that other officers can use to direct response efforts and/or answer questions from the public.

Task Formulation

We formally define the TREC-IS *Classifying Tweets by Information Type (high-level)* task as follows: Given a single social media post p published at time t (p_t), assign a high-level information type i (e.g. "call for help") from a set I ($i \in I$) to p_t, and provide a critically score c to p_t, where $0 \leq c \leq 1$. Higher criticality scores indicate that the post contains more important actionable information. Systems may use information that is publicly available prior to t when processing a post p_t.

Mapping this definition to our use-case, the information type (i) assigned to a post indicates the 'feed' to which the post belongs. The criticality score identifies posts that need to be shown to an officer immediately as an alert.

INFORMATION TYPE ONTOLOGY

We next define the information types I that systems may assign to a post. To identify our information types, we build upon past works that examine how to categorize emergency related content. In particular, a survey (Castillo 2016) of previous categorization efforts identified eight main dimensions of categorization, namely: by information provided/contained (Truelove et al. 2015); fact vs. subjective vs. emotional content (Kumar et al. 2013); by information source (Olteanu, Castillo, et al. 2014); by credibility (Castillo et al. 2013); by time (Chowdhury et al. 2013); by location (De Longueville et al. 2009); by embedded links (Shaw et al. 2013); or by environmental relevance (physical, built or social) (Mileti 1999). Given our use-case, our primary requirement is that information types represent categories of information that emergency response officers might be interested in, such as 'Reports of Road Blockages' or 'Calls for Help'. We therefore are mainly concerned with categorization by information provided/contained. However, in some scenarios it may also be valuable to consider categorization by information source (to help find first-hand reports) or credibility.

We also analysed incident management ontologies such as MOAC (Management of a Crisis)[3], response documentation (FEMA 2011) and discussed the challenges with experts. This provided a small number of additional information types, some of which were specific to an event type (e.g. 'Are the Assailants Armed?' for terrorist attacks). Aggregating information categories from prior research with categories derived from emergency management documentation and practitioners provides us with a granular view of what information is valuable during an emergency.

[3] http://observedchange.com/moac/ns/

High-Level Information Type	Description	Example Low Level Types
Request-GoodsServices	The user is asking for a particular service or physical good.	PsychiatricNeed, Equipment, ShelterNeeded
Request-SearchAndRescue	The user is requesting a rescue (for themselves or others)	SelfRescue, OtherRescue
Request-InformationWanted	The user is requesting information	PersonsNews, MissingPersons, EventStatus
CallToAction-Volunteer	The user is asking people to volunteer to help the response effort	RegisterNow
CallToAction-Donations	The user is asking people to donate goods/money	DonateMoney, DonateGoods
CallToAction-MovePeople	The user is asking people to leave an area or go to another area	EvacuateNow, GatherAt
Report-FirstPartyObservation	The user is giving an eye-witness account	CollapsedStructure, PeopleEvacuating
Report-ThirdPartyObservation	The user is reporting a information from someone else	CollapsedStructure, PeopleEvacuating
Report-Weather	The user is providing a weather report (current or forecast)	Current, Forecast
Report-EmergingThreats	The user is reporting a potential problem that may cause future loss of life or damage	BuildingsAtRisk, PowerOutage, Looting
Report-SignificantEventChange	The user is reporting a new occurrence that public safety officers need to respond to.	PeopleTrapped, UnexplodedBombFound
Report-MultimediaShare	The user is sharing images or video	Video, Images, Map
Report-ServiceAvailable	The user is reporting that someone is providing a service	HospitalOperating, ShelterOffered
Report-Factoid	The user is relating some facts, typically numerical	LandDevastated, InjuriesCount, KilledCount
Report-Official	An official report by a government or public safety representative	OfficialStatement, RegionalWarning, PublicAlert
Report-CleanUp	A report of the clean up after the event	CleanUpAction
Report-Hashtags	Reporting which hashtags correspond to each event	SuggestHashtags
Other-PastNews	The post is generic news, e.g. reporting that the event occurred	NewsHeadline
Other-ContinuingNews	The post providing/linking to continuous coverage of the event	NewsHeadline, SelfPromotion
Other-Advice	The author is providing some advice to the public	SuggestBestPractices, CallHotline
Other-Sentiment	The post is expressing some sentiment about the event	Sadness, Hope, Wellwishing
Other-Discussion	Users are discussing the event	Causes, Blame, Rumors
Other-Irrelevant	The post is irrelevant, contains no information	Irrelevant
Other-Unknown	Does not fit into any other category	Unknown
Other-KnownAlready	The Responder already knows this information	KnownAlready

Table 1. Ontology High-level Information Types

Such valuable information is rare on social media, as most information shared during emergencies is of lower importance, such as news reports or shocking images. On the other hand, these other types of information may be valuable to researchers studying emergencies in the future when tackling other use-cases. Moreover, providing more resolution on what is likely 'non-relevant' for our use-case may help systems avoid miss-categorizing that content. We then expanded our initial set of information types via a bottom-up analysis of Twitter content from a small sample of events. This resulted in additional information types such as 'Sentiment Expressed', 'Press Releases' and 'Sharing Best Practices'.

In this way, we created a broad ontology of over 100 information types that are either important to emergency response officers or are commonly shared during events.[4] For the purposes of the track, asking participants to categorize posts into over 100 distinct types is unreasonable for the first year of the track. We instead grouped the individual low-level ontology entries into higher-level types. For example, we merged low level entries such as 'Hospital Operating', 'Shelter Offered' and 'Food Distribution Point' into the higher-level type 'Service Available'. In total, we defined 25 high-level types, as shown in Table 1, which form our information type categories I.

DATASET CREATION

A core component of TREC-IS is a set of evaluation datasets. A dataset is comprised of two components: a series of topics, each representing an emergency event; and the social media posts for each of those events. We summarize the creation of these below.

Twitter as a Data Source

The field of social media for emergency management is broad (Palen and Liu 2007; Hughes and Palen 2009; Middleton et al. 2014) in that a wide variety of data types and sources exist that we might desire to analyze. The majority of prior research into social media during emergencies, however, has focused on Twitter data (Reuter, Backfried, et al. 2018), likely due to ease of access. As a new initiative that aims to bring together researchers already working in the field, for the first year of TREC-IS we maintain this trend by using Twitter data, although we are interested in additional sources in future years.

Topics/Events

Our goal is to provide a sound, reproducible experimental environment, where researchers and practitioners can evaluate systems for the TREC-IS task. While most studies in this context have focused on small numbers of events, this choice is problematic; while interesting observations can be made on such datasets, we cannot show how systems generalize across events of the same type or across types. Moreover, with small datasets, illustrating statistically significant differences between systems becomes challenging. Hence, we need to create a dataset that

[4]An early visualization of the ontology can be seen at http://trecis.org/WebVOWL/#trecis

Dataset	Identifier	Event Name	Event Type	Source
Training	TRECIS-CTIT-H-Training-001	2012 Colorado wildfires	wildfire	CrisisLexT26 (Olteanu, Vieweg, et al. 2015)
	TRECIS-CTIT-H-Training-002	2012 Costa Rica Earthquake	earthquake	CrisisLexT26 (Olteanu, Vieweg, et al. 2015)
	TRECIS-CTIT-H-Training-003	2013 Colorado Floods	flood	CrisisLexT26 (Olteanu, Vieweg, et al. 2015)

Table 2. TREC-IS 2018 Training and Test Events

covers a sufficient number of events for performance patterns to become identifiable. Furthermore, state-of-the-art approaches in information categorization for emergency-related content involve training supervised machine learned models, which need training examples to learn. To ensure a realistic evaluation of these models, we create two datasets, one for training such models and one for testing those models.

As a track, we are interested in emergency events, either natural or man-made. Furthermore, we anticipated that effective systems for the task may require customization for different types of event (McCreadie et al. 2018). For example, there is no point in looking for tweets with information about 'Are the Assailants Armed?' during earthquakes. For this reason, we first selected a small set of six event types to target rather than considering any event type:

Wildfire, Earthquake, Flood, Typhoon/Hurricane, Bombing, Shooting

Given these event types, we needed to decide what events to use. In a real deployment of an information-type categorization system for social media content, one would need to tackle irrelevant or off-topic content within the stream (e.g. due to imperfect data collection (Saleem et al. 2014)). For the first year of the track, we simplified the task and use only on-topic data. For this reason, we collected existing event datasets shared by other emergency management initiatives that had already been manually filtered for relevance. We then combined those datasets together to form the training and test datasets for TREC-IS 2018. In particular, we collected 19 events across the CrisisLex (Olteanu, Vieweg, et al. 2015) and CrisisNLP (Imran, Mitra, et al. 2016) initiatives. We also crawled two additional datasets ourselves for the purposes of comparison. The resultant 21 events and their sources are summarized in Table 2, the first 6 of which form the training dataset, while the latter 15 events form the test dataset.

Datasets From Social Media Streams

Data Collection: For the events listed in Table 3, we provide a stream of tweet statuses (JSON format) collected during that event for download. For the 19 events derived from either CrisisLex or CrisisNLP, we first independently crawled the tweets listed in those datasets by their unique identifier using the Twitter Streaming API . For TRECIS-CTIT-H-Test-020 (a contemporary event from 2018), we also used the Twitter Streaming API to crawl the event while as it occurred. Meanwhile, for TRECIS-CTIT-H-Test-021 we retrospectively collected unique tweets using the GNIP service .

Filtering: To reduce the barrier to entry for the first year, we desired a relevant-only set of tweets for systems to process. For the CrisisLex and CrisisNLP datasets, we pre-filtered using the human annotation labels provided, removing tweets marked with labels such as 'Not Related' or 'Not Relevant'. For the two events collected by the organizers (TRECIS-CTIT-H-Test-020 and TRECIS-CTIT-H-Test-021), we lacked human-generated relevance labels and instead performed KMeans clustering for each event. Each event was clustered into 10k clusters based on textual similarity, and we selected one tweet per cluster (the centroid tweet) to be subsequently labelled. For these two events, due to their size, we also performed additional manual keyword filtering (using terms extracted from an associated Wikipedia page for each event) to reduce it to a diverse and relevant set. We also removed non-English tweets for all events. The statistics of the tweet streams for each event are shown in Table 3.

Dataset	Identifier	Event Name	# Posts Pre-Filtering	# Posts Post-Filtering
Training	TRECIS-CTIT-H-Training-001	2012 Colorado wildfires	3,275	744
	TRECIS-CTIT-H-Training-002	2012 Costa Rica Earthquake	1,880	288

Table 3. TREC-IS 2018 Stream Statistics

LABELING TWEETS WITH INFORMATION TYPES AND PRIORITIES

To evaluate systems' performance, we required ground truth information-type and criticality labels for training and test sets. A team of TREC assessors created this ground truth by reviewing each event and hand-labeling tweets in that event, one tweet per assessor, using the assessment interface shown in Figure 1. These TREC assessors were experienced information generalists with a strong analytical background. For labeling tasks, NIST trains assessors using sample materials and works closely with them to ensure label quality and consistency.

Tweets from the 15 test events were labelled by TREC Assessors during August 2018. TREC assessors were contracted for this assessment and brought into a controlled lab environment for the duration of the job. Six TREC assessors contributed to the labelling of the events. Assessors were trained in following the ontology and identifying critical tweets using the 2012 Colorado, US wildfires event. As a group, the assessment team labeled tweets in the training event and discussed how to make decisions for confusing or ambiguous cases. Furthermore, each event type was accompanied by an information sheet defining the critical types of information expected during an event of that type. This information sheet was also provided to TREC-IS participants in the form of user profiles for each event type.

Two events were large (2014 Typhoon Hagupit and 2015 Nepal Earthquake) and were divided among multiple assessors (the partitions are denoted *DATASET*S1, *DATASET*S2, etc.). Labelling statistics divided by assessor and event are provided in Table 4. Note that as the assessment interface performed automatic textual de-duplication of tweets, the number assessed is lower than the number of tweets in each dataset.

One interesting factor to consider about this labelling task is that it involves markedly more effort by the assessors than a classical tweet categorization task, as can be seen by the high average time spent assessing each tweet across assessors (see column 4 in Table 4). This effort results from the assessors not only reading the text of each tweet but also examining linked content (e.g. news articles) and any attached videos. The level of effort required in labeling prevented a balanced study of agreement. Across the six TREC assessors, the track's test dataset contains 19,784 labeled tweets with 43,514 category labels.

METRICS

Participating organizations could submit up to four *runs*. Each submitted run gives a predicted information type and criticality score to each tweet. Participant runs are evaluated against two criteria: 1) how well did they identify the information type of the tweet (Information Type Categorization); and 2) how accurately did they estimate the criticality of the information within each tweet (Information Criticality).

Information Type Categorization

The first evaluation axis for a TREC-IS system is how effectively it can categorize tweets into the 25 high-level information types in the TREC-IS Ontology. Notably, participant systems for 2018 were tasked with assigning one

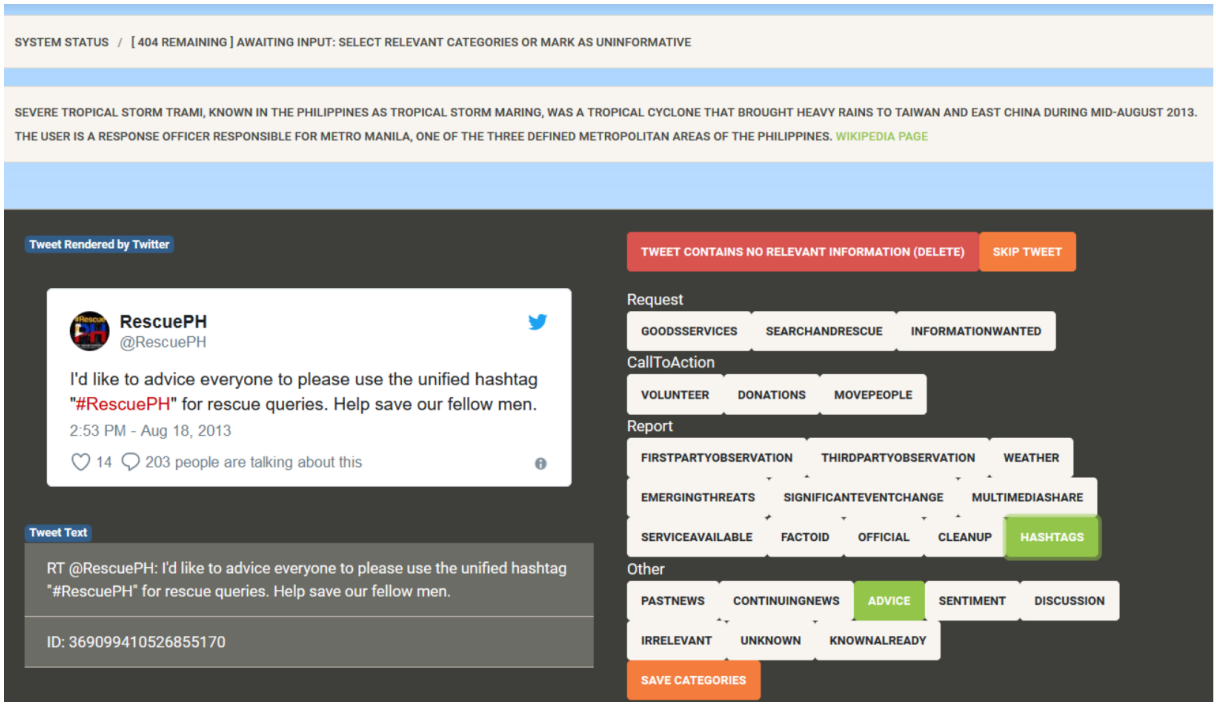

Figure 1. TREC-IS Task Assessment Interface

information type per-tweet (the most representative one). When creating the ground truth, however, TREC assessors were allowed to select multiple information types. For this reason, we evaluate information type categorization in two ways: multi-type and any-type.[5]

- **Multi-Type**: Under multi-type evaluation, we calculate categorization performance per information type in a 1-vs-All manner. A system is considered to have categorized a tweet correctly if both the system and human assessor selected that category. Note that since a system can only select one category per tweet but the assessors can select multiple categories per tweet, system performance across information types cannot be perfect under this metric. For instance, if a tweet had three information types assigned to it by the human assessor, then a system can only receive a maximum of a 1/3 score for that tweet. Multi-type evaluation is primarily useful for contrasting performance between information types or between events. We evaluate multi-type classification performance under four metrics: Precision/Recall/F1 (Positive Class) and Accuracy (Overall).
- **Any-Type**: Under any-type evaluation, a system receives a full score for a tweet if the system assigned any of the categories that the human assessor selected for that tweet. This metric provides absolute classification performance of a TREC-IS system but is more heavily influenced by larger events and more common information types (which may be less valuable for our end-users). For Any-Type, we report Precision/Recall/F1 (micro averaged) and Accuracy (micro averaged).

Information Criticality

The second axis of evaluation for a TREC-IS system is the extent to which it can identify key information that emergency response officer needs to see. This evaluation is operationalized by comparing a tweet's information priority score provided by a system to the criticality label provided by the human assessor.

To enable this comparison, two transformations were first performed. First, four information criticality labels used by the human assessors were mapped into numerical scores as per the guidelines. In this case, low=0.25, medium=0.5, high=0.75 and critical=1.0. Second, as some participant systems did not provide scores within a 0-1 range, all system scores were subject to a max-min normalization, with a minimum score cap of 0.25. Criticality estimation performance was then measured in terms of the *Mean Squared Error* between the human assigned score and the normalized system criticality score (lower is better).

[5]See http://trecis.org/2018/Evaluation.html for details.

ANALYSING ASSESSOR AND PARTICIPANT RESULTS

After collecting information-type and criticality labels from assessors and track participants, we investigate two groups of research questions regarding information posted on social media and TREC-IS participants' performance in the track. First, questions that relate specifically to the 19,784 unique tweets labeled by our assessors:

- **RQ1.1** How common are different types of information posted to Twitter during emergencies?
- **RQ1.2** How prevalent is critical/actionable information on Twitter?

Second, by analysing the performance of the 39 systems submitted to the 2018 track we investigate the following:

- **RQ2.1** How well can systems identify different information types?
- **RQ2.2** Are specific information types generally more difficult to identify?
- **RQ2.3** How well do systems perform at information criticality classification?

RQ1.1: How Prevalent is Information on Twitter during Emergencies?

The first question concerns how common different information types are on Twitter based on the TREC-IS test dataset (15 events). This statistic is valuable as it provides insights on how much actionable information one may find on social media.[6] To contrast general and actionable information, for our analysis in this section, we consider the following types of information as actionable: Requests for Goods/Services, Requests for Search and Rescue, Calls to Action for Moving People (Evaluations), Reports of Emerging Threats, Reports of Significant Event Changes and Reports of Services becoming available. This definition of actionability differs from works like (Zade et al. 2018) as it is information type-based. We assume an "actionable" post that generates an immediate alert will be useful to an individual responsible for that type (optionally considering criticality as well). Table 5 reports the number of tweets labeled with each of the 25 information types in the test dataset. Our expectation is that distributions of information types will differ across event types, so we divide these counts across our six event types. The percentage reported after each count is the proportion of tweets for that information type and event type.

[6]Note this is subject to both the sampling strategies employed by the CrisisLex and CrisisNLP original sources and the subsequent filtering we applied.

High-Level Information Type	Wildfire	Earthquake	Flood	Typhoon/Hurricane	Bombing	Shooting
Request-GoodsServices	0 (0%)	72 (0.49%)	48 (0.87%)	5 (0.04%)	1 (0.02%)	0 (0%)

Table 5. Prevalence of High-level Information Types across Event Types. Information Types highlighted in bold are those we consider 'actionable'.

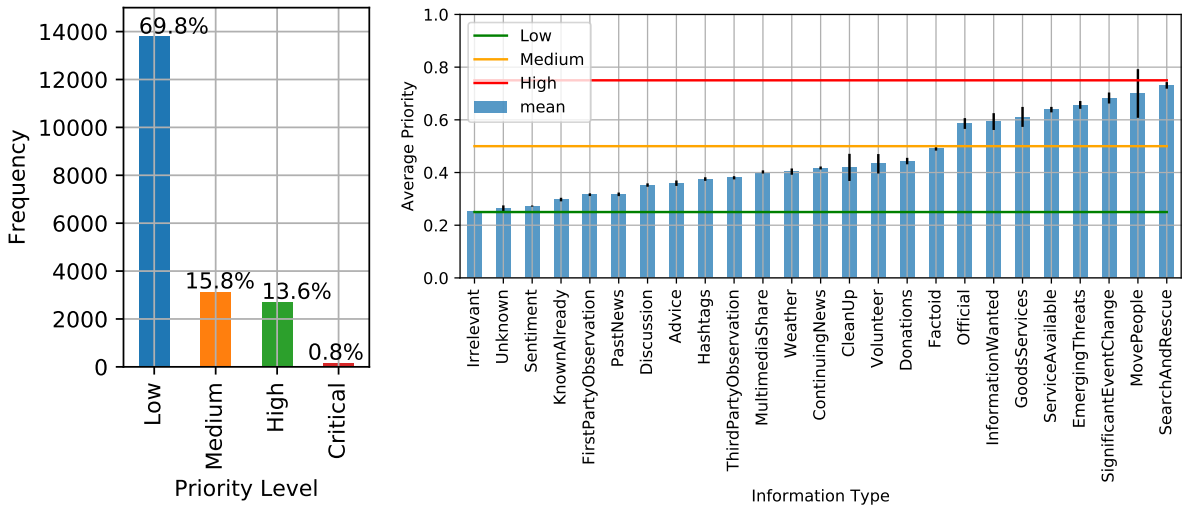
Table 5 shows the following interesting trends: For Wildfire events, the main types of information reported in Twitter are Third Party Observations (29%), Factoids (12%, typically the amount of area destroyed) and News reports (24%). Restricting to actionable information types totals around 4%, which is almost all reports. For Earthquake events, we see a more even spread of information types. The most prevalent information type is Sentiment (23%), with First Party Observations (10%) and Multimedia Sharing (9%) also being popular. In terms of actionable information, this event type has the largest proportion of reports of Services becoming Available again (1.2%) and has the highest proportion of actionable information overall (10%). For Flooding events, First Party Observations (14%), Third Party Observations (10%) and News Reports (16%) are the most common. Meanwhile, this event type has the highest proportion of requests for Search and Rescue (2%), with around 7% of the tweets belonging to our 'actionable' information types. During Typhoon/Hurricane events, we again see a high prevalence of First Party Observations (10%) and Third Party Observations (14%), with Multimedia Sharing (10%), News Reporting (14%) and expressing Sentiment (12%) also being popular. The amount of actionable information here appears to be lower, with very few requests for aid, and only around 2.5% of posts containing potentially valuable reports. Moving to the man-made emergency event types, for Bombings, Third Party Observations (12%) and Sentiment (20%) are the most common information types. Around 6% of tweets contain potentially actionable information, which is almost exclusively reports rather than requests for aid. Finally, for the shooting event (only one exists in the test dataset), we see a markedly different distribution of information types: The most common are Multimedia Sharing (17%), Past News (29%, analysing the shooter's history) and related discussions (22%, about gun control in the U.S.). Almost no actionable information exists on social media during this event (1%).

In conclusion, we can see marked differences between the information types that are prevalent during different types of events. However, in terms of potentially actionable information from the perspective of a response officer, there appears to be valuable information here that can be accessed, with up-to 10% of the tweets containing actionable information according to our definition (although some of that information may be redundant).

RQ1.2: How Much Information is Critical?

Having examined the information type distribution within our test dataset from the perspective of types that we might consider actionable, we next contrast this result against what our assessors judged to be critical information. Recall that for each tweet, our assessors assigned a criticality label (Critical, High, Medium or Low) to each tweet, which we then mapped into a criticality score (Critical=1.0, High=0.75, Medium=0.5 and Low=0.25). In this section we examine the distribution of criticality among the tweets in the test dataset.

We first averaged the criticality scores for all 15 test events, resulting in an average tweet criticality of $\mu = 0.3632$, with a standard deviation $\sigma = 0.1880$. This result suggests, as we might expect, the majority of crisis-related



(a) Criticality Distribution **(b) Average Criticality by Information Type (95% Confidence)**

Figure 2. Criticality Distributions Across and Within Information Types

tweets are between low and medium criticality. Figure 2a shows number of tweets assessed for each criticality level, while 2b reports criticality by information-type. Figure 2a shows the majority of tweets are of Low and Medium criticality (69.8% and 15.8%, respectively), i.e. a response officer would not need to see these tweets. However, we do see a relatively large proportion (14.4%) of tweets our assessors judged as important for a response officer to see promptly. Examples include pictures and videos taken during the emergency or status updates from the ground. For instance, during Typhoon Hagupit, the tweet *"Borongan, Eastern Samar's communication lines and power & water lines are still down. /via @EdwinSevidal #RubyPH"* was judged as having a high priority. Furthermore, while the proportion is small (0.8%), we also see tweets that are critical for an emergency response officer to see (and act on) immediately. These are often timely updates on potentially life-threatening impacts. For example, during Typhoon Hagupit again, the tweet *"Typhoon Hagupit hit Eastern Samar. ACTalliance local partners see transitionsal shelters blown away. Need to assess damage and respond asap"* was judged as critical. This result shows important information gets transmitted via social media during crises, supporting the idea that emergency response agencies should consider it a primary communication channel.

RQ2.1: Can Systems Effectively Identify Information Types?

Having analysed information type labels, we next examine whether current systems can automatically identify these types. Since TREC-IS's overall goal is to advance the TRL of current (automated) social media crisis monitoring solutions, rather than to study how humans annotate social media data, remaining sections focus on systems participating in TREC-IS 2018. Eleven research groups from eight countries participated in this track in 2018, submitting a total of 39 runs (each representing a different implementation).

The first question we examine is to what extent these systems able to automatically identify the 25 information categories. Table 6 reports system performance, ranked by the Any-Type, Micro Avg F1 metric (best score under each metric is highlighted in bold). Our analysis focuses on the Multi-Type metrics, as they provide more insights into categorization performance.

Multi-Type metrics have two sub-types: *Positive Class*, or how effectively a system classifies each information type in a one-versus-all manner; and *Overall*, that calculates (overall) classification accuracy. To perform well under the Multi-Type Positive Class metrics, a system needs to be effective at identifying tweets that belong to each information type (we only consider true positives and true negatives here). Moreover, it needs to perform well for the majority of the information types, as we uniformly average across information types. In contrast, Overall (Accuracy) also considers when a system correctly did not assign a category.[7] Table 6 shows that under the Multi-Type Positive Class metrics, performance is low across all 39 systems, with F1 scores ranging from 4% (lowest) to 15.7% (highest). One should recall this estimate underestimates the true performance of these systems, as systems only assigned a single type per tweet, while the assessors could assign multiple types. Even

[7]Most tweets belong to one or two categories, meaning that true negatives are vastly more common than true positives, hence Overall scores will be much higher than Positive Class scores.

Run	Information Type Categorization								Information Criticality
	Multi-Type, Macro Avg.				Any-Type, Micro Avg.				
	Positive Class			Overall	Precision	Recall	F1	Accuracy	Mean Squared Error
	Precision	Recall	F1	Accuracy			(Target Metric)		(Lower is better)

Table 6. TREC-IS 2018 Participant Run Performances.

accounting for this difference, the low performance of these systems indicates they are not yet sufficiently effective at discriminating information types. This result motivates the need for a concerted effort to bring performance up to a level that is deployable by end-users. While performance seems better when examining Overall accuracy, this increase is a reflection of the high frequency of true negatives. Potential users primarily care about getting the true positives correct (e.g., having systems that can correctly identify that urgent request for search and rescue). Hence, in summary, participant systems are getting between 85-90% of categorization decisions correct under the one-versus-all scheme, but the remaining 10-15% are often the cases that our end-users actually care about. It is thus fair to conclude that this technology is currently insufficient for deployment in practice.

RQ2.2: What Information Types are Difficult to Identify?

Insights on where current state-of-the-art systems tend to succeed or fail is important for focusing future research. While a deep analysis of individual systems is beyond this paper's scope, we perform a meta-analysis of systems by information type. In particular, we identify the best performing system for each information type and plot those best per-information type performances. This meta-analysis represents the performance distribution if we could combine all of the best-performing aspects of participant systems into a single '(beyond) state-of-the-art system'. This is informative, as we can observe gaps where participating systems performed poorly, identifying areas where the most effort is needed.

Figure 3 shows the best participant system's performance when ranked by Multi-Type, Macro Avg. Positive Class per information type under the Positive Class metrics. Across information types, the average F1 score is 0.2953, with precision 0.4151 and recall 0.3167, representing a large and statistically significant improvement over the

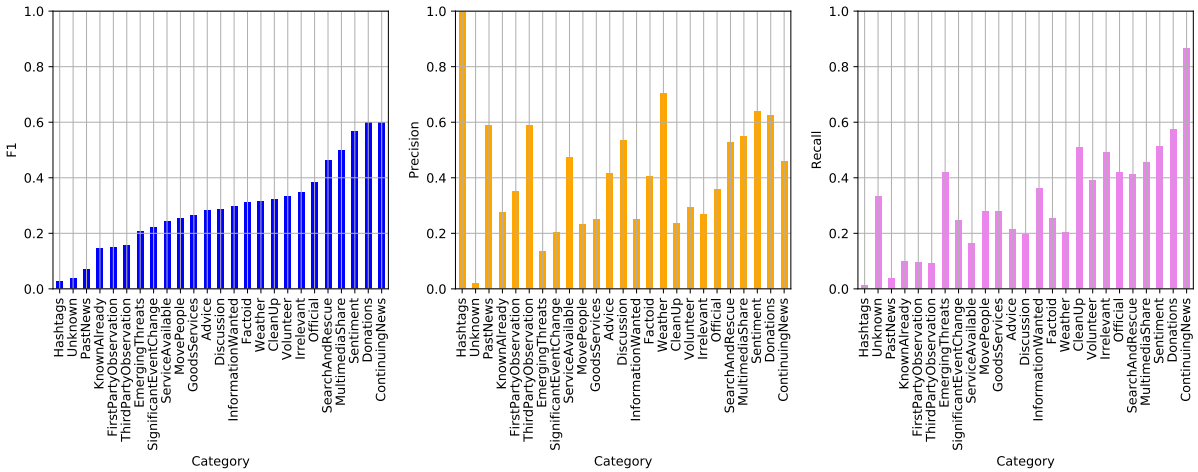

Figure 3. F1, Precision, and Recall for Best Performing Systems by Information Type

0.1571 F1 previously observed for the best single system in Table 6. While this gain is expected, the magnitude of this difference suggests high variance exists in performance among systems for each information type.

Furthermore, from Figure 3, we see the best performing systems are quite effective at identifying continuing news, donations, and expressions of sentiment. Alternatively, of the six actionable information types, all but the search-and-rescue type are in the bottom half of this ranking, suggesting even the best participant systems have difficulty with identifying this important information. We also note a weak correlation exists between the per-type F1 scores and the amount of training data made available for this edition of the track (the training dataset), which accounts for 29% of variation in scores. Given the rarity of critical information in social media data, this result reinforces the necessity of a large-scale and standardized dataset of emergency-related content. Indeed, this gap is a motivation for a continuing initiative that produces datasets with increasing size.

RQ2.3: Are Systems able to Accurately Estimate Information Criticality?

Having examined system performance for information type categorization, we next examine efficacy of criticality assessment. We measure this performance by comparing the (normalized) criticality score provided by a system for a tweet against the criticality label assigned by the assessor for that tweet. The smaller this difference (the lower the error) the better. The final column in Table 6 reports this estimation error for each system, while Figure 4 reports the average criticality scores for each system.

We make the following observations: First, Table 6 shows a more positive picture than when examining information type categorization performance, with prediction errors ranging from 0.06 to 0.16, a fairly low level of error.[8] Second, when examining systems' criticality scores, we see a markedly higher average ($\mu = 0.6067$, $\sigma = 0.2193$) than the assessors criticality scores ($\mu = 0.3632$). This result suggests participating systems tend to over-estimate the priority of messages rather than under-estimate criticality. This over-estimation is especially apparent in eight systems ("cbnu" and "umdhcil") that give all messages a score of "Critical". Within groups variations are also low, with many groups' systems returning the same average criticality score. Removing these eight systems yields an average criticality score of $\mu = 0.5053$, which is closer to the assessors' scores but still overestimating importance. We also note the lack of correlation between systems performing well on information type categorization and those performing well on information criticality estimation.

CONCLUSIONS

This paper describes the 2018 edition of the TREC-IS initiative. TREC-IS 2018 developed test collections and evaluation methodologies for automatic and semi-automatic filtering approaches that identify and categorize information and aid-requests made on social media during crisis situations. It also provides an evaluation challenge in which researchers/developers can participate. This paper also provides an overview of TREC-IS's evaluation methodology, an ontology of emergency information types, and summarizes the creation of a large dataset of 19,784

[8]Although we note the macro averaging across information types being performed here may be masking higher error rates on the rarer information criticality levels (Critical and High).

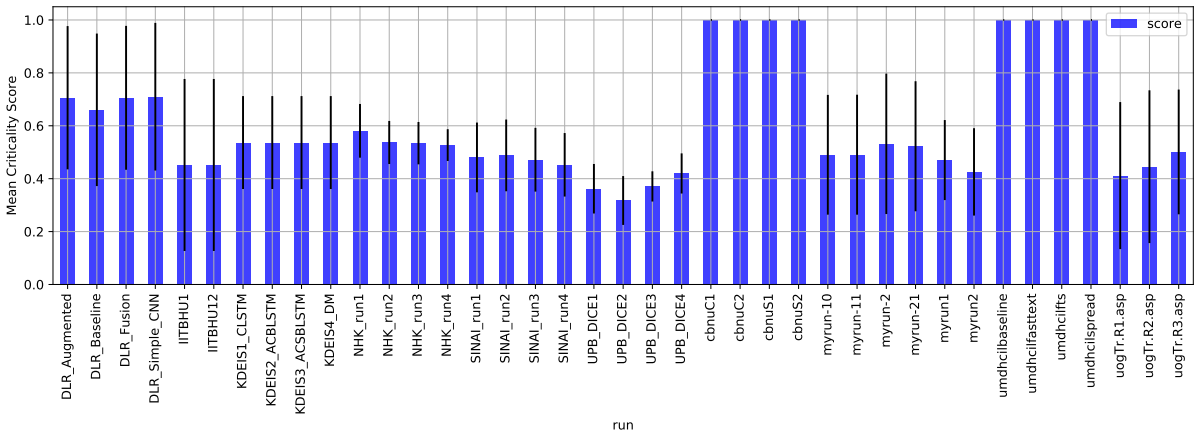

Figure 4. Mean Critical Scores Per Run (+/- one standard deviation)

hand-labeled social media messages from Twitter, in which assessors identified actionable and critical information for each event.

In addition, we examine this labelled Twitter data, showing the amount of actionable information for emergency response officers on Twitter is significant (up-to 10% post-filtering), but varies greatly with event type. This result is supported by information criticality labels produced by our assessors, which indicates that ~15% of tweets were judged as being of 'High' or 'Critical' importance to response officers.

Finally, as an evaluation challenge, eleven teams participated in TREC-IS 2018. This paper summarizes performances of these systems and implications for the maturity of the state-of-the-art. Given the eleven participating teams and 39 submitted systems, we show the current state-of-the-art is not sufficiently effective to be considered deployable by end users. While participants are relatively effective at identifying common information types such as news reports and sentiment, identifying actionable information types like search and rescue requests is still challenging. Alternatively, systems are more accurate at estimating information criticality, although they tend to over-estimate.

TREC-IS has been approved to run at TREC 2019, yielding an opportunity to develop larger, more robust, and standardized assessment datasets spanning multiple years, thereby reducing this reliance on training data and allowing technologists to better serve responders' needs. Up-to-date information and all of the data for the track are available from the TREC-IS track website:

ABSTRACT

Enhancing situational awareness by mining social media has been widely studied, but little work has been done focusing on recovery phases. To provide evidence to support the possibility of harnessing social media as a sensor of recovery activities, we examine the correlations between topic frequencies on Twitter and people's socio-economic recovery activities as reflected in the excess demand for used cars and housing, after the Great East Japan Earthquake and Tsunami of 2011. Our research suggests that people in the disaster-stricken area communicated more about recovery and disaster damages when they needed to purchase used cars, while the non-local population communicated more about going to and supporting the disaster-stricken area. On the other hand, regarding the excess demand for housing, when the local population of the disaster-stricken area started to resettle, they communicated their opinions more than in other periods about disaster-related situations.

Keywords

Social Media, Topic modeling, Socio-economic recovery, Used-car demand, Housing demand.

INTRODUCTION

There have been various efforts to use social media data to detect the situation surrounding disaster-stricken communities. However, few studies focus on detecting recovery. This paper explores the possibilities of detecting socio-economic recovery activities by exploring social media communication topics and market data. To build resilient communities after a large-scale disaster, improving mid-to-long-term situational awareness could enhance recovery efforts. This is because traditional socio-economic recovery indicators (e.g., observing changes in population and consumption, and conducting questionnaire surveys) are not published in a real-time way. Social media data hold the possibility of filling this gap by its timeliness. This study conducts topic analysis on Twitter communication data for the first six months after the Great East Japan Earthquake and Tsunami of 2011, and looks into the relationships between the topic appearance ratios and two types of socio-economic activities, namely, excess demand for used cars and excess demand for housing. The Great East Japan Earthquake and Tsunami occurred on March 11th, 2011. It caused devastating building damage across the coastal areas. According to the Japanese Fire and Disaster Management Agency[1], 19,667 people were killed, and 2,566 people went missing. The disaster destroyed 121,787 buildings.

This study takes these two goods as proxies of people's socio-economic recovery activities to rebuild their daily-lives because related research and reports have demonstrated that both used cars and housing are in higher demand in affected communities when a large-scale water-related disaster hits (the details are explained later). According to Drabek (1986), a disaster involves four phases: (1) preparedness, (2) response, (3) recovery, and (4) mitigation. This study focuses on the recovery phase. We particularly analyze the data collected during the first six months after the disaster.

The rest of the paper is constructed as follows. First, we review related literature and introduce research questions. Secondly, the data are described. Then we conduct topic analysis on social media communication data and topic frequency scores are calculated. To analyze the possibility of using social media data as a sensor of recovery activities, we analyze the correlations between the topic frequency ratios and the proxies of socio-economic

[1] http://www.fdma.go.jp/bn/higaihou_new.html

recovery activities. Lastly, we explain and discuss the results, and conclude with implications for future study.

RELATED LITERATURE

Socio-economic Recovery Activities: The Excess Demand for Used Cars and Housing

When a large-scale water-related disaster (e.g., hurricane, typhoon, tsunami) hits a community, there tends to be an excess demand for used cars and for housing in the local community. For example, after Hurricane Harvey and Irma in 2017, the media reported excess demand for used cars around the flooded areas (Breuninger, 2017; Chee, 2017; Lang, 2017). Likewise, after the Great East Japan Earthquake and Tsunami, newspapers reported a rise in the demand for used cars in the disaster-stricken area to replace water-damaged vehicles. Used cars were preferred over new cars because of their lower prices and quicker registration process (e.g., Nikkei Sangyo Shinbun, 2011, The Tohoku Finance Bureaus, 2017). In addition, Shibuya and Tanaka (2018a) conducted interviews with used-car dealers in disaster-stricken areas and revealed that the affected population needed to buy used cars when they became active in restarting their daily-lives (e.g., restarting working).

Regarding housing, various reports described the excess demand for non-inundated housing after a large-scale disaster. For instance, after Hurricane Sandy which flooded more than 300,000 homes and approximately 23,400 businesses (Bloomberg, 2013, p.13), the media reported increased demand for dry houses near the damaged areas (Kearns, Park and Buhayar, 2012; NBC, 2014; Racioppi, 2014). Another example of increased demand for housing occurred after the Great East Japan Earthquake and Tsunami, which destroyed 121,783 buildings across the coastal areas[2]. The newspapers reported that although the land values declined in the inundation zones, lands located on hills were in higher demand, causing increased land prices (Asahi Shimbun, 2011).

Both used-car and housing market data have been widely analyzed based on the Hedonic model (e.g., Barr et al., 2017; Haan and Boer, 2010; Hallstrom and Smith, 2005; Kooreman and Haan, 2006; McCoy and Zhao, 2018; McKen-zie and Levendis, 2010). The Hedonic model is an economic model that postulates that the price of a product reflects a bundle of embodied characteristics valued by some implicit or shadow prices (Prieto et al., 2015). With the Hedonic model, we can examine used-car/housing prices, which reflect the demand controlled by used-car/housing characteristics. For example, if there is excess demand for housing in a particular area, the prices of housing in the area may rise to re-equilibrate the excess demand. Also, if the amount of supply of goods is the same or more than those of corresponding periods of the previous year, the rises in prices could be explained by the excess demand. Therefore, although analyses focus on prices, the changes in prices controlled by the used-cars/housing characteristics also reflects excess demand for used cars/housing. The previous studies examined the used-car/housing market data by applying the Hedonic model and clarified the excess demand for used cars/housing after large-scale disasters. More specifically, Shibuya and Tanaka (2019) statistically showed that there was an excess demand for used cars, particularly for Light Motor Vehicles[3] in the disaster-stricken area after the Great East Japan Earthquake and Tsunami. Also, Shibuya and Tanaka (2018b) analyzed housing market data of New York City and found there was an excess demand for dry housing in New York City after Hurricane Sandy. Another empirical study (Shibuya and Tanaka, 2018c) analyzed the leased housing market data after the Great East Japan Earthquake and Tsunami, and found there was an excess demand for dry houses located within 3km to the building damage zones. These excess demands for both used cars and housing after the large-scale disasters can be used as proxies of one of the socio-economic disaster recovery activities because people in the disaster area needed these goods and were willing to pay to purchase them. Furthermore, as to used cars, the interviews with used-car dealers showed that people purchased used cars when they started to be active in rebuilding their daily lives, resuming their work and shopping (Shibuya and Tanaka, 2018a). Regarding housing, people from the disaster areas seeking new housing means that people moved their physical locations, for example, from an evacuation shelter to an apartment, and thus, were active in restarting their lives or moving forward to the next stage of recovery. Therefore, in this study, we use used-car and housing market data as proxies of socio-economic recovery activities in the case of the Great East Japan Earthquake and Tsunami.

Social Media for Improving Disaster Situational Awareness

When a disaster hits a community, a massive amount of information that includes individual discussions, and personal experiences and thoughts, is created. Because acquiring useful information about the situations in the disaster-stricken area is critical for relief operations and preventing further losses, social media users have been recognized as "people as sensors" (Laituri and Kodrich, 2008), "citizen sensing" (Castillo, 2016; Sheth, 2009), or " human sensors" (Yuan et al., 2013). Various related works have looked into the potential usefulness of social media as "people as sensors" by investigating the correlations between cyber and real-world activities. For instance, the relationships between chatter on Twitter and donation amounts (Korolov et al., 2015), the proximity

[2] http://www.fdma.go.jp/bn/higaihou_new.html (accessed September 30, 2018, in Japanese)
[3] A Japanese car category whose engine volumes are 660cc or less.

of a hurricane path and social media activities (Kryvasheyeu et al., 2016), and sentiment on social media and actual disaster damage (Guan and Chen, 2014; Kelly and Ahmad, 2014; Nguyen et al., 2014) have been addressed. Also, other researchers argue that social media can be used as earthquake detectors (Kropivnitskaya et al., 2017; Sakaki et al., 2013, 2010), water level sensors (de Albuquerque et al., 2015; Zhang et al., 2016), and sensors of evacuation activities (Kibanov et al., 2017; Martin et al., 2017; Wang et al., 2016; Yuan et al., 2013). These studies suggest that social media data can promote "people as sensor" approaches for disaster management by providing effective and near real-time complement data for detecting or assessing disaster-related incidents (Martin et al., 2017). However, little work has been done on adapting the "people as sensors" approach in recovery. Some of the examples of studies focusing on social media use in recovery are Su et al (2017) and Yan et al. (2017). Yan et al. (2017) analyzed geotagged Flickr (a photo-based social network) photos after the 2013 Earthquake and Typhoon in the Philippines (ranging from April 2004 to July 2016) to identify remaining damage by mining tourist photos. Su et al. (2017) investigated the social media communication patterns after the Great East Japan Earthquake and Tsunami by focusing mainly on nueclear-related topics. In terms of the recovery phase, social media data have the potential to complement traditional socio-economic recovery indicators (e.g., changes in population and consumption, and conducting questionnaire surveys) because such data can provide fine-grained measurements of behavior over time while taking advantage of significant population sample sizes (Gruebner et al., 2017). Detecting recovery activities in a near real-time way may help recovery-related agencies, local public officials and recovery practitioners to obtain a big picture. Furthermore, improving the affected areas' real-time situational awareness may help create an evidence-based and more effective recovery plan.

Local and Non-local to a Disaster

In terms of social media communication data after a large-scale disaster, existing studies have recognized different communication patterns between locals and non-locals during disasters. Starbird et al. (2012) argue that social media contents shared by local citizens in a disaster-stricken area can provide unique and critical information for emergency responders and other diverse stakeholders. Kogan et al. (2015) and Starbird and Palen (2010) found that Twitter users, in general, were more likely to re-tweet the accounts of people local to emergency events. Bica et al. (2017) investigated an imaginary representation of a disaster via images shared on Twitter. They found that locals focus more on the business details of the response and the damage in their cities while a non-local population focus more on the images of people suffering (Bica et al., 2017). In addition, there have been various efforts to make it easier to find communication posted by people local to disaster-stricken areas. For example, Grace et al. (2017) investigate how to effectively discover local populations by using social network ties. Other typical ways to identify local communications are using disaster-related keywords and location-based tweet collections (Olteanu et al., 2014). This study also applies the keyword-based tweet collection and divides local and non-local communication according to whether communication contains disaster-impacted locations' names (details are described in the Data section).

RESEARCH QUESTIONS

Based on the previous studies cited above, this study investigates the following three research questions. First, although only limited research has been done on whether or not we can improve situational awareness during recovery phases and how we can do so, using social media data as a sensor of recovery activities has the potential to improve recovery efforts because social-media generated information may be able to complement existing recovery indicators by its timeliness. Thus, for the first step to explore the possibility of using social media data to detect recovery activities, we analyze whether there were correlations between people's communication in the virtual world and people's activities in the real world.

- RQ1: Did social media communication topics have relationships with the excess demand for used cars and housing in the disaster-stricken area?

Secondly, although both used cars and housing are likely to be in higher demand after a large-scale water-related disaster, the two goods have different characteristics and thus, when and which people in the disaster-stricken area needed to buy these two goods may be different. In this study, our hypothesis is that the two types of goods had different types of correlations with social media communication.

- RQ2: Did the excess demand for used cars and the excess demand for housing correlate differently with social media communication?

Lastly, related works investigating relatively short-term restoration and response found the different types of communication patterns between people local to a disaster-stricken area and people non-local to the disaster. Our hypothesis in this study is that even during recovery phases, the local and non-local population communicate differently, and thus we consider the following RQ3.

- RQ3: Did social media communication posted by people local and non-local to the disaster-stricken area have different types of correlations with the excess demand for used cars and housing?

DATA

Socio-economic Recovery Activity Data

Used-car market data

As one of the proxies of socio-economic recovery activities, we use the Japanese used-car market data sourced from advertisements posted on one of the most dominant used-car magazines in Japan, "Goo[4]," which is published every two weeks. We used the data posted by dealers in the tsunami-damaged areas for six months after the disaster. For the analysis, we selected a body type named Light Motor Vehicle Cab Van because both quantitative research (Shibuya and Tanaka, 2019) and qualitative reports, such as interviews in the newspaper and in government reports showed that there was an excess demand for the Light Motor Vehicle Cab Van. The data include used-car characteristics such as age, price, and transmission. The real prices of used cars were calculated based on the fiscal 2015 Consumer Price Index[5].

Housing market data

This study uses the leased housing market data from six months after the disaster provided by At Home Co., Ltd[6]. The data include housing characteristics such as the lease price, the size of the building area, the age of a property, and the address. The lease prices were adjusted as real prices with the residential property price index[7]. To exclude outliers, the real sales price per square meters of each property was calculated. Properties whose price per square meter was more than or less than the mean real sales price ± the standard deviation × 4 were excluded. Each property was checked to see if it was in the building damaged zones, and if not, the distance to the building damage zones was calculated based on the survey results of building damages conducted by the Ministry of Land, Infrastructure, Transport, and Tourism[8]. The distance from each property to Sendai station as a proxy of the city center was calculated. The minutes from the nearest station of each property to Sendai station by a train was also added as a feature. The current study only uses the leased houses located in plains and within 3km to the building damage zones because the quantitative research (Shibuya and Tanaka, 2018c) reveals that there was an excess demand for leased properties, particularly those located in plains and within 3km to the building damage zones. Table 1 describes the numbers of used cars and housing for the analysis every two weeks.

Table 1. Observation numbers of used cars and housing every two weeks

	Mar-2	***Apr-1***	***Apr-2***	***May-1***	***May-2***	***Jun-1***	***Jun-2***	***Jly-1***	***Jly-2***	***Aug-1***	***Aug-2***	***Sep-1***
Used Cars	14	118	132	124	129	114	114	104	104	134	106	121
Housing	656	287	436	343	468	389	344	363	349	309	348	266

Note 1: Mar-1 represents the first half of March; Mar-2 represents the second half of March. The same applies hereafter.
Note 2: In this study, we set a one-month time lag for used-car data because our used-car target data are sourced from a paper-based magazine. It took about one month for the magazine to be organized and to publish the data after collecting data from town shops. For example, in this study, used-car data from the second half of April (*Apr-2*) is treated as the second half of March (*Mar-2*). On the other hand, we did not set any time lags for housing market data because they are sourced from an online platform, and they were published in real-time way.

Social Media Communication Data: Twitter Data

Twitter is a platform that allows users to post messages (tweets) to their followers and the public (if a user permits), and to receive posted messages from other users. The target data in this study were collected through an Internet service called "Kuchikomi@kakaricho" (http://kakaricho.jp)[9]. We selected Japanese tweets posted for six months after the disaster (March 11th to September 11th of 2011) that contained at least one of the 16 Japanese keywords deemed to be relevant to our study purposes:[10] "earthquake," "disaster," "affected," "evacuation," "thank you," "temporal," "restart," "recovery," "information," "appreciation," "support," "tsunami," "damaged," "car," "light,"

[4] The used-car data were provided by "Proto corporation" which publish "Goo."
[5] We used "automobile" deflator sourced from http://www.e-stat.go.jp/SG1/estat/List.do?bid=000001074278&cycode=0 (accessed October 17, 2018).
[6] The study is supported by Joint Research Program No.823 at CSIC, The University of Tokyo ("Real Estate Database 1999-2016" by At Home Co., Ltd.)
[7] Average of 2010 = 100, http://www.mlit.go.jp/totikensangyo/totikensangyo_tk5_000085.html, accessed September 21st, 2018
[8] http://www.mlit.go.jp/toshi/toshi-hukkou-arkaibu.html
[9] Although Twitter API allows collecting public tweets, we cannot collect tweets seven years ago (when the disaster happened). Therefore, we use an internet service Kuchikomi@kakaricho which provides historical tweets.
[10] We applied keywords-based tweets search approach based on related works (e.g., Wendland et al, 2017; Musaey et al., 2017; Alam et al., 2017). Before selecting the 16 keywords, the authors manually checked various types of tweets relevant to the disaster. After discussing the appropriateness of the keywords among authors, we carefully chose 16 Japanese keywords.

"evacuation" (all keywords are translated by the authors). In total, we collected 11,676,929 tweets.

Selection of disaster-related communication based on machine-learning

To select social media communication that related to the disaster, we classify the originally collected data based on machine learning techniques. First, after removing duplicated and re-tweeted tweets from the initially collected data, we randomly sampled a subset of about 2,000 tweets. After manually annotating the subset of 2,000 tweets based on whether the subset was disaster-related or not, we developed several classifiers including Naive Bayes, Support Vector Machine (SVM), and Logistic Regression along with a 10-fold cross-validation technique to compare the accuracy of these classification models. We found that the Naive Bayes classifier is the best predictor (Accuracy: 0.932, Precision: 0.945, Recall: 0.939)[11]. We then predicted and labeled the rest of the Twitter data with the Naive Bayes classifier. As a result, this study labeled 817,084 tweets as disaster-related. For further research, we only use these disaster-related labeled tweets.

Table 2. The Number of Local and Non-Local Tweets Datasets

	Number of Tweets											
	Mar-2	***Apr-1***	***Apr-2***	***May-1***	***May-2***	***Jun-1***	***Jun-2***	***July-1***	***July-2***	***Aug-1***	***Aug-2***	***Sep-1***
Local	728	549	393	529	401	357	415	385	322	326	307	463
Non-Local	209,346	94,748	60,211	48,653	47,174	49,436	43,040	50,053	42,699	41,301	45,270	79,978

Selection of tweets posted from the local and non-local population

As a means to examine whether a communication posted by the local and non-local population had different types of relationships with the excess demand for used cars and houses (RQ3), we further categorized the data based on tweets with geo-information. We made two datasets; a *Local Tweets dataset* and a *Non-Local Tweets dataset*. The *Local Tweets dataset* consists of tweets either whose tweeters' profile shows that they were in tsunami-stricken cities[12], their profile description contains any of the tsunami-stricken cities' names, or tweets with geo-tagged information that declares that they were in the tsunami-stricken area. The *Non-Local Tweets dataset* are the remainder of the data. Table 2 shows the number of each dataset every two weeks.

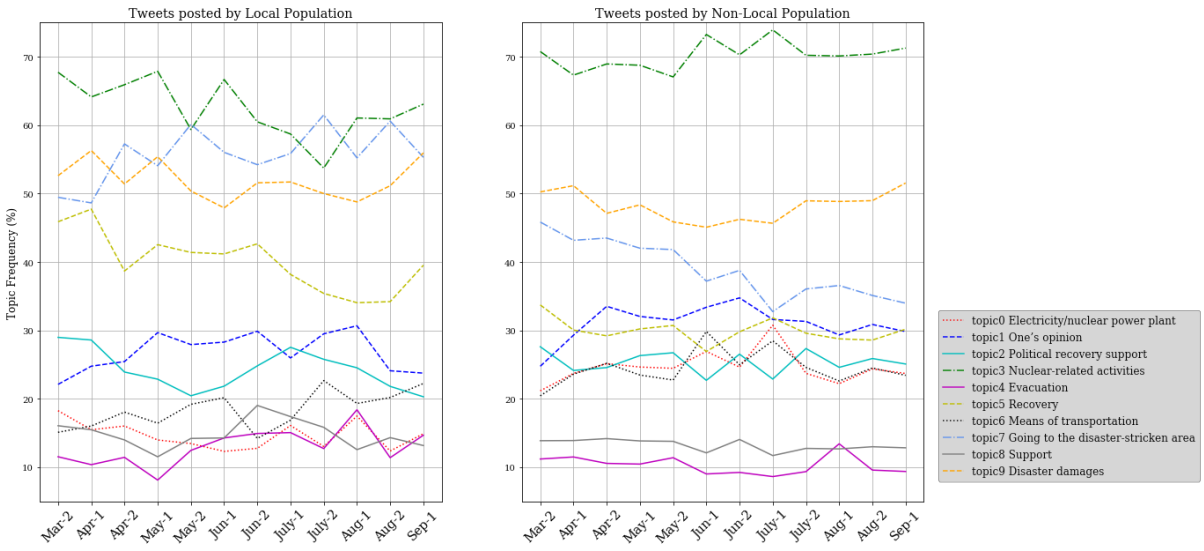

Figure 1. Topic Frequency ratio (T_i^n) of Tweets Posted by Local and Non-Local Populations

[11] SVM: Accuracy: 0.592, Precision: 0.592, Recall: 0.992. Logistic Regression: Accuracy: 0.928, Precision: 0.933, Recall: 0.9458.
[12] This study uses tsunami-stricken cities' names listed on the "Area of inundated area" by the Geospatial Information Authority of Japan (http://www.gsi.go.jp/kikaku/kikaku60004.html). We only used tsunami-stricken cities' names in Miyagi prefecture and Iwate prefecture. Fukushima prefecture was also one of the devastated areas of the disaster, but we did not include cities in Fukushima prefecture because Fukushima prefecture suffered more from the nuclear incident and thus, it should be treated differently.

Table 3. LDA topics

#	Proposed label	Top 10 most probable words	Tweet examples
0	Electricity/nuclear power plant	restart, power saving, summer, rice, electricity, non-nuclear power, shortage, Kesennuma (city name), Hokkaido (region name), machine	"Now is not the time to criticize the government, but the time to look at the reality and figure out what we have to do. Radioactive substances are detected but we need electricity, and we cannot store it up."
1	One's opinion	think, oneself, thing, myself, say, appreciation, watch, what, now, direction	"I think it is unfair that you need a local government's permission to send relief supplies. I cannot believe that. We have watched affected towns suffering, and I think they have no time to give permission to individuals. "
2	Political recovery support	free, support, person, service, site, governor, consultation, minster, freely, photo	"The Councilors' budget committee will restart the day after tomorrow. I heard that members are preparing to consult about the disaster-stricken area's situations and how to support them."
3	Nuclear-related activities	recovery, nuclear power, Japan, evacuation, country, Fukushima, issue, say, government, China	"I met an elderly person who evacuated from the nuclear-affected area. The lifeline utilities are in need of repair, and we still have family there."
4	Evacuation	evacuation, children, child, shelter, kid, target, need, parent, work, school	"Several people asked us to evacuate to another country.", "Evacuation places are in need of diapers, water, and rice."
5	Recovery	affected-area, affected, recovery, land, use, message, think, smile, Japan, support	"To support recovery efforts, the company bought a boatload of fish."
6	Means of transportation	use, car, vehicle, tax increase, restoration, accident, technology, automobile, ization/ize, need	"We need to send gasoline for cars to the disaster-stricken area." "Timely recognition of priority issues is needed to send relief supplies to the disaster-stricken area." "The train line in the disaster-stricken area is moving towards recovery."
7	Going to the disaster-stricken area	car, go, think, come, inside, time, house, evacuation, go out, myself	"I went back to the disaster-affected area and saw many volunteers who came and helped with the cleaning." "Does anyone know the website informing people how to go or send supplies to the disaster-stricken area?"
8	Support	support, affected area, the Great East Japan Earthquake and Tsunami, recovery, direction, activity, volunteer, participation, recovery support	"If anybody is looking for a place to sleep, please come to Nihonmatsu town. There is a shelter." "We need to support one another." "Photographers are holding an exhibition to support the disaster-affected area."
9	Disaster damages	tsunami, earthquake damage, evacuation, information, occurrence, news, the Great East Japan Earthquake and Tsunami, Mainichi newspaper, Miyagi prefecture	"The height of the first tsunami was over 10 meters. The second one was over five meters." "Teachers and children of the school are still left behind on the third floor of the building in Miyagi prefecture."

Note: All original tweets are in Japanese. All tweets in the table are trasnlated by the authors.

Topic Analysis: Latent Dirichlet Allocation (LDA)

Before conducting the primary analysis, we conducted topic analysis to explore what kinds of topics were on Twitter after the disaster. In doing so, we applied the Latent Dirichlet Allocation (LDA). LDA is a probabilistic topic modeling widely used in natural language processing to summarize and extract topics from documents. The intuition behind LDA is that documents exhibit multiple topics and a topic should be a distribution over a fixed vocabulary (Blei, 2012). When we manually looked into various tweets from the target dataset, we found each tweet could be categorized into several topics (for example, a tweet contains two topics; the disaster's damage and emotional encouragement). Thus, LDA, which assumes that one document contains multiple topics, was chosen for this analysis. By treating one tweet as one document, we conducted LDA with ten topics for the

predetermined topic number[13]. The ten topics found by LDA and the most probable terms and proposed labels are shown in Table 3. Next, every tweet in our dataset was automatically labeled with the ten topics based on the results of LDA; If a tweet had more than 10% probability of being categorized as topic *n*, the tweet was labeled as the topic of *n* related. Next, the topic frequency ratio (T_t^n) for every two weeks was calculated as follows: $T_t^n = \frac{Topic\ labeled\ Tweet_t^n}{All\ Tweet_t}$ where $All\ Tweet_t$ denotes the number of all tweets in *t* period and $Topic\ labeled\ Tweet_t^n$ denotes the number of tweets labeled with the topic of *n* in *t* period. Figure 1 describes the chronological changes of the topic frequency ratio (T_t^n) of tweets posted by local and non-local populations, respectively.

Note 1: L_k denotes the topic frequency ratio of topic *k* within the *Local Tweets dataset.* NL_k in the table denotes the topic frequency ratio of the topic *k* within the *Non-Local Tweets dataset.*

MODEL

To address how the topic frequency ratio on Twitter correlated with used-car prices, we developed a model below (equation 1) based on the Hedonic model as described in the section on Related Literature. By controlling used-car/housing characteristics, such as age and how many kilometers were driven, the Hedonic model allows us to assess the correlation between the used-car/housing prices, which reflect the demand for used-car/housing, and the topic frequency ratios on Twitter.

$$\ln P_i = \beta_0 + \beta_j X_{ji} + \beta_k T_{ki} + \varepsilon_i \quad (1)$$

where $\ln P_i$ is the natural logarithm of the real price of the *i* th product, X_{ji} is a vector of *j* th observable characteristics of the used cars or the houses. T_{ki} is the *k* th topic frequency ratio (L0 to T9 and NL0 to NL9 in

[13] To decide a suitable number of topics, the author applied LDA with several topic numbers, including 10, 20, 30, 50 and 100. As a result, when the topic number is 10, the results are most convincing and understandable to people although the perplexity is not the best.

Table 4). ε_i is the error term. We apply equation 1 to each topic frequency ratio[14] and used-car and housing market data respectively. For the used-car market data, the following control variables X_i are used:
Transmission:
X_{1i} = Transmission Dummy (Automatic=1, others=0)
Fuel:
X_{2i} = Special types of fuels Dummy (LPG, CNG or FC=1, others = 0)
Age:
X_{3i} = Age (in years)
Kilometers driven:
X_{4i} = 100,000km Dummy (over 100k km driven=1, others=0)

For the housing market data, the following control variables X_i are used:
X_{1i} = Apartment dummy (apartment = 1, others = 0)
X_{2i} = Distance to Sendai station (1/1000 km)
X_{3i} = Time from the nearest station to Sendai station by a train/subway (1/1000 minutes)
X_{4i} = Age (1/1000 year)
X_{5i} = Accessibility to the nearest station by walking (1/1000 min)
X_{6i} = Size of building area (1/1000 m^2)
X_{7i} = Height of a property (the sum of property's levels × 1/1000)

The statistical summary of our model is shown in Table 4.

RESULT

Table 5 shows a summary of the estimated coefficients of the topic frequency ratios (T_{ki}) of equation 1[15]. In the table, if an estimated coefficient of a topic frequency ratio has a significant correlation with the excess demand of used cars or housing at a 5% significance level, the cell is shaded. Other estimated coefficients of our model and adjusted R^2 are presented in Tables 6 and 7.

Regarding the excess demand for used cars, there were significant positive correlations between the used-car demand and the topic frequency ratio of Topic 3 (Nuclear-related activities), Topic 5 (Recovery), and Topic 9 (Disaster damages) within the *Local Tweets dataset*. On the other hand, there were significant negative correlations between the used-car demand and the topic frequency ratio of Topic 4 (Evacuation) within the *Local Tweets dataset*. In contrast, there were significant positive correlations of the topic frequency ratio of Topic 7 (Going to the disaster-stricken area) and Topic 8 (Support) with the prices of used cars within the *Non-local Tweets dataset.*

Regarding excess demand for housing, there were statistically significant positive correlations between the excess demand for housing and the topic frequency ratio of Topic 1 (Electricity/nuclear power plant) and Topic 6 (Means of transportation/ logistics) within the *Local Tweets* dataset. On the other hand, we did not find any significant correlations between the demand for housing and the topic frequency ratios within the *Non-Local Tweets* dataset.

Table 5. Estimated Coefficients of Topic Frequency Ratio

		Topic0	Topic1	Topic2	Topic3	Topic4	Topic5	Topic6	Topic7	Topic8	Topic9
		Electricity/ nuclear power plant	One's opinion	Political recovery support	Nuclear-related activities	Evacuation	Recovery	Means of transportation	Going to the disaster-stricken area	Support	Disaster damages
Used cars	Local	0.19	-0.49	0.06	**0.56****	**-1.08*****	**0.64****	-0.62	-0.41	-0.48	**0.96****
	Non-Local	-0.37	-0.06	0.41	-1.05	0.42	0.74	-0.51	**0.94*****	**3.22****	0.48
Housing	Local	-0.14	**0.25*****	-0.11	**-0.16****	0.07	-0.07	**0.24****	0.13	-0.12	-0.05
	Non-Local	-0.08	0.08	0.23	-0.2	0.1	-0.07	-0.06	-0.04	-0.01	0.01

Note1: **: $p < 0.05$, ***: $p < 0.01$. The same applies hereafter.

[14] We apply equation (1) to each topic frequency ratio respectively because the correlations between each topic are from 0.08 to 0.8 and several topic frequency ratios would cause multicollinearity.
[15] We note that this study uses relatively large numbers of observations, and statistical significances (p-values) do not directly estimate the strength of related variables. Among the statistically significant topic frequency ratios (Tk), the largest effect size (Cohen's f^2) is 0.01. Future studies need to analyze how to improve accuracy of estimating disaster recovery activities with social media related variables by, for example, applying other social media related variables and by applying different models.

Note2: We found that both heteroskedasticity and serial correlation exist (Breusch-Pagan statistics' p-value are all less than 0.01. Durbin-Watson statistics' p-values are less than 0.01). Therefore, the standard errors are corrected for serial correlation and heteroscedasticity by using the Newey-West procedure.

Note3: The Variance Inflation Factor (VIF) of each regression for the housing datasets is from 1.00 to 2.08. The VIF of each regression for used cars is from 1.00 to 1.18. These VIF scores suggest there are no multicollinearity problems.

DISCUSSION

By applying the Hedonic model, this study observed whether there were correlations between social media communication topics and the excess demand for used cars and housing as proxies of socio-economic recovery activities in the disaster-stricken area (RQ1). Also, we analyzed whether the excess demand for used cars and housing correlated differently with communication topics (RQ2) and whether there were any differences in social media communication posted by people local and non-local to the disaster-stricken area (RQ3). We present our discussion according to these research questions.

Regarding RQ1, by applying equation 1, we found that several topic frequency ratios had statistically significant correlations with the excess demand for used cars and housing. These results imply that the topic appearance ratios on Twitter might be useful in detecting people's socio-economic recovery activities in the real world.

Regarding RQ2, the results suggest that the different types of the two goods correlated to different topic frequency ratios. To be specific, regarding used cars, we found that the excess demand for used cars correlated to the frequency ratios of topics related to nuclear-related activities (Topic 3), evacuation (Topic 4), recovery (Topics 5) and damage (Topic 9) within the Local Tweets dataset. Also, the frequency ratios of topics related to going to (Topic 7) and supporting (Topic 8) the disaster-stricken area within the *Non-Local Tweets dataset* correlated with the excess demand for used cars. On the other hand, regarding housing, we found that the excess demand for housing correlated to frequency ratios of topics related to people's opinion (Topic1), nuclear activities (Topic3) and means of transportation/logistics (Topic 6) within the *Local Tweets dataset*. It is interesting to focus on topics related to nuclear activities (Topic 3) because the excess demand for both goods, used cars and housing, correlated with the topics (Topic3), but they correlated in different ways: The excess demand for used cars had positive correlations with nuclear activities while the excess demand for housing had negative correlations with the topic. This implies that because nuclear-related issues caused anxiety among people in the disaster-stricken area, they started to rent new places to resettle when uncertainty about nuclear-related issues gradually diminished. On the other hand, locals might have started to purchase used cars even while there were concerns related to nuclear-

related issues.

Regarding RQ3, the analysis implies that communication posted by locals and non-locals correlated differently with the excess demand for used cars. This study found that there were negative correlations between the used cars and the frequency ratios of topics related to evacuation (Topic 4). This implies that when people in the disaster-stricken area were still in evacuation shelters, there was less need to obtain or replace vehicles. Moreover, we found positive correlations between the excess demand for used cars and the frequency ratios of topics related to nuclear-related activities (Topics 3), recovery (Table 5) and damage (Topic 9) within the *Local Tweets dataset,* and topics related to going to and supporting the disaster-stricken area (Topics 7&8) within the *Non-Local Tweets dataset*. This implies that the local population might have communicated more about nuclear-related activities (Topic 3), recovery (Topics 5) and damage (Topic 9) while people became active in recovery efforts and restarted their daily lives as observed in the excess demand for used cars. Meanwhile, people outside of the disaster-stricken area tended to communicate more about going to and supporting the affected area (Topics 7&8). These results are similar to the findings of the previous study that found local people tended to share images of response, recovery and damages while the non-local population tended to share images of people suffering (Bica et al., 2017). This is because local residents needed to face realities and be strong in order to return back to normal routines while people from the outside may have tried to support the disaster-stricken area because they knew of local people's continuous struggles to recover. Our results imply that, for recovery phases, it is also important to distinguish communications posted by locals and non-locals.

In addition, regarding housing demand, we found positive correlations between the excess demand for housing and the frequency ratios of topics related to people's opinions (Topic1) and the means of transportation/logistics (Topic 6) within the *Local Tweets dataset* while there were no correlations between topic frequency ratios within the *Non-Local Tweets dataset* and the excess demand for housing. These results imply that people in the disaster-stricken area started to express their opinions about the situations surrounding them, such as recovery progress while people in the disaster-stricken area started to resettle as observed in the excess demand for housing. Although it is difficult to interpret the correlations between the excess demand for housing and the topic frequency ratios of topics related to transportation means (Topic6), this result might be reflected in the contents of tweets labeled as Topic 6. The tweets categorized as Topic 6 include less communication about car scarcity and the need to buy cars while Topic 6 tweets include more communication about a lack of gas, which might have tended to occur after people purchased used cars, and more communication about public transportation system recovery updates (e.g., tweets sharing the information about train service status).

CONCLUSION

The object of this study was to address how social media data could be used for detecting recovery in disaster-stricken communities. We empirically analyzed the correlations between topic frequency variations in disaster-related tweets after the Great East Japan Earthquake and Tsunami of 2011 and two types of proxies of socio-economic recovery activities, namely the excess demand for used cars and the excess demand for housing. The results showed several statistically significant correlations between social media communication topic frequency ratios and the excess demand for both used cars and housing. These results provide evidence to support the possibility of using social media communication for detecting socio-economic recovery activities in a disaster-stricken area. Furthermore, the excess demands for two different types of goods (used cars and housing) had different types of correlations with socio-economic recovery activities. More specifically, our study implies that people in the disaster-stricken area started to be active in recovering and restarting their daily-lives as observed in the excess demand for used cars when there were more communications related to recovery and disaster damage among them. Also, during those periods, there tended to be more communication related to going to and supporting the affected area among the non-local population. In contrast, when the local population started to resettle, they might have communicated more opinions about their situations. Furthermore, our results imply that tweets posted by people local and non-local to the disaster-stricken area might have had different types of correlations with the socio-economic recovery activities.

The academic contribution of this study is that we were able to show the potential usefulness of social media for detecting socio-economic recovery activities, which has not been adequately studied among previous related studies. Furthermore, we were able to demonstrate that communication posted by local and non-local populations had different types of correlations with people's activities in the real world. This indicates that when we study social media communication for recovery, different communication patterns among local and non-local populations should be considered.

However, the authors acknowledge that this work is the first of its kind to examine the possibility of using social media data for detecting recovery activities. There are several limitations. This study collected tweets that contained specific words related to the disaster and disaster recovery activities as explained in the Data section and thus, the keywords might have affected the overall findings. In addition, we note that there is a likelihood of there being other intervening variables for topic frequency ratios. Further research is needed to analyze causality

and direct relationships between topic frequency ratios and recovery activities. There is a need to expand the current study by, for example, analyzing the relationships between social media data and other types of recovery activities in the real world, as well as investigating recent large-scale disasters to understand general baselines of disaster recovery activities. Extracting variable communication topics which are beneficial for disaster responders and managers is another important study topic to demonstrate how social media could be used in all the stages of disaster management. Future studies also need to find effective way to distinguish between posts by locals from those by non-locals.

ACKNOWLEDGEMENTS

This study was partially supported by a research grant, "Proto Award.". The author would like to show gratitude to the Proto Corporation for providing various used-car market data and financial support. This study is also partially supported by the Graduate Program for Social ICT Global Creative Leaders (GCL). In addition, the study is supported by Joint Research Program No.823 at CSIC, The University of Tokyo ("Real Estate Database 1999-2016" by At Home Co., Ltd.).

ABSTRACT

Over the last few years, extensive research has been conducted to develop technologies to support humanitarian aid tasks. However, many technologies are still limited as they require both manual and automatic approaches, and more importantly, are not ready to be integrated into the disaster response workflows. To tackle this limitation, we develop automatic data processing services that are freely and publicly available, and made to be simple, efficient, and accessible to non-experts. Our services take textual messages (e.g., tweets, Facebook posts, SMS) as input to determine (i) which *disaster type* the message belongs to, (ii) whether it is *informative* or not, and (iii) what *type of humanitarian information* it conveys. We built our services upon machine learning classifiers that are obtained from large-scale comparative experiments utilizing both classical and deep learning algorithms. Our services outperform state-of-the-art publicly available tools in terms of classification accuracy.

Keywords

Social media, humanitarian data processing, text classification, application programming interfaces, data processing services.

INTRODUCTION

In the last decade, we have witnessed a significant increase in the use of Information and Communications Technologies (ICT), mobile devices, and sensors during time-critical events such as natural or human-induced disasters (Wattegama 2014; Imran, Castillo, Diaz, et al. 2015). This increase in the number of data sources results in producing more and more data each day. These data sources include social media platforms (e.g., Facebook and Twitter), WhatsApp groups, SMS communications, web blogs, news articles, RSS feeds, and many more. The combination of easy-to-use technologies and data sources generate vast amounts of data at high velocity, i.e., thousands of documents appear each second.

Extracting useful information from these sources is highly important for humanitarian organizations, government agencies, and public administrative authorities to make timely decisions and to launch relief efforts during emergency situations (Starbird et al. 2010; Vieweg, Hughes, et al. 2010). The information needs of these stakeholders vary depending on their role, responsibilities, and the situation they are dealing with (Vieweg, Castillo, et al. 2014). Often extracting such information becomes difficult for non-technical domain experts from these high volume data sources. It is reported in the literature that manual analysis of such high-volume and high-velocity social media data streams is impossible (Hiltz et al. 2014; Ludwig et al. 2015).

*Corresponding author

Dealing with such large data sources and extracting useful information from them involve many challenges such as parsing unstructured and brief content, filtering out irrelevant and noisy content, handling information overload, among others. Over the last few years, many Artificial Intelligence (AI) techniques and computational methods have been proposed to process social media data for disaster response and management. These techniques aim to solve various challenges ranging from information filtering, overload, and categorization to summarization (Castillo 2016; Rudra et al. 2018; Imran, Castillo, Diaz, et al. 2015). In addition, there have been publicly available tools that collect social media data and automatically categorize them during disaster events (Imran, Castillo, Lucas, et al. 2014; Burel, Saif, Fernandez, et al. 2017; Meier 2012; Okolloh 2009). The common features of these systems include classifying tweets, grouping them into clusters, visualizing them into timelines, geotagging them onto maps, and visualizing topics, sentiment, and concepts over time. We elaborate further on these systems in the Related Work section.

In this paper, as an attempt to shed more light in the direction motivated by the aforementioned studies, we develop automatic data processing services to assist both technical and non-technical end-users including crisis managers, officials from formal humanitarian organizations, first responders, volunteering organizations, non-governmental organizations (NGOs), and researchers in the crisis informatics community in their humanitarian tasks. Specifically, we provide the following services, which are also the contributions of this paper:

- **Disaster type classification:** This service aims to determine whether a text message (e.g., a tweet or a Facebook post or an SMS) is about one of the six disaster types, namely *earthquake*, *fire*, *flood*, *hurricane*, *bombing*, and *shooting*.
- **Informativeness classification:** This service determines whether a text message is *informative* for humanitarian aid purposes or not. Informative messages contain useful information for response organizations to plan and launch relief efforts.
- **Humanitarian information type classification:** The aim of this service is to classify whether a text message is about one of the following ten humanitarian information types: *affected individual*, *caution and advice*, *displaced and evacuations*, *donation and volunteering*, *infrastructure and utilities damage*, *injured or dead people*, *missing and found people*, *response efforts*, and *sympathy and support*. More details about these humanitarian information types are given in the later sections.
- **Crisis Data Processing Services (CrisisDPS):** To provide the aforementioned three classification services to end-users, we develop an end-to-end system that offers various RESTful Application Program Interfaces (APIs). Specifically, we provide separate APIs for (i) single item processing and (ii) batch processing in addition to (iii) a file processing service.
- **State-of-the-art classification models:** We develop state-of-the-art supervised machine learning models to support the aforementioned three classification services.

To develop the underlying machine learning models, we have conducted extensive experiments using both classical and deep learning algorithms. The classical algorithms include Naïve Bayes (NB) (McCallum, Nigam, et al. 1998), Support Vector Machines (SVM) (Hearst et al. 1998) and Random Forests (RF) (Liaw, Wiener, et al. 2002) whereas the deep learning algorithms include Convolutional Neural Networks (CNN) (LeCun et al. 1989), and Long Short-Term Memory Neural Networks (LSTM) (Hochreiter and Schmidhuber 1997). We have also collected and combined many publicly available datasets such as CrisisLex[1], CrisisNLP[2], among others. While consolidating these datasets, one of the challenges was the mismatch between class labels across datasets. We manually mapped the mismatches and selected the class labels that can effectively serve humanitarian purposes. More details can be found in the Datasets section. We make all of our services publicly available to potential end-users at no cost.

The rest of the paper is organized as follows. In the next section, we present a literature review. Next, we describe our data processing services. After that, we present the details of the datasets that we used to develop our machine learning models. Then, we present our experiments, results and discussion. Finally, we conclude the paper in the last section.

RELATED WORK

There has been significant progress in crisis computing research with a particular focus on mainly facilitating humanitarian organizations in their relief efforts and supporting their decision-making processes. One of the key research activities has been analyzing social media content. There are many studies that leverage social media such as Twitter, Facebook and YouTube for curating, analyzing, and summarizing crisis-related information in order to extract situational awareness and actionable information (Zade et al. 2018; Imran, Castillo, Lucas, et al. 2014; Vieweg, Hughes, et al. 2010; Terpstra et al. 2012; Tsou et al. 2017). Among different social media platforms, Twitter has been used extensively due to the fact that information appears timely and can be accessed and processed effectively, which are the required key features for the humanitarian organizations. Apart from research studies, many systems have been developed over time, some of which are publicly and freely available. We briefly cover some of these research studies and tools in this section.

Below we provide a list of available tools and systems that utilize social media data to extract crisis-related information.

- Ushahidi (Meier 2012; Okolloh 2009)[3]: Ushahidi is a platform that started its journey back in 2008 as a free and open-source platform that allowed interested individuals and groups to create live, interactive maps. Initially, it aimed to visualize post-election messages on a map. Its current functionality includes mapping and visualization tools to create real-time, dynamic, and multifaceted crisis maps. It allows for visualizing how a crisis situation is evolving over time. A notable deployment is the 2010 Haiti earthquake (Goolsby 2010). It is currently providing one-month-free and premium supports to its users.
- TweetTracker (Kumar et al. 2011)[4]: TweetTracker is another application aimed at supporting Humanitarian Aid and Disaster Relief (HADR) responders to monitor and analyze social media content during crisis situations. The functionality of this tool includes analyzing location, real-time trending, data filtering, and historical analysis.
- Tweedr[5]: Tweedr is another tool that aimed to extract actionable information during natural disasters from Twitter. The functionality of the tool includes clustering and classification.
- Artificial Intelligence for Disaster Response (AIDR) (Imran, Castillo, Lucas, et al. 2014)[6]: AIDR is an active system that facilitates users (e.g., humanitarian organizations) to collect tweets during disaster events and create classifiers on-the-fly by annotating incoming Twitter data according to the categories of their own choices. It is freely available with minimal usability effort.
- Twitris (Purohit and Sheth 2013)[7]: Twitris application is also targeted for Twitter content analysis. The functionality of this system includes collecting, aggregating, and analyzing tweets to give deeper insights as well as facilitate the research and development process.
- SensePlace2 (MacEachren et al. 2011)[8]: SensePlace2 application is focused more on extracting spatiotemporal information with analytic capabilities to deal with large volumes of tweets.
- Enhanced Messaging for the Emergency Response Sector (EMERSE) (Caragea et al. 2011): This system has been developed to analyze tweets and SMS messages. The major functionality of this system includes Twitter crawler, machine translation system, and classification modules while also supporting users with an iPhone application.
- Emergency Situation Awareness (ESA) (Yin et al. 2012)[9]: ESA is aimed at enhancing situational awareness with respect to crises induced by natural hazards, particularly earthquakes. They focus on spatio-temporal information and functionalities include event detection, text classification, online clustering, and geotagging.
- Twicident (Abel et al. 2012)[10]: Twicident is a framework and system that automatically track and filter information, which is relevant for real-world incidents or crises.

[9] https://esa.csiro.au/aus/index.html
[10] http://www.wis.ewi.tudelft.nl/twitcident/

- Pipeline for Post-Crisis Twitter Data Acquisition (Kejriwal and Gu 2018): This is an ongoing effort that aims to develop a system that requires minimal supervision in an active learning framework.
- Crisis Event Extraction Service (CREES) (Burel and Alani 2018)[11]: CREES is an open-source web API to automatically classify social media posts during crisis situations. The system is developed for three different tasks, where the classification models are based on deep learning algorithms. One can deploy the system on their own server to use the API functionality. This system is currently integrated into the Ushahidi platform as part of the COMRADES project[12].
- Botometer (Varol et al. 2017)[13]: Botometer is an application aimed to detect accounts that are controlled by automated tools, termed as social bots. Such an application is important to detect and filter fake or manipulated content on social media.

As for the crisis-related tweet classification research, current literature explores both classical algorithms (e.g., Maximum Entropy, Logistic Regression (LR), Random Forest (RF), Naïve Bayes (NB) classifier, Support Vector Machines (SVM), and Conditional Random Fields (CRFs)) and deep learning techniques (e.g., Convolutional Neural Networks (CNN), Recurrent Neural Networks (RNN), and Long Short-term Memory Neural Networks (LSTM)). In (Imran, S. Elbassuoni, et al. 2013; Imran, S. M. Elbassuoni, et al. 2013), authors report different datasets and NB- and CRF-based classifiers to extract actionable information during disaster events. The feature sets used for developing the classifiers include word unigrams, bigrams, Part-of-Speech (POS) tags, among others. In (Nguyen et al. 2017), authors report a comparative study using classical and deep learning-based algorithms, including SVM, LR, RF, and CNN. Their experimental setting also consists of in-domain and out-domain configurations. Across all experimental configurations, CNN outperforms other algorithms. A similar comparative study has been conducted in (Burel, Saif, Fernandez, et al. 2017; Burel and Alani 2018), where the authors explore different types of features. Their study includes three classification tasks such as (i) related *vs.* not-related, (ii) event types, and (iii) information types. Their findings suggest that SVM and CNN provide very competitive results. The study of Aipe et al. 2018 explores CNN with other tweet-centric (e.g., user mentions, hashtags, and their combinations) features. They report results that outperform state-of-the-art results, which used a similar dataset such as CrisisNLP[14]. However, different than our work, they map class labels of CrisisNLP with a set of their own classes. In another study, Neppalli et al. 2018 compare NB, CNN and Recurrent Neural Network (RNN) with different feature combinations and suggest that CNN outperforms the other models. For a more extensive literature review on this subject, we refer the reader to the study conducted by Imran, Castillo, Diaz, et al. 2015.

SYSTEM AND DATA PROCESSING SERVICES

In this work, we present CrisisDPS, a system to process crisis-related data to support multiple humanitarian tasks. The system is developed to facilitate both technical and non-technical users in the domains of crisis informatics and humanitarian aid working at various levels in an organizational hierarchy, e.g., in an Incident-Command System (ICS)[15], Public Information Officers (PIOs), Safety officers, logistics sections, etc. As most humanitarian organizations already have their information systems, our goal is to provide them with ready-to-use data processing services that can be easily integrated into their existing systems, for example, through a new widget backed by one of the CrisisDPS services.

Figure 1 depicts various functionalities of the CrisisDPS system at a high-level. The system mainly provides three types of data processing services, namely (i) disaster type classification, (ii) informativeness classification, and (iii) humanitarian information type classification. We describe each of these services in detail later in this section. Each classification service offers three types of functionality: (i) single-item processing API, (ii) batch processing API, and (iii) file processing service. Furthermore, we also offer a web demo service to test the system online.

Data Processing Services

The three types of data processing services provided by the CrisisDPS system are described below.

1. Disaster type classification: This service aims to classify a given text message into one of the six disaster types, namely, *earthquake*, *fire*, *flood*, *hurricane*, *bombing*, and *shooting*. We also offer a general category called *none*,

[11] https://evhart.github.io/crees/

[13] https://botometer.iuni.iu.edu/#!/api
[14] http://crisisnlp.qcri.org/
[15] https://en.wikipedia.org/wiki/Incident_Command_System

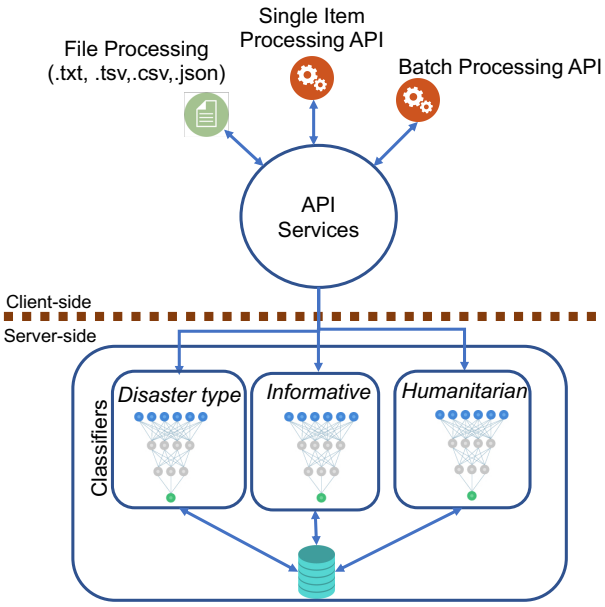

Figure 1. CrisisDPS: Crisis Data Processing Services

which represents everything else that does not belong to any of the six disaster types. The motivation behind this service is to determine whether a message belongs to a particular disaster event or not before dispatching it for further processing. Moreover, this service could be useful for decision-makers in an emergency department who are dealing with multiple disasters at a time helping them to distinguish disaster-specific messages.

2. Informativeness classification: To determine whether a text message contains some useful information for disaster managers or not, we provide the "informativeness" service. Given a text message, the service classifies it either as *informative* or *not informative*. We consider a message as *informative* if it contains some useful information for humanitarian aid; such as disaster-related warnings, reports about injured, dead, or affected people, rescue requests, volunteering or donation offers, reports of damaged houses, roads, etc.

3. Humanitarian information type classification: Given a message is *informative*, which means it contains some useful information for humanitarian aid, the next task is to determine what kind of useful information it conveys. For this purpose, we provide humanitarian information type services. These services correspond to a set of automatic classification services to classify a given text message into one of the ten humanitarian information types described below:

1. *Affected individual:* messages that contain information about affected people due to a disaster event;
2. *Caution and advice:* messages that report warnings, cautions, and give advice to people in the disaster area;
3. *Displaced and evacuations:* messages that report about displaced people or evacuations due to the disaster event;
4. *Donation and volunteering:* messages that request for donations, e.g., food, water, shelter, or offer help or volunteering services;
5. *Infrastructure and utilities damage:* messages that report damages to built structures such as buildings, roads, and bridges;
6. *Injured or dead people:* messages that report injured or dead people due to the disaster event;
7. *Missing and found people:* messages that report missing or found people due to the disaster event;
8. *Requests or needs:* messages that contain requests or urgent needs of affected people;
9. *Response efforts:* messages that report ongoing response efforts by humanitarian organizations, NGOs, and volunteers;
10. *Sympathy and support:* messages that convey thoughts, prayers, sympathy, and support to the victims of the disaster;

11. *Not informative:* messages that do not belong to any of the previous categories or do not contain any useful information.

All three types of classification services are backed by state-of-the-art machine learning classifiers. Specifically, we used supervised machine learning approaches to train the classifiers. More details about these classifiers and the datasets used for training them are given in the next section.

CrisisDPS APIs

The CrisisDPS system provides three types of RESTful APIs for each one of the three classification services. Next, we describe these APIs:

1. Single-item processing API: This programmatic API provides support to classify a single item (e.g., one tweet, or a Facebook message) at a time. Given an item, one can specify one or more classification services to classify it. For example, given a tweet, we want to determine whether it is an *earthquake* or a *hurricane* tweet and whether it contains some useful information or not. Moreover, if it contains useful information, what type of information it contains.

2. Batch processing API: To process more than one items in a batch, the system provides a batch processing programmatic API. For example, given a set of 10,000 tweets, the task is to classify each tweet to determine their informativeness or what humanitarian information they report.

3. File processing service: For non-technical end-users who cannot use our programmatic APIs, we provide a file processing service through a web interface. Figure 2 shows the file uploading interface. Given a file containing a list of messages, tweets, or Facebook posts, this API can classify each message using one or more of the classification services that the end-user selects. Currently, we support four file types: TXT (text files), JSON (JavaScript Object Notation), TSV (Tab-separated values), and CSV (Comma-separated values). Non-technical end-users can easily use the file processing interface to facilitate their humanitarian tasks.

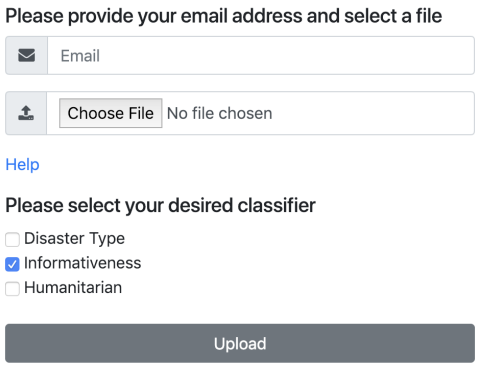

Figure 2. Web interface of the file processing service.

The APIs are implemented in the Java language using the Jersey framework[16], which is an open source and production quality framework for developing RESTful web services in Java. It is combined with Spring[17] and Hibernate[18] frameworks to communicate with databases. The single-item and batch processing APIs only offer programmatic access to use the classification services. However, the file processing API offers a web interface. All the services, APIs, and technical details regarding how to use these APIs with examples are provided on the CrisisDPS website: `http://crisisdps.qcri.org/`. Figure 3 shows a screenshot of the demo page with example tweets and outputs of the selected classification services.

DATASETS

In this work, we use several publicly available datasets including CrisisLex, CrisisNLP, among others. One of the difficulties that arise while combining different datasets is the discrepancies in the class labels. For example, in one dataset, the negative class is labeled as *not-related* while in another one as *not-informative*. Even though these two labels are semantically the same in theory, they are still two different labels in practice. Therefore, for our task

[16] `https://jersey.github.io`. Currently, we use Jersey, in future we might consider to use Spring REST.
[17] `https://spring.io/`
[18] `http://hibernate.org/`

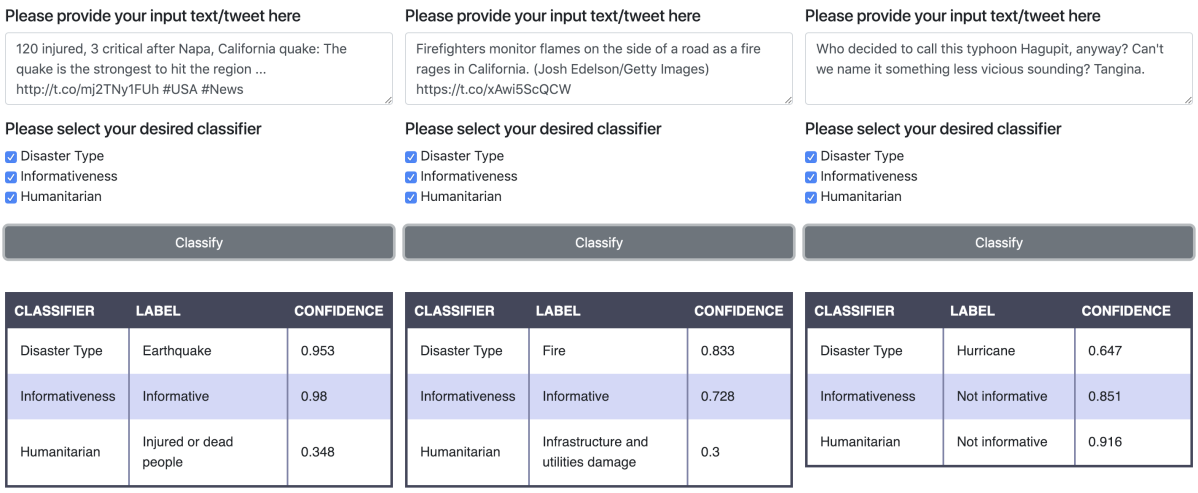

Figure 3. Example usages of the demo page.

we mapped the semantically similar categories to have a unique class label. In addition, we have also filtered out instances with low frequencies and less relevance to the humanitarian tasks at hand. For example, we removed the instances with class labels such as *animal management*, *non-government*, *traditional media*, *terrorism-related*, and *terrorism-related information*. We also removed non-English tweets.

For this study, we aim to develop three different classifiers to serve three different classification tasks: (i) disaster type classification, (ii) informativeness classification, and (iii) humanitarian information type classification. To prepare the data for the informativeness task, we selected all the tweets with *informative/related* class labels and the tweets with humanitarian categories as *informative* and considered the rest as *not-informative*. For the humanitarian information type classification task, we selected data that are labeled with humanitarian categories, which resulted in ten categories as listed in Table 3. In this dataset we have also included instances with *not-informative* label, however, we have only selected a random sample from the whole set of *not-informative* instances. For the disaster type classification task, we selected tweets with the following six disaster types: *bombing*, *earthquake*, *fire*, *flood*, *hurricane*, and *shooting*. In addition, we have also included *none* category as the "background" class. That is, the tweets that do not belong to any of the mentioned six disaster types are considered as belonging to the *none* category.

For the sake of completeness, we provide below brief descriptions of the datasets consolidated for the experiments.

- AIDR[19] is a publicly available system that has been developed to support humanitarian organizations and research community. The system has a functionality that allows users to annotate data while collecting tweets. Over time, AIDR has collected data from many events both labeled and unlabeled. We only selected manually labeled data that are relevant to this study.
- CrisisLex[20] comprises two different datasets, i.e., CrisisLexT26 and CrisisLexT6, that have been used and reported in the literature for crisis informatics research. The CrisisLexT26 is one of the largest datasets consisting of 26 different crisis events that took place in 2012 and 2013 (Olteanu et al. 2014). This dataset was prepared to explore two different crisis dimensions. First dimension is the disaster type (natural *vs.* human-induced), their sub-type (e.g. meteorological, hydrological, etc.), temporal characteristics (instantaneous *vs.* progressive), and geographic spread (focalized *vs.* diffused). The second dimension is the content type in which several type of categories and sub-categories were identified, including informativeness (informative *vs.* not-informative), information type (six different subcategories), and source of information (i.e., an eyewitness, government, NGOs, Business, Media, and Outsiders). The second dataset, CrisisLexT6, consists of six disasters that took place between October 2012 and July 2013 in USA, Canada, and Australia. Crisis keywords and locations have been used during the data collection process (Olteanu et al. 2014). Approximately $10K$ tweets have been annotated using Figure Eight[21] (also known as CrowdFlower) from each crisis event. Annotation of this dataset includes *related vs. not-related*.

[19] http://aidr.qcri.org/
[20] https://crisislex.org
[21] https://www.figure-eight.com/

- CrisisMMD[22] is a multimodal dataset consisting of tweets and associated images (Alam, Ofli, et al. 2018). Tweets have been collected from seven natural disasters that took place in 2017. The annotations include three tasks: (i) *informative vs. not-informative*, (ii) humanitarian categories (eight classes), and (iii) damage severity (three classes). The third annotation task, i.e., damage severity, was applied only on images. The annotation for text and images was run independently for each event using Figure Eight.
- CrisisNLP[23] consists of ~50K tweets, which have been collected from 19 different disasters that took place between 2013 and 2015. The dataset was annotated in two steps. The first set of annotations was obtained using Stand-By-Task-Force (SBTF)[24] volunteers. The second set of annotations was curated using Figure Eight.
- Disaster Response Data[25] contain 30K tweets collected during disasters such as an earthquake in Haiti, 2010; an earthquake in Chile, 2010; floods in Pakistan, 2010; Hurricane Sandy in USA, 2012, and news articles. The annotations include 36 different categories.
- Disasters on Social Media[26] dataset consists of 10K tweets collected and annotated with labels *related* vs. *not-related* to the disasters.
- SWDM[27] consists of two data collections. The Joplin collection contains tweets collected during the tornado that struck Joplin, Missouri on May 22, 2011. The Sandy collection contains tweets collected during Hurricane Sandy, that hit Northeastern US on Oct 29, 2012. The Joplin dataset consists of 4,400 labeled instances and the Sandy dataset consists of 2,000 labeled instances (Imran, S. Elbassuoni, et al. 2013).

After consolidating data from all these collections, we prepared three datasets for three different classification tasks. Tables 2, 3 and 1 present the class distributions of our datasets for disaster type, informativeness, and humanitarian information type, respectively. We split each dataset into three subsets using 70%, 10% and 20% as training, development and test, respectively. The training set is used to learn the model, the development (dev) set is used for parameter tuning, and the test set is used for the model evaluation.

Table 1. Data split for disaster type classification.

Classes	Train (70%)	Dev (10%)	Test (20%)	Total	Class Dist.
Bombing	378	53	109	540	0.007
Earthquake	9,088	1,285	2,611	12,984	0.162
Fire	2,185	309	628	3,122	0.039
Flood	10,156	1,436	2,917	14,509	0.181
Hurricane	23,491	3,322	6,746	33,559	0.418
Shooting	527	74	153	754	0.009
None	10,306	1,457	2,961	14,724	0.184
Total	56,131	7,936	16,125	80,192	

Table 2. Data split for informativeness classification.

Classes	Train (70%)	Dev (10%)	Test (20%)	Total	Class Dist.
Informative	131,028	18,531	37,624	187,183	0.639
Not-informative	74,104	10,480	21,280	105,864	0.361
Total	205,132	29,011	58,904	293,047	

EXPERIMENTS, RESULTS, AND DISCUSSION

In this section, we describe the details of our extensive experiments, report our results, and provide a discussion.

Preprocessing

The tweet texts are noisy, usually consisting of many symbols, emoticons, and invisible characters. Therefore, we preprocessed them to use in classification experiments. The preprocessing part includes removal of stop words, non-ASCII characters, punctuations (replaced with whitespace), numbers, URLs, and hashtags.

Classification Experiments

For this study, we have conducted classification experiments using both classical and deep learning algorithms. As for the classical models, we used the three most popular machine learning algorithms, i.e., (i) Naïve Bayes (NB), (ii) Random Forest (RF), and (iii) Support Vector Machines (SVM). The usefulness of these algorithms have been reported in several studies in crisis computing literature (Burel, Saif, and Alani 2017; Neppalli et al. 2018; Imran, Mitra, et al. 2016). As for the deep learning algorithms, we used a Convolutional Neural Network (CNN), which has also been reported as successful in many studies for disaster tweets classification (Nguyen et al. 2017; Burel and Alani 2018).

- The NB algorithm (McCallum, Nigam, et al. 1998) is a simple probabilistic method that calculates a set of probabilities by counting the frequency and combinations of values in a given dataset. The algorithm uses Bayes theorem and stands on the assumption that all attributes are independent given the value of the class variable, which is rarely true in real applications, but it still performs well and learns rapidly in many supervised tasks (Neppalli et al. 2018; Imran, Mitra, et al. 2016).
- The SVM algorithm (Platt 1998) is based on the Structural Risk Minimization principle from computational learning theory. The algorithm is established as universal learners and well-known for its ability to learn independently of the dimensionality of the feature space. These properties of the algorithm make it one of the most popular supervised classification methods.
- Unlike the previous two classical algorithms, the RF algorithm (Liaw, Wiener, et al. 2002) is an ensemble learning algorithm, comprising multiple decision trees where each tree contributes to the classification decision with a single vote. A final class label is assigned based on majority voting. RF reduces variances in the classification by randomizing features and training instances.
- In Figure 4, we present the architecture of our CNN model. The input to the network is a tweet $\mathbf{t} = (w_1, \ldots, w_n)$ containing words each coming from a finite vocabulary $\mathcal{V}$ that we obtained from our training dataset. The first layer of the network maps each of these words into a distributed representation $\mathbb{R}^d$ by looking up a shared embedding matrix $E \in \mathbb{R}^{|\mathcal{V}| \times d}$. We initialized E using a publicly available pre-trained embedding model designed using disaster related tweets[28] (Alam, Joty, et al. 2018). The output of the look-up layer is a matrix $X \in \mathbb{R}^{n \times d}$, which is passed through a number of convolutional and pooling layers to learn higher-level feature representations. A convolution operation applies a *filter* $\mathbf{u} \in \mathbb{R}^{k.d}$ to a window of k vectors to produce a new feature $h_t = f(\mathbf{u}.X_{t:t+k-1})$, where $X_{t:t+k-1}$ is the concatenation of k look-up vectors, and f is a nonlinear

[28] http://crisisnlp.qcri.org/data/lrec2016/crisisNLP_word2vec_model_v1.2.zip

activation. We used rectified linear units (ReLU) as a nonlinear activation function. We apply this filter to each possible k-length windows in X to generate a *feature map*, $\mathbf{h}^j = [h_1, \ldots, h_{n+k-1}]$. This process is repeated N times with N different filters to get N different feature maps. We then apply a *max-pooling* operation, $\mathbf{m} = [\mu_p(\mathbf{h}^1), \cdots, \mu_p(\mathbf{h}^N)]$, where $\mu_p(\mathbf{h}^j)$ refers to the max operation applied to each window of p features in the feature map $\mathbf{h}^i$. Intuitively, the convolution operation composes local features into higher-level representations in the feature maps, and max-pooling extracts the most important aspects of each feature map while reducing the output dimensionality. Since each convolution-pooling operation is performed independently, the features extracted become invariant in order. In order to incorporate order information between the pooled features, we use a fully-connected (dense) layer $\mathbf{z} = f(V\mathbf{m})$, where V is the weight matrix. From which we have another dense layer $\mathbf{z}_c = f(V_c\mathbf{z})$ where V_c is the corresponding weight matrix. The activations $\mathbf{z}_c$ are used for classification. Formally, the classification layer defines a Softmax

$$p(y = k|\mathbf{t}, \theta) = \frac{\exp\left(W_k^T \mathbf{z}_c\right)}{\sum_{k'} \exp\left(W_{k'}^T \mathbf{z}_c\right)} \tag{1}$$

where W_k are the class weights and $\theta = \{V, V_c, W\}$ defines the relevant parameters.

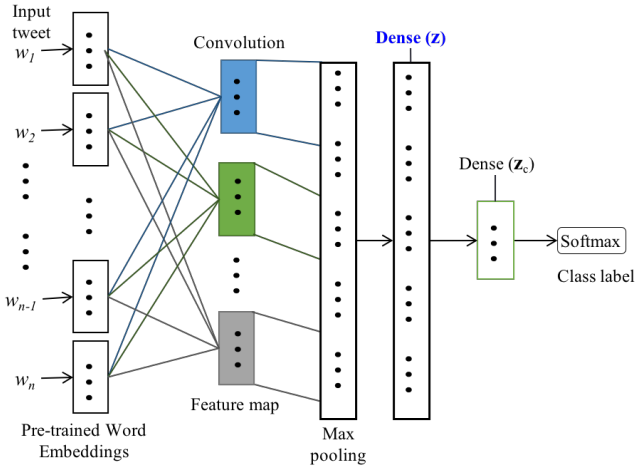

Figure 4. The architecture of the CNN.

To train the classifiers using these classical algorithms, we converted the preprocessed tweets into bag-of-ngrams vectors weighted with logarithmic term frequencies (tf) multiplied with inverse document frequencies (idf), as shown in Equation 2.

$$tf \times idf = log(1 + f_{ij}) \times log\left(\frac{\text{number of tweets}}{\text{number of tweets that include word i}}\right) \tag{2}$$

where f_{ij} is the frequency for word i in tweet j. To take advantage of the contextual benefits of n-grams, we extracted tri-gram features. Because this resulted in a large dictionary and we filtered out lower frequency features by preserving $40K$ most frequent n-grams. For the experiments with SVM and its linear kernel we tune the c parameter, and with RF we tune the number of trees on the development set.

We trained the CNN models using the Adadelta optimizer (Zeiler 2012). The learning rate was set to 0.01 when optimizing on the classification loss. The maximum number of epochs was set to 1,000, and dropout (Srivastava et al. 2014) rate of 0.02 was used to avoid overfitting. We did *early stopping* based on the accuracy on the development set with a patience of 50. We used 100, 150, 200, and 250 filters with the corresponding window size of 2, 3, 4, and 5 respectively. We used a pooling length of 2. We did not tune any hyperparameter (e.g., the size of hidden layers, filter size, dropout rate) in the experimental setting. We also applied batch normalization due to its success reported in the literature (Ioffe and Szegedy 2015).

Table 4 summarizes the results obtained by different classification algorithms described above. We provide weighted average precision (P), recall (R) and F1-measure (F1) for each task. The rationale behind choosing the weighted metric is that it takes into account the class imbalance problem. The performance of the NB model is lower than other models. Whereas RF and SVM model provides competitive results across different tasks. For the informativeness task RF outperforms SVM, whereas for humanitarian and disaster type tasks SVM outperforms RF. We obtain higher results consistently across all the tasks using CNN.

Table 4. Classification performance comparison of all the classifiers on three different tasks.

	Disaster Type				Informativeness				Humanitarian			
	Acc	**P**	**R**	**F1**	**Acc**	**P**	**R**	**F1**	**Acc**	**P**	**R**	**F1**

Other useful information	X
Sympathy and support	*Sympathy and support*

X indicates the CREES class labels that were not considered in this work.

Baseline Comparisons

To compute the baseline results we used the publicly available deep learning models[29] reported in (Burel and Alani 2018). The CREES API consists of three models for three different tasks such as (i) related *vs.* not-related, (ii) event type (11 class labels), and (iii) information type (i.e., humanitarian categories). To evaluate the performance of the CREES models and have the baseline results for our study, we used our test set and mapped the class labels as shown in Table 5.

Table 6. Comparative results for disaster type classification.

	CREES			CrisisDPS		
Classes	**P**	**R**	**F1**	**P**	**R**	**F1**
Bombing	0.54	0.83	0.66	0.94	0.93	**0.94**
Earthquake	0.96	0.66	0.78	0.92	0.94	**0.93**
Fire	0.85	0.88	0.86	0.95	0.93	**0.94**
Flood	0.35	0.94	0.51	0.94	0.93	**0.93**
Hurricane	0.98	0.1	0.18	0.93	0.96	**0.95**
Shooting	0.97	0.96	0.97	1.00	0.99	**0.99**
None	0.45	0.73	0.55	0.94	0.87	**0.91**
W/Avg	0.76	0.50	0.45	0.93	0.93	**0.93**

In Tables 6, 7, and 8, we provide class-wise precision (P), recall (R) and F1-measure (F1) as well as their weighted average both for the baseline CREES models and the proposed CrisisDPS models. We observed that there is a significant performance difference across all classification tasks compared to the results reported in the study of CREES (Burel and Alani 2018). For the humanitarian categories, the CREES model is designed using eight class

[29] https://github.com/evhart/crees

labels, whereas our model is designed with eleven class labels. Hence, in Table 8, we do not have results for some class labels using the CREES model. In Table 8, the weighted average results for CrisisDPS are computed using only the subset of categories available in CREES for a fair comparison.

Table 7. Comparative results for informativeness classification.

* computed using only the subset of categories available in CREES.

Discussion and Future Directions

We have provided comparative results between classical and deep learning models. We have also compared the performance of our best model with publicly available models. Even though we have only provided an end-to-end comparison with the CREES models in this study, our models also outperform some other existing works such as (Nguyen et al. 2017; Neppalli et al. 2018).

To estimate the load of our system, we plan to have an extensive study in the future and plan to deploy the system accordingly. We also plan to make the system more scalable. Other future work includes integrating image processing modules such as finding an informative image, identifying their humanitarian information type, and assessing the damage content.

Even though we developed the classification models using only social media data such as tweets, the CrisisDPS system can easily be extended by integrating other models. The benefit of CrisisDPS is that it provides services with RESTful APIs by taking the burden of running them on a local server. Such facilities can be helpful for humanitarian organizations and crisis computing research community to develop their own applications and systems using our services. Our goal is to make the CrisisDPS freely available, however, an authentication system will be implemented to control the rate limit (e.g., data processing limit per day per user) and to prevent potential abuse of the system so that every user can get equal benefit from the system.

CONCLUSIONS

In this study, we introduced CrisisDPS, a system for automatic data processing services, which comprises state-of-the-art information classification models that enable humanitarian organizations and crisis informatics research community to develop their own applications and systems. Currently, CrisisDPS provide services that can facilitate three important humanitarian tasks: (i) determine which disaster type a text message belongs to, (ii) determine

whether the message is informative for disaster response, and (iii) determine whether it manifests about any humanitarian information type. Such information is highly relevant for humanitarian organizations if processed timely and effectively. The classification models that we developed for these three tasks outperform existing publicly available models. We aim to provide as much flexibility as possible to the end-users who are willing to use our system. For example, our current implementation supports single item and batch processing through different APIs, file processing for different formats, and an online demo page for quick testing purposes. We plan to improve our services based on a thorough user study in the future. We also plan to make the system more scalable and extend it with automatic image processing capabilities.

ABSTRACT

Emergency dispatchers typically answer 911 calls and relay information to first responders; however, new workflows arise when social media analysts are included in emergency dispatch work. In this study we examine emergency dispatch workflows as distributed sensemaking processes performed among 911 call takers, dispatchers, and social media analysts during simulated emergency dispatch operations. In active shooter and water rescue scenarios, emergency dispatch teams including call takers, dispatchers, and social media analysts make sense of unfolding events by analyzing, aggregating, and synthesizing information provided by 911 callers and social media users during each scenario. Findings from the simulations inform design requirements for social media analysis tools that can help analysts detect, seek, and analyze information posted on social media during a crisis, and protocols for coordinating analysts' sensemaking activities with those of 911 call takers and dispatchers in reconfigured emergency dispatch workflows.

sensemaking, emergency dispatch, social media, simulation

INTRODUCTION: INTEGRATING SOCIAL MEDIA IN NEXT-GENERATION EMERGENCY DISPATCH

When someone dials an emergency telephone number like 911, they begin an information processing task that culminates when a first responder arrives at the scene of an emergency. While information dispatched to first responders (i.e. fire, medical, police) constitute the output of this task, the inputs, traditionally provided by 911 callers, are increasing in volume and variety. The development of Next-Generation 911 infrastructure will soon allow people to call, text, or use web-based applications to contact emergency dispatch centers (Holland, 2018), known as Public-Safety Answering-Points (PSAPs), which, increasingly, seek to detect emergencies and gather situational awareness information using data collected from physical and social sensors, including social media.

In the new, data-rich PSAP, the work of emergency dispatchers coordinating information flows between citizens and first responders— the throughput of emergency response— becomes much more complex. Anticipated by data analytics in policing beginning with early statistical tools such as CompStat in New York City and, more recently, dedicated Strategic Decision Support Centers in Chicago (Smith, 2018), PSAPs are beginning to process an array of data inputs from physical (e.g. cameras, license plate readers, and gunshot detectors) and social (e.g. 911 calls and social media) sensors, and digital records databases (e.g. arrests, complaints, summonses, and firearm registries) (Levine & Tisch, 2014). Consequently, PSAPs are transforming from reactive call centers to proactive data analytics and coordination hubs providing first responders with real-time information before, during, and after emergencies.

In this regard, integrating social media in emergency dispatch operations presents PSAPs with distinct opportunities. PSAPs can use social media to disseminate warnings and other emergency-related information during crises when call processing may be disrupted or delayed due to high-call volumes. Utilized for situational awareness, social media can alert PSAP staff to developing emergencies and augment information provided by 911 callers (Grace, Kropczynski, & Tapia, 2018). While prior studies examine the coordination of emergency

dispatch work surrounding traditional call taking and dispatch activities (Furniss & Blandford, 2006; Norri-Sederholm, Seppälä, Saranto, & Paakkonen, 2016; Preusse & Gipson, 2016), Boersma et al. (2016) describe the novel trial of Twitcident, a web-based system for filtering, searching, and analyzing social media data within Dutch emergency dispatch centers. The trial proved "disappointing" as dispatchers had trouble selecting search terms to filter social media data as well as difficulty integrating information from social media and existing information sources. As a result, the system often provided redundant information that did not enhance emergency dispatch operations (p. 243-4). The findings of Boersma et al. suggest that integrating social media in emergency dispatch requires, first, developing social media analysis tools that can provide dispatchers-turned-analysts with relevant information and, second, integrating social media monitoring within emergency dispatch workflows already responsible for gathering and integrating information from multiple 911 callers.

Consequently, this study examines how PSAPs can incorporate social media analysts and social media analysis tools within workflows integrating information from social media and 911 calls during an emergency. We approach these workflows as distributed sensemaking processes performed among 911 call takers, dispatchers, and social media analysts. Whereas prior studies examine sensemaking among social media users posting and engaging social media content during a crisis (Mirbabaie & Zapatka, 2017; Stieglitz, Mirbabaie, & Milde, 2018), or among officials gathering information only from emergency callers (McMaster, Baber, & Duffy, 2012), this study explores how emergency dispatch teams make sense of events during an emergency by analyzing, aggregating, and synthesizing information from social media and 911 calls to address the evolving situational awareness needs of first responders. Conducting simulations to explore new workflows and distributed sensemaking processes of emergency dispatch teams in active shooter and water rescue scenarios, the findings of this study inform design requirements for social media analysis tools that can help analysts detect, seek, and analyze information posted on social media during a crisis, and protocols for coordinating analysts' sensemaking activities with those of 911 call takers and dispatchers in reconfigured emergency dispatch workflows.

THEORY: EMERGENCY DISPATCH AS DISTRIBUTED SENSEMAKING

Following Klein et al. (2007), we approach sensemaking as "a deliberate effort to understand events" (p. 114). Figure 1 illustrates the Data-Frame model of sensemaking, an iterative process of modifying or replacing the current understanding of a situation or "frame." According to Klein et al. (2007), a frame is "an explanatory structure that defines entities by describing their relationship to other entities" (p. 118). Frames can take the form of stories, maps, or scripts (p. 118). Stories provide chronological orderings and causal relationships, while maps provide spatial arrangements from which routes to landmarks can be inferred. Scripts, in contrast, outline cooperative roles and coordinate action by meshing together actors' activities. Importantly, frames both explain a situation and guide information seeking: "a frame is a structure for accounting for the data and guiding the search for more data" (p. 118).

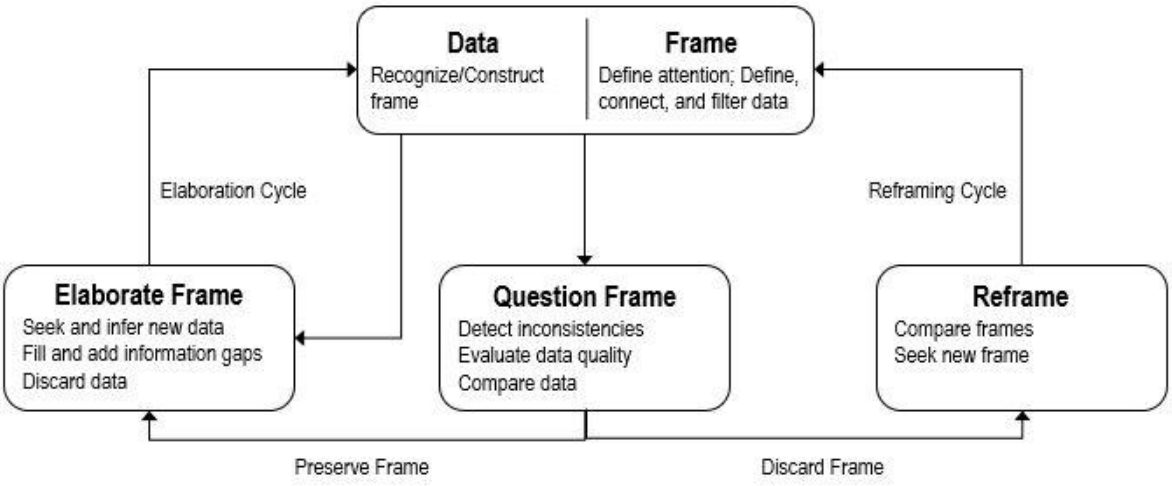

Figure 1. Four Functions of Sensemaking Cycle (Klein et al., 2007)

Shown in Figure 1, sensemaking develops within a frame (A) providing understanding of the situation at hand, to include gaps in understanding that can be addressed by seeking further information. When encountering a new situation, actors can infer frames using only a few data points referred to as "cues" (Weick, Sutcliffe, & Obstfeld, 2005) or "anchors" (Klein et al., 2007): "the initial one or two key data elements we experience sometime serve as anchors for creating an understanding. These anchors elicit the initial frame, and we use that frame to search

for more data elements" (p. 122). Incorporating social media in emergency dispatch requires understanding the repertoire of explanatory frameworks (i.e. frames) dispatchers use to interpret and seek information on social media, as well as the characteristics of social media data (i.e. cues) that facilitate analysis and information seeking (McMaster et al., 2012). To examine how dispatchers use frames in the context of emergency dispatch work, we therefore ask: *(RQ1) How do dispatchers analyze social media data within emergency dispatch workflows?*

The existing frame is elaborated (B) when new information is discovered that provides additional details about the situation. The elaboration loop in Figure 1 represents the process of seeking information to fill (or identify) information gaps and establish new relationships among newly-discovered and existing information characterizing the frame. Incorporating social media in emergency dispatch requires understanding a distributed process of elaboration in which call takers, analysts, and dispatchers seek, analyze, and integrate information from multiple data sources in ways that add to the collective understanding of an emergency. To examine how dispatchers discover new details and elaborate existing frames, we therefore ask: *(RQ2) How do dispatchers search social media data and integrate information from social media and 911 calls?*

Encountering inconsistent data calls into question (C) the existing frame, which can either be preserved and elaborated (to include discarding anomalous data), or reframed (D) by selecting a new frame. These encounters are critical insofar as they allow us to recognize errors and adjust our understanding of dynamic events. As dispatchers use information gathered from social media users and 911 callers to understand evolving emergency events, we ask: *(RQ3) How do dispatchers discover inconsistencies among information from social media and 911 calls?* Moreover, when information about an emergency (e.g. where, what, who) varies among social media posts and 911 calls, dispatchers must compare multiple, incomplete, and inconsistent reports across data sources and determine whether the information provides new details about a known emergency (i.e. elaboration), redundant information (i.e. preservation), or identifies a hitherto unreported emergency (i.e. reframing). Therefore, and lastly, to examine how dispatchers evaluate inconsistent information, we ask: *(RQ4) How do dispatchers determine if information from social media is supplemental, redundant, or novel?*

METHOD: EMERGENCY DISPATCH SIMULATIONS

This study reports findings from scenario-based emergency dispatch simulations conducted at a large, urban PSAP which processes approximately 3000 calls a day. The simulations were organized to provide the PSAP with procedural and technological requirements for incorporating social media in its emergency dispatch operations. Drawing on role play methods in interaction design, the simulations involved participating dispatchers performing the roles of call taker, dispatcher, and social media analyst in a constructed scenario (Medler & Magerko, 2010; Svanaes & Seland, 2004). Widely used in human-centered design, role playing allows researchers to observe plausible interactions among domain-experts and prospective end-users as they develop within hypothetical situations (Medler & Magerko, 2010), especially emergency situations which are difficult to directly observe and inappropriate for research activities (Valkonen & Liinasuo, 2010). The simulations involved six dispatchers performing in teams including a call taker, dispatcher (participants' professional duties in the PSAP), and social media analyst (new specialization under consideration by PSAP administrators), tasked with processing information from synthetic 911 caller and social media datasets using a simulated Computer-Aided Dispatch (CAD) system and analytic dashboard during two mock emergency scenarios.

During a prior workshop held at the PSAP in May 2018, researchers conducted activities with six dispatchers and 25 first responders (fire, medical, and police) to inform the design of two scenarios and associated synthetic social media and 911 call datasets. The workshop involved two activities. First, dispatchers and first responders composed "golden tweets," examples of social media posts that would support situational awareness needs of first responders (blinded for review). Discussed among the examples were golden tweets based on a mall shooting encountered by the PSAP the year prior. These motivated the creation of the *mall shooting dataset*, consisting of 20 emergency-related tweets, four mock 911 calls, and 1000 tweets collected for Charleston County on March 19th, 2018 from 4-6pm (as background noise). Second, sets of 50 weather-related tweets were provided to first responders to sort into piles of "actionable" and "non-actionable" information. The tweets were collected for Charleston County on April 15th, 2018 when the PSAP experienced high call volumes during a severe storm that caused flooding throughout the area. Using the sorted tweets and flood-related golden tweets, researchers created the *severe flooding dataset*, consisting of three emergency-related tweets, 1000 "noise" tweets collected on April 15th, and six mock 911 calls. Importantly, and inspired by our discussions with dispatchers and first responders, the mock tweets and 911 calls in both datasets provide incomplete information (e.g. "what" without "where" information), and therefore required dispatchers to compare and integrate information across these reports to support the situational awareness needs of first responders during each scenario.

Taking place during a follow-up workshop in August 2018, the simulations mimicked a live emergency environment by placing the participating dispatchers in the auxiliary dispatch room of the PSAP in which the call

taker, analyst, and dispatcher took up individual workstations and interacted asynchronously via text-based communication using the simulated CAD environment. The analyst was additionally provided with an analytic dashboard (Toepke, 2018), which included a map to examine geotagged tweets, tweet filtering and visualization using search terms, and word cloud displaying trending hashtags that could be individually selected to visualize associated tweets on the map and tweet list displays (Figure 2). A researcher with an audio recorder was present at each workstation where talk-aloud methods were employed to collect data from the call taker, analyst, and dispatcher as they processed calls or analyzed social media data during each scenario (Jaspers, Steen, Van Den Bos, & Geenen, 2004). The participant in the role of call taker communicated directly with the 911 caller (research confederate) and talked aloud with a researcher while entering information in the simulated CAD. Using activities of the sensemaking cycle- framing, elaboration, questioning, and reframing- as sensitizing concepts, researchers coded the transcribed audio recordings and textual data participants entered in the simulated CAD environment (Strauss, 1987). The researchers discussed and iteratively refined the coded data to address emergent aspects of the distributed sensemaking process, for instance, the use of cues and search heuristics among dispatchers when searching and filtering tweets during each scenario.

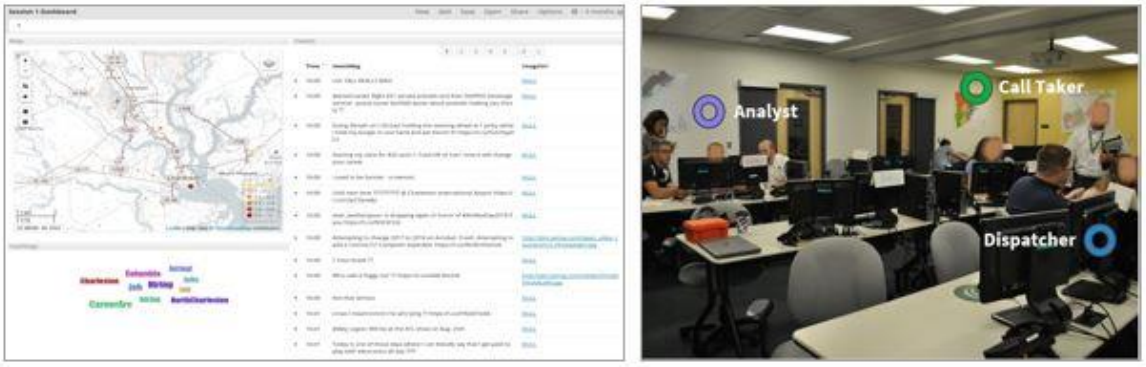

Figure 2. Social media analytics dashboard (left) used in simulations with mock CAD workstations (right)

ANALYSIS: MALL SHOOTING AND FLOODING SCENARIOS

For simulation scenario, a synopsis describes the actions performed by the call taker, dispatcher, and social media analyst, while annotations (*in italics)* associate these distributed activities with sensemaking activities of framing, elaborating, questioning, and reframing. The following discussion analyzes these sensemaking functions in detail by drawing on data collected as call takers, dispatchers, and, especially, social media analysts, explained aloud their actions during each scenario.

Scenario One: Mall Shooting

Scenario one begins when a 911 caller reports gunshots at Citadel Mall and, simultaneously, a dashboard alert identifies tweets describing a "shooting" (Table 1). The dispatch team next processes two additional 911 calls and multiple tweets reporting information on wounded victims, survivors sheltered in place throughout the mall, and the description and whereabouts of the suspect(s). Framing the Emergency using Primary Cues

Alerted that "shooting" had been tweeted, the analyst employs the word as a search term to identify three tweets reporting an emergency:

> #citadellMall #shooting Hiding in Journeys @NCPD 3 people here not injured @CCSO
>
> There are people running and screaming in the mall. Someone is shooting
>
> Shooting at citadel mall in Food Court. Shooter in just walked out

The call taker simultaneously answeres a 911 call describing "loud pops, like someone is shooting here...People were screaming and just running out of the store." Based on primary information cues (e.g. "Citadel Mall," "shooter," "loud pops"), the call taker and analyst recognize the incident type and location, and quickly enter calls 1-2 for an "active assailant" at Citadel Mall. By establishing the primary information necessary to dispatch a response (i.e. where and what), the call taker and analyst contribute to the emergency frame that will guide information seeking and integration among the call taker, analyst, and Dispatcher throughout the duration of the scenario.

Elaboration by Seeking Secondary Information

Next, the analyst searches for secondary information (e.g. weapons, who, when, why) that will support situational awareness among first responders now en route to the scene. Importantly, the emergency frame functions as a story, providing dispatchers with a likely order of events taking place at Citadel Mall, as well as a set of corresponding information requirements:

> For the initial response I want to know who the suspect is and what they look like and where they go… several people have reported that they've ran away so did they run out of the food court, did they run out of where? Did they get into a car? Everything about the suspect.
>
> Once the suspect issue has been dealt with by the police department, then… they can find out where the victims are… From there we would go into where people are sheltered in place. So suspect information first, then where the victims are, and then the sheltered in place. (Analyst, Scenario 1)

The emergency frame, in this case an active assailant incident at Citadel Mall, prioritizes situational awareness (i.e. secondary information) requirements to guide information seeking between the call taker and analyst as they search for new information and, ostensibly, dispatch information first responders need when they need it.

Table 1. Four phases of mall shooting scenario

Call Taker	Answers 911 call: "I'm outside Citadel Mall and there are loud pops like someone is shooting here. I just ran out of target and am driving away…" Enters an active assailant call (2) into CAD *[Framing: Active Assailant]*, and notes that there is no further information on potential suspects or injuries. *[Elaboration: Information gap]*
Analyst	Alerted to tweets describing a "shooting," searches and identifies three tweets and opens a call (1) for an active assailant in CAD *[Framing: Active Assailant]*: "several tweets reporting active shooter at the mall, one person reports near the food court and suspect is possible gone on arrival...one person reports 3 survivors sheltered in place in Journeys, negative injuries with this report." *[Elaboration: Survivors, Information gap]*
Dispatcher	Combines information entered by the call taker and analyst for dispatch (Call 1,2). Sends an alert tone for emergency units to respond to an active assailant incident in progress; begins to provide situational updates to first responders.
Analyst	Searches map; identifies geotagged tweet reporting injuries and enters additional call notes (1) in CAD: "multiple shot near food court and shooter is gone on arrival, no descriptions or specific locations of victims or suspect." *[Elaboration: Victims, Information gap]*
Dispatcher	"One party advising incident occurred near food court, suspect possibly gone on arrival, one party reporting three people sheltered in place at Journeys. Negative injuries reported at this time" (Call 1).
Call Taker	A second call comes in: "I'm in a back room in the store Belk. Someone is shooting and we are hiding here. There are three of us…" Enters a new call (3): "shots coming from inside the mall, poss. not in Belk; negative on any suspect information; negative on any known injuries; weapon unknown." *[Framing: Active Assailant; Elaboration: Information Gap]*
Analyst	Uses the search term "Belk" to discover reports of shots fired near the department store. Compares this information with call notes entered in CAD (3), and concludes the information is redundant. *[Questioning: Preserve frame (discard data)]*
Dispatcher	"Notification that there are still shots fired at this time, use caution. one caller advising they and two others are in Belk storage rooms sheltering in place… still no suspect info" (Call 3).
Call Taker	Another call (4): "I am outside Belk in the parking lot… I think there are two white guys with guns… Lots of people are running through the parking lot…" Makes further entries into CAD: "Parking lot outside of Belk; two white males, negative on clothing, unknown further; caller on the line, pending more suspect information." *[Elaboration: Suspects]*
Dispatcher	"Be advised, two white male suspects, armed, reported in the Belk parking lot" (Call 4). Requests further information from the call taker still speaking with the 911 caller: "...which parking lot of Belk?"

In the scenario, however, this never happens. The analyst adopts ineffective search terms and fails to discover most of the suspect information available in the tweet dataset during the scenario, notably:

> I'm locked in the women's room. There's a tall skinny white guy in blue jeans and a white tshirt.
>
> man with a gun just got into a red SUV and turned right on Orleans Rd
>
> shirtless man with assault rifle running to car outside the mall [picture of shirtless man next to a red SUV]

During both scenarios, analysts rely on search heuristics employed as 911 call takers, but which prove ineffective when adapted to filtering social media data (i.e. poor recall). Explaining that he has "seen a lot of people using the business name versus an address or road name," the analyst uses the department store name "Belk" referred to by an earlier 911 caller (Call 3). Relying on cues provided by 911 callers, analysts adopted similar heuristics, typically using the names of businesses or other geographic landmarks, to search generally for emergency-related information.

Consequently, analysts did not select search terms associated targeting specific, priority information. Instead, analysts provided information for dispatch as discovered, such as when the analyst provided information on survivors sheltered in place (Call 1) early in the response when suspect and victim information remained priorities. By using search terms explicitly provided by 911 callers or alerts provided by the analytic dashboard, the analyst reactively filtered social media data in ways that often proved ineffective at identifying and triaging priority information.

Elaboration by Identifying Gaps in Situational Awareness

Whenever entering new information into CAD, the call taker and analyst also described what information remained unknown: "negative injuries with this report" (Call 1), "unknown any injuries… no suspect information" (Call 2), "negative on any suspect information; negative on any known injuries; weapon unknown" (Call 3), "negative on clothing, unknown further" (Call 4). By identifying information gaps in CAD, the call taker and analyst support shared awareness among dispatchers and first responders during the response:

> When we got the additional tweet of multiple people shot, I went back to the original [call] notes I had [for Call 1] to report multiple people shot near the food court... the shooter is gone, and... that there are no descriptions or specific locations because some of these officers are going to ask for that. I know they are going to ask for that so I go ahead and tell them there is nothing more specific. (Analyst, Scenario 1)

Information gaps can be determined with respect to secondary information associated with the emergency frame: an active assailant at Citadel Mall. In scenario one, missing information included descriptions of weapons, the shooter, as well as potential victims and survivors sheltering in place. As previously described, however, the analysts' inflexible search heuristics precluded targeted information seeking to address information gaps articulated among the dispatchers.

Questioning and Discarding Redundant Information

In phase three of the scenario, the call taker enters a call (3) from a survivor sheltering in place in Belk, a department store in Citadel Mall. The analyst subsequently uses the search term "Belk" and identifies two tweets reading "loud pops near Belk in the mall. Sounds like a gun people running screaming" and "In Belk 🙏🙏🙏 #help #pray #charleston." The analyst compares this information to existing information entered in CAD and already dispatched to first responders:

> I searched for "Belk." I had one [tweet] pop up basically reporting what sounds like pops, or a gun going off… There is no additional information I can pull out of that. They already know there is a shooting at the mall near Belk, they already know people are running around and screaming. It's an active shooter incident. So, there is nothing additional I can pull from here to put into there… It's redundant information because everything that is here is already here [in CAD]. (Analyst, Scenario 1)

Although the tweets provide information related to the emergency, the analyst does not consider them relevant in the situation given the information already available and the evolving information requirements of the response. From a sensemaking standpoint, the phase illustrates the analyst questioning encountered information to gauge its quality with respect to information characterizing the existing frame. Concluding the former corroborates the frame without providing any new information for its elaboration, the analyst discards the data.

Scenario Two: Severe Flooding

Scenario two involves roadway flooding in different locations causing traffic hazards and the need for two water rescues. Table 2 provides a synopsis of the role play in three phases.

Discovering Inconsistencies among Information from Social Media and Emergency Callers

As in scenario one, the analyst did not readily discover information during each emergency, to include the discovery of inconsistencies among information that might lead to a reframing of awareness. In phase two, for

instance, the analyst enters a call for a traffic hazard on Harbor View Boulevard after searching "flooding" and discovering a tweet reporting flooding on Harbor View near Harris Teeter, a supermarket. What the analyst did not discover, however, was a tweet requesting a water rescue in the same location:

> So much water at Lake Francis near CVS. Rd. impassable. ONE PERSON STUCK IN CAR.

Lake Francis Drive intersects with Harbor View Boulevard immediately across from the shopping center parking lot in which both Harris Teeter and CVS, a pharmacy, are located. The analyst later discovers this tweet by accident when searching for "Pier One" after the store name was mentioned by a 911 caller reporting flooding eight miles away on Sam Rittenberg Boulevard- an unrelated incident. That the search results for "Pier *One*" returned a tweet reporting "*One* person stuck in a car" was purely serendipitous.

Table 2. Three phases of flooding scenario

Call Taker	Enters a call (1) into CAD when someone reports roadway flooding near the Dollar General on Camp Road. *[Framing: Traffic Hazard]*
Analyst	After checking tweets appearing on the map, then searching for "Dollar General" and "flooding," discovers tweet reporting a trapped person at the intersection of Dills Bluff and Camp Road. Determines this a distinct incident and enters a call (2) into CAD. *[Questioning: Inconsistent location; Reframing: Water Rescue]*
Dispatcher	Uses radio to dispatch a police unit to Camp Road (1), and then police, fire, and medical units to the Dills Bluff incident (2), noting: "units dispatched to both sides of the roadway to set up cones and Traffic and Transportation notified [of lane closures]."
Analyst	Also discovered when searching for "flooding," a tweet shows an image of flooding in the parking lot of Harris Teeter. Enters a call (3) into CAD. *[Framing: Traffic Hazard]*
Dispatcher	Dispatches a police unit to the Traffic Hazard near Harris Teeter (3) and asks the analyst to clarify the depth of the water in the tweeted picture: "what is a 4-5 drop zone?"
Call Taker	Another call arrives reporting more roadway flooding, this time near Pier One Imports on Sam Rittenberg Road. Enters another call (4) for a Traffic Hazard into CAD. [*Framing: Traffic Hazard*]
Analyst	Searching "Pier One," finds tweet reading "So much water at Lake Francis near CVS. Rd. impassable. ONE PERSON STUCK IN CAR." Determining that the CVS is in the same parking lot as the Harris Teeter, enters call notes (3) requesting a Water Rescue. *[Questioning: Inconsistent location; Reframing: Water Rescue]*
Dispatcher	Dispatches police to Traffic Hazard on Sam Rittenberg and uses CAD to ask the call taker if anyone is in the vehicles. "Caller did not advise," answers the Call taker. Dispatches units to a water rescue. In call notes (3) the dispatcher writes, "Copy, duplicating call for emergency Fire Rescue (EFR). Confirming information with police department on the scene."

As the example illustrates, the types of cues provided by 911 callers and entered into CAD by call takers condition analysts' discovery of emergency-related information. The previous example also illustrates the difficulty of discovering an emergency when no one calls 911; the initial call entered into CAD for a traffic hazard on Harbor View near Harris Teeter was entered earlier by the analyst after discovering a picture of the flooding on Twitter. That the analyst was not initially aware of the trapped person at the Harborview and Lake Francis intersection demonstrates, again, the difficulty of discovering unknown information about an unknown emergency.

Evaluating Inconsistencies among Information from Social Media and 911 Callers

Searching and filtering tweets, however, constitutes only the first step of integrating information from social media within 911 dispatch operations. Next analysts must compare newly-obtained information from social media displayed on the dashboard interface with existing, integrated information from 911 callers and social media displayed on CAD and shared among the call taker, dispatcher and analyst. At this stage inconsistencies appear when analysts cannot not determine if a discovered tweet(s) reports a new emergency not yet entered into CAD, new situational awareness information for a reported emergency, or redundant information about an already-reported emergency.

Consequently, the ability of analysts to evaluate inconsistencies among information displayed on the analytic dashboard, and between information displayed on the dashboard and CAD, becomes critical to effectively integrating information from social media and 911 callers for emergency dispatch. In phase one, for example, the analyst must determine if the trapped person at the intersection of Camp Road and Dills Bluff is related to the flooding earlier reported on Camp Road (near the Dollar General) by a 911 caller. Comparing the available

location information for each incident, the analyst determines them to be separate and therefore enters a new call into CAD for a water rescue, rather than adding additional information to the existing call for the traffic hazard.

To do this, however, the analyst uses primary information cues in the tweets, words that indicate the incident type and location of the emergency. When asked to consider a likely counterfactual, if the tweet had provided less detailed location information by omitting reference to Dills Bluff, the analyst describes *how* dispatchers evaluate and compare inconsistent information from multiple emergency reports:

> If this Dills Bluff thing wasn't here, and it just said lots of flooding on Camp Road, my car's flooded, I need a boat, [then] flooding on Camp Road is related to the Dollar General on Camp Road where there is a lot of flooding reported. I would add it to the same call then. However, because there is this specific location, I would probably create an entirely separate call. (Analyst, Scenario One)

Lacking the primary cue "Dills Bluff," and therefore presented with less exact location information, the analyst would infer that the traffic hazard and water rescue are colocated- both on Camp Road near Dollar General- and refer to the same roadway flooding. However, when presented with more detailed location information, the analyst concludes that the incidents are distinct, occurring at different locations along Camp Road.

The analyst is working with protocols for dispatching a response that require classifying an incident type- in this case a water rescue- and an exact location. If the cue "Dills Bluff" was omitted by the social media user or not presented to the analyst, only the Camp Road at Dollar General location would meet this latter criterion. From a sensemaking perspective, the example illustrates how the analyst relies on cues in data to either elaborate an existing frame (Camp Road at Dollar General) or construct a new frame using cues sufficient to classify an exact location (Camp Road at Dills Bluff). Importantly, the analyst relies on the bottom-up presentation of cues available in the data and, at the same time, the top-down recognition of sensemaking frames from the repertoire of locations available for dispatch in Charleston County.

Similarly, in phase three, when the analyst serendipitously discovers the tweet requesting a water rescue on Lake Francis Boulevard near CVS, he must still evaluate the tweet in comparison to inconsistent information entered into CAD for dispatch:

> So when I was looking for Pier One there weren't any geotagged tweets from the area [on the map] but it looks like there are additional ones that popped up [in the tweet search]. I found one tweet here, "water at Lake Francis near CVS, road impassable, one person stuck in the car." So now I would identify where this is, looking up Lake Francis, looking up some of the CVSs trying to figure out where this was. (Analyst, Scenario 2)

The report of someone trapped in their car near Lake Francis near CVS is not immediately intelligible as the same location as the traffic hazard on Harbor View near Harris Teeter. Both roadways are long thoroughfares, and there are multiple chain supermarkets and pharmacies with the same name in Charleston.

To compare this new information with that already entered into CAD, the analyst again looks to primary information cues in the tweet that allow dispatchers to classify information for emergency dispatch:

> I can use the CAD system to determine where is Harris Teeter, where is Lake Francis, and where is the CVS near Lake Francis.... I would just look for Lake Francis Drive and see if I could find a CVS near there, and then compare this report to the CAD to see if there was a call already entered and, if not, then I would go ahead and enter one for water rescue. So they wouldn't be getting much information but they would be getting enough for a location and a basic response for one person stuck in a car due to possible flooding. (Analyst, Scenario 2)

Using the names of roadways and stores as primary cues, the analyst uses mapping applications (typically integrated in CAD) to classify the location of the emergency and determine if an emergency has already been reported in the same location. In this situation, the analyst determines that the newly-reported water rescue, and the already-dispatched traffic hazard are colocated: "if this is the same location...the person stuck in the water in the car is due to the flooding, basically" (Analyst, Scenario 2).

DISCUSSION: INTEGRATING SOCIAL MEDIA VIA DISTRIBUTED SENSEMAKING

In contrast to prior studies which examine sensemaking among social media users posting and engaging social media content during a crisis (Mirbabaie & Zapatka, 2017; Stieglitz et al., 2018), or among officials gathering information from emergency callers (McMaster et al., 2012), this study examines how emergency dispatchers make sense of information gathered from social media and 911 calls to address evolving situational awareness needs during an emergency. Importantly, this study examines sensemaking as a distributed process performed among emergency dispatch teams including existing (call takers and dispatchers) and future (social media

analysts) specializations. Findings from the emergency dispatch simulations described in this study point to design requirements for social media analysis tools that can help analysts make sense of social media data created during an emergency, and protocols for coordinating analysts' sensemaking activities within emergency dispatch workflows capable of processing heterogeneous data to create actionable information.

Analyzing Information from Social Media and 911 Calls: Framing the Emergency

The simulations demonstrate how emergency dispatch teams make sense of information gathered from social media and 911 calls in sequences of sensemaking activities, or sensemaking workflows, which process and integrate information from heterogenous information sources to address the evolving situational awareness needs of first responders during an emergency. Drawing on Klein et al. (2006; 2007), this study observes four sensemaking activities constituting sensemaking workflows: framing, elaborating, questioning, and reframing. For each sensemaking activity, this study points to design implications for social media analysis tools that can help analysts make sense of social media data and protocols for coordinating analysts' sensemaking activities in workflows performed among emergency dispatch teams (Table 3).

Table 3. Design requirements supporting sensemaking by social media analysts

(Re)Framing	Cue Filtering	Identification and visualization of 6W cues in social media posts
	Domain Ontology	Incident determinant codes and information requirements (6Ws)
	COP	Situational awareness of calls and responding units
Elaborating	Assisted Search	6W-based classifiers to discover targeted information
	IS Protocols	SOPs to proactively address information gaps
Questioning	Alerts	Notifications to initiate sensemaking
	6W Visualizations	Visualizations contrasting 6W cues to reveal inconsistencies

The first activity, framing, sees dispatchers-turned-analysts make sense of social media data as they would 911 calls: associating data cues with a frame(s) explaining the situation. To analyze cues in social media data, analysts draw on the repertoire of frames commonly referred to as the "6Ws": Where, What, Weapons, Who, When, and Why (Kropczynski et al., 2018). The 6Ws represent a domain ontology organizing emergency dispatch work in which determinant codes representing classes of emergencies (i.e. what) are defined by attributes (i.e. where, weapons, who, when, why) with a set of possible values (e.g. street address in jurisdiction). Thus, analysts frame cues such as "loud pops," "shooting," and "Citadel Mall" with a determinant code indicating the class of emergency (e.g. 136E-1: Active Assailant) and a street address (e.g. 2070 Sam Rittenberg Blvd, Charleston, SC 29407). Thus, for analysts, effectively analyzing social media requires social media analysis tools that can filter information whose relevance is defined by the presence of cues enabling analysts to classify the attributes of an emergency (Kropczynski et al., 2018; Zade et al., 2018).

Framing practically involves entering a "call" in CAD whose primary information includes the "where" and "what" associated with an emergency, the minimum information required to dispatch emergency units. Highlighting the role of artifacts as frames (McMaster et al., 2012), and paired with the 6Ws domain ontology, calls displayed in CAD create a Common Operating Picture (COP) for a dispatch team, providing awareness of available information, information gaps, and the progress of emergency response operations. Together, cue filtering, the 6W domain ontology, and the function of CAD as a COP, enable analysts to create frames which, in turn, condition subsequent opportunities for distributed sensemaking activities of elaborating, questioning, and reframing.

Integrating Information from Social Media and 911 Callers: Elaborating the Emergency Frame

When a call is entered in CAD, the second phase of sensemaking proceeds as call takers and analysts seek to elaborate the existing frame by providing additional details about an emergency. As a frame, call information in CAD orients analysts' information seeking by articulating information requirements associated with gaps in "weapons," "who," "when," and "why" information prioritized according to the evolving needs of emergency responders. The simulations demonstrate how 911 calls entered in CAD provide analysts with resources for searching social media data and coordinating information seeking between call takers and analysts. However, the simulations also suggest analysts require assisted search features and information seeking protocols.

As a frame, a CAD call provides the dispatch team with a narrative of events happening during an emergency which analysts can, theoretically, use to search for priority information. In scenario one, for instance, the analyst knows that responders require immediate details about suspect(s) responsible for the mall shooting rather than survivors sheltering in place. However, while analysts use frames as stories to understand how information

requirements associated with chronological events will likely evolve during an emergency, the simulations suggest analysts must also use frames as scripts to coordinate proactive information seeking among dispatch teams. Such protocols would direct analysts to search social media data for priority information addressing the information gaps dispatchers describe in CAD whenever entering new information. Moreover, such protocols would encourage analysts to proactively search for missing information rather than reactively search for information when prompted by 911 callers.

Proactive information seeking, however, requires the ability to search and discover priority information. During both scenarios, analysts' search heuristics proved ineffective when filtering large social media datasets. To select search terms, analysts adapted techniques developed as call takers and searched for place names (e.g. "Camp Road," "Belk") mentioned by 911 callers. These queries resulted in poor recall of relevant information. Consequently, social media analysis tools in emergency dispatch will likely require assisted search capabilities leveraging, for instance, keyword-based classifiers that would allow an analyst working with a single cue, such as the department store name "Belk," to filter social media data associated with all toponyms in that geographic location. Similar approaches could be leveraged for each of the 6Ws, allowing, for example, an analyst using the cue "shot people" to filter social media data using keywords and n-grams associated with potential victims, i.e. "who." Future efforts to implement assisted search features in social media analytics dashboards can draw on the extensive research surrounding automated classification techniques for crisis-related information (Imran, Castillo, Diaz, & Vieweg, 2015), but must tailor these techniques to the domain ontology organizing information processing in emergency dispatch work (Kropczynski et al., 2018).

Evaluating Inconsistent Information: Questioning and Reframing the Emergency

When dispatchers discover inconsistencies, they must evaluate if the discovered information is novel, supplementary, or redundant in relation to information characterizing the existing frame. If determined novel, call takers or analysts can reframe the emergency by entering a new call in CAD or replace an existing call. Reframing produces a new frame for the dispatch team that, in turn, re-starts the distributed sensemaking cycle. For analysts, the emergency frame comes into question when noticing inconsistencies between newly-discovered information on social media and call information in CAD characterizing the existing frame. Analysts notice inconsistencies when comparing among information discovered on social media (e.g. do tweets refer to different locations?) and between information from social media and information in CAD (e.g. do tweets refer to the same locations as 911 callers?).

During the simulations, however, analysts recognize inconsistencies rarely and, in the case of the "Pier One" example, often inadvertently. Instead, analysts face a common problem in sensemaking: we don't know what we don't know. Consequently, analysts will likely require automated alerts to discover information about potential emergencies not yet reported by 911 callers. In the mall shooting scenario, the alert notifying the analyst that the word "shooting" was tweeted provides an example. Important questions regarding effective keywords, frequency thresholds, and other measures for triggering alerts extend beyond the scope of this study. Furthermore, analysts will likely require information visualizations that not only highlight relevant cues in social media data but draw attention to inconsistencies among (e.g. comparing all available location cues) and between (e.g. comparing location cues against incident cues) 6W information discovered on social media, and between 6W information discovered on social media and call information in CAD. The analytics dashboard employed during the simulations visualizes social media data in typical ways: plotted on a map, if geocoded, or filtered by search criteria in a social media stream. Understanding the domain ontology of emergency dispatch work, and how dispatchers use cues to frame social media data, can inform domain-specific visualizations that may help analysts detect inconsistencies challenging existing frames.

CONCLUSION

Our study must be considered in light of limitations attending simulated emergency dispatch work. Despite involving professional dispatchers in the design of the simulations, including the construction of the social media datasets, real-world conditions will, of course, vary significantly. Issues such as the need to verify information reported on social media were not fully addressed in this study although they remain an import consideration in emergency responders' uses of social media (Hiltz & Plotnick, 2016; Reuter, Ludwig, Kaufhold, & Spielhofer, 2016). Consequently, the design requirements offered here require further investigation and empirical evaluation. For instance, the design of alerts, as Boersma et al. (2016) observed, remains a difficult balance between recall and precision: too many undermine the value and effectiveness of user notifications while too few risk missing critical information. Moreover, the utility of alerts will necessarily depend on the information behaviors of social media users in a geographic community and use cases for emergency dispatch and response. Furthermore, additional research is required to design and evaluate visualizations that can support sensemaking activities such

as "questioning." While prior research can inform initial designs (Ntuen, Park, & Gwang-Myung, 2010; Stasko, Görg, & Liu, 2008), the domain-specific nature of information visualization will require iterative ideation and evaluation engaging dispatchers as domain experts and prospective end users.

Overall, the simulations conducted in this study suggest that social media analysts cannot adopt the reactive posture of call takers waiting on incoming 911 calls but must, instead, proactively seek and integrate missing information with information available from 911 callers. This proactive role will likely require effective filtering and automated alerts to notify the analyst of new and novel information, assisted search functions to increase the recall and precision of analysts' search queries, and information seeking protocols to address information gaps that evolve during an emergency response. Furthermore, analysts stand to benefit from custom visualizations that support top-down analysis by organizing and contrasting relevant information to assist sensemaking activities of framing, elaborating, questioning, and reframing.

ABSTRACT

With the increase of terrorist attacks and spreading extremism worldwide, countermeasures advance as well. Often social media is used for recruitment and radicalization of susceptible target groups. Counter narratives are trying to disclose the illusion created by radical and extremist groups through a purposive and educational counter statement, and to initiate a rethinking in the affected individuals via thought-provoking impulses and advice. This exploratory study investigates counter narrative campaigns with regard to their fight and prevention against terrorism in social media. Posts with strong emotions and a personal reference to affected individuals achieved the highest impact and most reactions from the target group. Furthermore, our results illustrate that the impact of a counter narrative campaign cannot be measured solely according to the reaction rate to their postings and that further analysis steps are therefore necessary for the final evaluation of the campaigns.

Keywords

Counter Narratives, Online Campaign, Social Media, Terrorism, Radicalization.

1. INTRODUCTION

Information technology plays a major role in context of peace and security (Reuter, 2019). Social media are increasingly used by terror organizations such as the Islamic State (IS) to recruit new fighters, for internal communication and as a marketing platform to promote their own victories as well as their ideology (Neer and O'Toole, 2014). At the same time, they are also used by governments, organizations and private persons who are fighting against terrorism (Reuter et al., 2017b). During the past years, many different strategies to prevent terrorism and its extension in social media have been developed. Educational messages should display and refute the content spread by the IS in a corrected form, e.g. by using parodistic images.

"*Counter narratives*" is a method that has been getting more important in the last years to challenge extremist campaigns in social media (Briggs and Feve, 2013; Schmid, 2014). According to Tuck and Silverman (2016), a counter narrative opposes extremist narratives by offering counter arguments, revealing harmful and contradictory content, decreasing trustworthiness and emphasizing positive instead of negative notions. As extremist narratives, we understand all expressions by recognized terrorist groups that aim to justify their cause, radicalize their audience and even recruit followers, while terrorism is defined as "violence intended to force changes in political decisions, actions, or relationships where victims are targeted without regard for their degree or form of involvement in the conflict" (Turk, 2015). For an effective and successful application of counter narratives, the original narrative must be identified, decrypted and understood (ibid.). In comparison to counter narratives, however, other campaigns achieved more success during the last five years (Russell and Rafiq, 2016). Accordingly, our exploratory study intends to answer the research questions: **(RQ1) What are characteristics of social media posts that elicit the most reactions by the target group of counter narratives? (RQ2) What are potentials to improve the impact for counter narrative campaigns in social media?**

As a first part of the investigation, there will be a theoretical introduction to the method "counter narratives", as well as an overview of the related work in this context to illustrate the research gap (section 2). Afterwards, the

approach of the data collection, reduction and analysis will be exemplified (section 3). The next section presents the results in the form of identified categories, which merge the most popular social media posts in counter narrative campaigns (section 4). These results will be discussed and evaluated to conclusively answer the research questions, reveal the limitations of the study and give an outlook for further research (section 5).

2. BACKGROUND AND RELATED WORK

It has become evident in recent examples, such as the bombings in Brussels in March 2016, that social media users perform an important role providing information and support in scenarios where confusion is prevalent, and are sometimes faster than traditional media sources (Hughes et al., 2008; Mirbabaie and Zapatka, 2017). Although many citizens still do not feel concerned by conflicts and crises themselves (Reuter et al., 2017a), they consider it important to be warned, informed and instructed by authorities and sometimes rely on social media even more than other forms of information and communication technology (ICT) when it comes to crises (Shklovski et al., 2008). The use of ICT in the disaster context has been researched for more than a decade under the term of *crisis informatics* (Soden and Palen, 2018). In terrorism, social media occupy an important key role between the participating actors, as they operate both in the center of terror propaganda and counter-terror propaganda (Kaufhold and Reuter, 2019). Due to their diffuse and collaborative characteristics, social media can help distribute up-to-date information to broader audiences and yield fast reactions, and thus has the potential to act as an impulse for producing change in communication patterns as well as in society (Fischer et al., 2016; Reuter and Kaufhold, 2018). Therefore, we focus on social media as an important channel of the dissemination of terrorist propaganda and counter narratives.

2.1 Narratives as a Propaganda Tool

The term "*narrative*" originated from the social sciences and describes a story as a manifestation of social practice (Gubrium and Holstein, 2009). As a construction of stories (Halverson et al., 2011), the process of narration is dynamic and permanently changing the outcome (Gubrium and Holstein, 2009). Narratives are also used to convey moral messages and ideologies (Schmid, 2014). Consequently, we can gain insights in how cultural groups view the world framed by their emotions, opinions, attitudes and values: "Narratives are powerful resources for influencing target audiences" (Corman, 2011, p. 42). They provide an alternative form of reality whose basis is deeply rooted in culture and can be effectively used to interpret and shape local events, as well as to strategically promote specific types of individual operations. The impact of these narratives appears through the coherences and trustworthiness for the target audience (Goodall Jr, 2010), so that narratives have an importance for terrorism, extremism and radicalization. Narratives are used in terrorism to promote violence and in extremism to facilitate values which abandon human rights to recruit exposed persons for their own use (Russell and Rafiq, 2016). Extremist narratives are a composition of ideological, political, moral, religious and social narrations which are based on true or phantasmal stories (Briggs and Feve, 2013). As a consequence, black and white thinking emerges along with desensibilization, dehumanization, victimization and a call for activism and militancy. The IS uses the characteristics of narratives for its own propaganda and ideology. The mentioned topics can be divided into six categories: brutality, compassion, war, sacrifice, affiliation and utopianism (Winter, 2015). Within the last five years, the counter-movement of counter narratives evolved to refute their narratives.

2.2 Counter Narratives

Counter narratives reveal an alternative view of the problem and, ideally, lead to a new appreciation and a rethinking of the topic. The guideline from "The Counter-Narrative Handbook" defines counter narratives not only as a counterstatement to another narrative, but additionally as a "message that offers a positive alternative to extremist propaganda, or alternatively aims to deconstruct or delegitimize extremist narratives" (Tuck and Silverman, 2016). Their aim is to reveal hypocrisy and discrepancies in extremist propaganda and to undermine the trustworthiness of extremist groups. Counter narrative campaigns can spread from civil society, youth campaigns and non-governmental campaigns to strategic communication of the government. A campaign should follow a comprehensive goal and a number of specific, measurable and accessible sub-goals for self-control. Furthermore, the characteristics of the audience should be determined, e.g. based on stereotypes (Tuck and Silverman, 2016) and by examining their online behavior (Van Ginkel, 2015). The message should be carefully chosen and designed, and the actors' trustworthiness should be considered. To get a high range of influence for counter narrative posts in social media, it seems to be an effective method to frame the posts with keywords which are used likewise in posts by extremists (Van Ginkel, 2015). According to Tuck and Silverman (2016), inherently provocative campaigns promote reaction from the audience.

3. METHODOLOGY

To gain insights into the presented research issues, our method comprises the 1) identification of relevant social media campaigns, 2) data collection and reduction, as well as 3) data evaluation using grounded theory.

3.1 Identification of Campaigns

As a first step we identified popular (campaigns which have many followers on Twitter or likes on Facebook: *Average Mohamed, Abdullah-X, Think Again Turn Away, UK against Daesh*) or current (new campaigns which exist only since 2016: *FATE, Extremely Together*) campaigns to obtain a short overview of methods and impact in this area between April 2013 and March 2017. Our summary includes the description of the campaign, its strategy, an evaluation as well as a summarized conclusion based on our own observation (Table 1).

Campaign name, organizer and time frame	Strategy	Evaluation	Conclusion
#ThinkAgainTurnAway since March 2016: The Global Engagement Center U.S. State Department December 2013 until October 2016	• Daily posts on current events, links to related websites and similar campaigns, information about the IS, using known hashtags • (*#DeashLiesExposed*) • Directly addressing IS accounts • Target audience: Not defined, "one size fits all"	• >27.000 followers on Twitter • >11.000 likes on Facebook • (Negative) coverage in newspapers	• Highly criticized campaign • One-sided communication, conservative use of social media • Involvement in discussions with IS followers, articles from questionable sources • Government as unsuitable message deliverer
UK against Daesh UK government since July 2015	• Daily tweets on current events, links to related websites, spreading UK narratives, revealing progress in fighting the IS, using known hashtags *(#DefeatingDaesh*) • Creating surveys and Q&A sessions • Target audience: English-speaking public	>21.000 followers on Twitter	• Interaction with followers, attempts of a two-sided communication with the audience • Government as unsuitable message deliverer
Average Mohamed Non-profit organization by Mohamed A. Ahmed since July 2014	• Production of 1-minute cartoon videos on topics such as religion, politics and culture in order to refute extremist narratives with logical arguments • Main topics: Peace, democracy, anti-extremism • Target audience: Young American Muslims (8-16 y.o.)	• >80.000 website views in the first year • >160.000 total views on YouTube • Coverage on TV and in newspapers	• Popular campaign • Regularly maintained social media pages with further information • Engagement by Ahmed at schools and universities
Abdullah-X Anonymous (former extremist) August 2013 until the end of 2016	• Production of short cartoon videos on current events and topics youth are concerned with. Here, the former extremist is using his own experience and knowledge to reveal narratives • Target audience: Adolescent British Muslims (10-24 y.o.)	• >50.000 views on YouTube during 6-week test phase, >130.000 views in total • >1.000 followers on Twitter • Coverage on TV and in newspapers	• Campaign with great audience engagement in discussing and sharing the videos • High viewer retention rate
Extremely Together Kofi Annan Foundation since April 2016	• Team of 10 young people of different origins with anti-extremism experience, who present ideas, exchange experiences and provide suggestions for the collective fight against terrorism • Links to related websites, sharing information events, creating surveys • Target audience: Young Muslims with potential for recruitment	• >8.000 likes on Facebook • >1.000 followers on Twitter • >7.000 total views on YouTube	• Little popularity (so far), few reactions from audience • Online and offline presence • Interaction with audience, information events

Campaign name, organizer and time frame	Strategy	Evaluation	Conclusion
Families against Terrorism and Extremism (FATE) Independent consortium of 20 European *CVE* groups since March 2016	• Pan-European network of families and organizations • Daily postings on current events, information on the IS, emotional appeals, links to related websites and campaigns, early detection of radicalization process • Target audience: Young Muslims with potential for recruitment and their families	• Reaching >1,5 mil. users on Twitter and >2.500 on Facebook in 6-week test phase • Worldwide range of >600 mil. people • Coverage on TV and in newspapers	• Wide range, multilingualism, multimedia internet presence • Online and offline presence • Interaction with audience: Events, workshops, counseling

Table 1. List of campaigns, strategies and evaluation data (source: own research)

3.2 Data Collection and Reduction

Based on the derived overview of different campaigns, we started our data collection by reviewing all posts from the Facebook and Twitter timelines of the respective campaign accounts. In the case that YouTube videos are the basis of the campaign, the user comments supply the collected data. The period under review varied between the different campaigns based on the availability of data and the existence of the campaign at that time, but overall, the period under review was between April 2013 and March 2017, and includes a data set from n>10.000 findings (Table 2).

For an appropriate subsequent evaluation of the data, the quantity was reduced to 500 posts by limiting them to those with a response rate of at least 10 reactions. The campaigns' own retweets were not counted towards the other posts because they mainly represent reactions to other sites instead of the actual campaign, while we were interested in original content. *Abdullah-X* reached less than 50 posts after the reduction and was not considered in the following analysis. The campaign *FATE* had too few posts as well, which is why only the data from the Twitter account was considered. The amount of relevant posts by *UK against Daesh* was still too high, so the posts were reduced from 174 to 102 while sorting out redundant posts (Table 2). While the quantity of posts does not directly influence the results of a qualitative approach, it helps maintain the overview for a better comparison and categorization of posts.

Campaign	Medium	Period	Posts before reduction	Posts after reduction
The GEC	Facebook	2015-08-06 to 2016-05-26	906	89
UK against Daesh	Twitter	2016-05-08 to 2017-03-24	3,206	102
Average Mohamed	Facebook	2014-05-16 to 2017-03-23	329	27
	Twitter	2013-04-13 to 2017-03-23	341	99
	YouTube	End of 2014/2015 to 2017	99	
Abdullah-X	Twitter	2013-08-27 to 2016-11-09	1,033	7
	YouTube	Start of 2014 to 2017	41	41
Extremely Together	Facebook	2016-05-24 to 2017-03-24	374	33
	Twitter	2016-05-23 to 2017-03-24	708	40
FATE	Facebook	2016-11-19 to 2017-03-22	348	62
	Twitter	2016-08-24 to 2017-03-24	3,241	
Total			9,346	500

Table 2. Sources and periods of collected data

3.3 Data Evaluation using Grounded Theory

The qualitative data evaluation was carried out based on the grounded-theory method according to Glaser and Strauss (1967), which is characterized by a constant change between data collection and reflection, so that a continuous dialog takes place between pre-assumptions and the gathered data. For the encoding of the data, the procedure by Strauss and Corbin (1996) was used, a method where the data material is coded ad hoc – which means assigning it to a code which best describes the piece of data in relation to the whole data material – and the category scheme emerges gradually. Additionally, we used knowledge gained from our literature review to adjust our categories. Throughout the analysis process, the following core categories have been revealed: *Success,*

failures, linguistic differences, self-promotion, localization, visualization and *suggestions*. Subsequently, the posts inside the categories were evaluated for significant characteristics and qualities. The categories are characterized as follows:

- **Success**: differentiation between general achievements, and success in terms of failures of the IS. (a) negative expressions (e.g., "decrease", "lost", "problems"), messages on IS failures; (b) positive expressions (e.g., "successful", "help", "beautiful"), campaign success, establishment of countermeasures
- **Determent**: negatively connotated expressions and emotions (e.g. "hate", "grief", "lie"), emphasis on reality, revelation of deficiency, personal fates, emotional appeals / warnings
- **Self-promotion**: mentioning their own campaign and internal hashtags, interaction with the audience (call to action, questions, surveys), announcement of campaign events
- **Linguistic Differences**: analysis of the personal pronouns "we", "I", "they" as well as their declined forms
- **Localization**: naming specific cities / countries as well as expressions including the word "world" (e.g., "worldwide")
- **Visualization**: image and / or video included in a post
- **Suggestions**: specific instructions, prompts to act, imperatives (e.g., "must", "don't"), thought-provoking content, abstract expressions (e.g., "belief", "peace")

4. EMPIRICAL RESULTS

4.1 Success – Transportation of Success Stories Most Common Category

More than half of the posts can be assigned to the success category (61.4% of the postings). Within the category, they can differ between the following aspects: Failure of the IS, success of the particular campaign or country, and specific examples of the campaign's achievement. Joy, relief, pride or spitefulness can be a motivation for a reaction to this type of posts. Concrete and concise figures of failure can act as an eye catcher for a faster perception by the audience. In the following example, the loss of territory is addressed and because of that the campaign members classify it as a positive development in the fight against terrorism.

> *"UPDATE: #Daesh have lost 61% of territory in Iraq & 28% in #Syria […] #Defeating Daesh #ISIS #ISIL" (@UKagainstDaesh, 48♥55♲) (2016-12-26; the status of all quotations is 2017-03-24)*

Another facet in the success category consists of reporting on the positive results or advancement of the respective campaign or the country. These success stories' purpose is to show the effectiveness of the campaign, so that in an ideal case, the audience will be convinced of the respective campaign and support it. Another example clarifies the presentation of the campaign's own success through emotional posts and highlights the joint effort.

> *"#Beautiful moment as a father whose son joined #Daesh hugs @MoChirani. FATE brings people together to make us stronger than violent extremism" (@FATE_EN, 16♥10♲) (2016-11-16)*

Beside these success stories about the campaign, the coverage and support of similar activities falls into this category, emphasizing the common aim to prevent and fight extremism. Posts in this category got a lot of encouragement and an accordingly large number of reactions from the audience.

4.2 Determent – Strong Emotions and Facts Evoke More Reactions

This core category can be subdivided into aspects of clarification, emotional appeal and reporting on the consequences of extremism. Only in two campaigns (*The GEC* und *FATE*), more than half of the successful posts contained warnings (59,5%), whereas in the other campaigns, less than a quarter of posts are concerned (16,7%). An emotional appeal is particularly well suited for the use of counter narratives to touch a deeper level apart from the facts and to evoke a reaction from the audience. These reactions are ideally communicated by relatives and friends of radicalized fighters, in the form of sad or desperate stories. Emotional, personal stories do not have a specific target group; they touch a great number of people, thereby receiving a high encouragement, supporting the audience in feeling empathy and reacting accordingly to the posts.

"Extremely together's Ilwad Elman experienced the ongoing Syrian horrors first hand. He explains how seductive the lure of extremists in broken society can be and what must be done to resist them." (Extremely Together via Facebook, 24👍 34 ➥) (2016-05-26)

In contrast to emotional posts, there are fact-based reports on deficiencies in crisis areas. Whereas the official instances such as government accounts aim to inform the audience and give them the opportunity to participate in current events, other campaigns try to actively take action against the consequences.

4.3 Self-Promotion – Campaigns Enlarge their Range of Influence

Posts assigned to the self-promotion category aim to publish announcements, recruit new members or generate information from the audience. Most campaigns use more than two third of their posts for self-promotion. In total, self-promotion is mentioned in 61% of the posts.

"Thrilled to announce we'll be gathering in Brussels this month to launch our new #CVEtoolkit! Stay tuned […]" (@Xtremely2gether, 14♥ 11↻) (2017-03-17)

The low rate of self-promotion posts by government campaigns can be traced back to the missing individual character, like an introduction of new members etc. Via self-promotion, campaign leaders provide information about their own activities such as events, TV shows or interviews to the audience. Hereby, the campaigns convey activity, up-to-dateness and engagement outside the social platforms. Such posts are designed for interested users to become members of the campaign or to support it. Support can take place through a membership or through financial aid.

"[…] I need your help. We have $11 dollars in the bank need $3000 to reach 10,000 folks on Somali Independence Day on July 9th. We need funds to do this. Please do contribute and share with friends. […]" (Average Mohamed via Facebook, 25👍 24 ➥) (2016-06-27)

Surveys and direct questions have the purpose to identify the audience's opinion to get in contact more effectively. A major proportion of the self-promotion serves to recruit new members. Therefore, the project concept is shortly summarized in the posts, or a link to the campaign's website is included. Highlighting a positive impact of support by the audience should motivate to participate.

"Be part of #ExtremelyTogether. Share this tweet and reach 1.8 billion young people to counter extremism better" (@Xtremely2gether, 133♥ 254↻) (2016-09-29)

Besides the membership request, the audience is animated to interact with the posts of the campaign and thus identify with it more strongly, which can happen through a call to action, as well as through direct questions. Additionally, a lot of reactions from the audience imply a more distinct evaluation of the campaign.

4.4 Linguistic Differences – Explicit Distinction between Extremist and Counter Campaigns

The campaigns use linguistic differences between the extremists and their opponents by including different personal pronouns and direct forms of address. There is a differentiation between personal (I), connectedness (we), the others (they) and the direct address (you). The "I" form is used to express personal experiences, thoughts, opinions and feelings. The person in question talks directly to the audience or is directly quoted.

"They killed my parents. But I am still proud to call myself Belgian-Moroccan. "Not a dry eye at FATE right now." (@FATE_EN, 13♥ 7↻) (2016-11-15)

The sense of unity is intensified through emphasizing a common task and a common goal: By combining the forces, the goal can be easily achieved and obstacles can be overcome. "They" is used to include more people, but the speaker is clearly distancing themselves from them. This way, extremism opponents use "we" to draw a clear line between themselves and the terrorists who are referred to as "they".

"We are with you, we will stand together and take on the task of preventing radicalization in our young people. […]" (@FATE_EN, 10♥ 4↻) (2016-10-14)

The different perspectives of "I" and "we" are used to enhance the audience's identification with the campaigns, to not only address the counter terrorism movement, but also adolescents who are potential recruits. Government accounts do not apply this change of perspective, because there are no specific persons behind the accounts but employees of the government, who are representative of the whole country. The personal pronoun "we" is the most used personal pronoun inside campaigns and should convey a feeling of community and connectedness.

4.5 Localization – Used by all Campaigns to Strengthen the Benchmark

The posts in this category can be divided into cities or countries, crisis areas, and territorial limitlessness. All campaigns contain posts with location details (46.6% on average). The localization of events or incidents in crisis areas provides more detailed information about the topic of terrorism and counter narratives to the audience: Where is help needed? What countermeasures are taken in my city? Which areas have been taken by the IS?

"Follow us today as we get the #ExtremelyTogetherRoadshow rolling making counter narratives in Portsmouth" (@Xtremely2gether, 7♥ 10↻) (2017-02-07)

In contrast to this, phrases such as "worldwide" are showing the territorial limitlessness of posts. More than half of the most popular posts from government campaigns contain details on localization, for *UK against Daesh* this can be attributed to mentioning their own country in the campaign name. Therefore, it is surprising that a transnationally active campaign such as *FATE* contains the least location specifications.

4.6 Visualization – Pictures and Videos Serve as an Eye Catcher

The visualization of facts is useful in the international context to overcome linguistic barriers. Pictures (53.4%) and videos (26,6%) support the message, so that it is not surprising that all campaigns using visual content and visually supported posts show a higher response rate than purely textual posts.

Figure 1: Characteristic Pictures and Videos

We can differentiate between automatically displayed images, e.g., by linked articles, or consciously placed pictures or video screenshots. An article linked in a post can be viewed as an additional animation for the audience, yet the campaigns have no influence on displayed pictures. The majority of the campaigns' visual material can be attributed to this preview function. For graphics uploaded by the campaign leaders themselves, the campaigns apply different strategies for the use of visual material. For one part, it is used to introduce the team to create a personal bond with the audience; other motives can be to establish credibility or to visually support the post content. The other part is the promotion of self-produced video material, which are also published on platforms such as YouTube.

4.7 Suggestions – Too Few Thought-Provoking Impulses in the Campaigns

We found suggestions for preventing and fighting radicalization, which can be subdivided into one or more categories such as thought-provoking impulses, suggestions for countermeasures, and appeals. Accordingly, it is surprising that in almost all campaigns, posts with suggestions account for roughly a quarter of the most popular posts (26%). While in *Extremely Together*, at least a bit more than half of the most popular posts can be assigned to the category of suggestions, *UK against Daesh* offers no thought-provoking impulses at all. An important thought-provoking impulse, especially for family members and friends of individuals who have the potential to be recruited, is the sensibilization for the recruiting and extremism issue.

"Has your #friend's/#daughter's/#son's/#sibling's #behaviour changed quite a lot? Don't ignore the signs! #radicalisation #findFATE" (@FATE_EN, 10♥ 9↻) (2016-11-22)

Such thought-provoking impulses can be internalized by the audience, but in the fight against extremism, not only the right attitude is crucial, but also the following actions. Therefore, all campaigns provide concrete suggestions how one can actively operate against extremism. Because most of the evaluated counter narrative campaigns concentrate on social media, as a logical consequence, one suggestion which all campaigns give is: Fight extremist ideas online! The campaigns' prompts mostly contain no specific instructions, but are expressed in a rather abstract way:

"If you see something – say something #OYWOttawa #xtremely2gether" (@Xtremely2gether, 19♥ 24↻) (2016-09-29)

5. DISCUSSION AND CONCLUSION

Since 2012, a variety of counter narrative campaigns and projects with the aim to prevent and fight extremism and terrorism have emerged in social media (Tuck and Silverman, 2016). Our paper summarized many of them in Table 1 as a groundwork for our study. In most cases, the decisive criteria of success are set by the campaigns' founders or leaders in relation to their own aims, so that the result will be assessed in accordance with those aims. Their prevention work focusses on the target groups of teenagers who are in danger of being recruited in order to prevent their radicalization, since extremist narratives have the most effect on this target group.

With regard to our first research question (**RQ1: What are characteristics of social media posts that create the most reactions by the target group of counter narratives?**), we found out that success stories, determent, self-promotion, linguistic differences, localizations, visualization and suggestions are characteristics of social media posts that promoted most reactions by the target group. The audience prefers posts in the form of reactions connected to a feeling of *success*, since more than 61% of the posts can be assigned to this category. Similarly, personal fates as well as stories of former extremists, victims' family members or campaign leaders are popular (*determent*). The purpose of strong emotions is one of the characteristics responsible for the success extremist campaigns gain with their narratives (Winter, 2015), so it is understandable that those aspects produce the highest effect in a counter campaign as well. While emotional appeals evoke the respective emotion, surveys are more suitable for obtaining required information from the audience. An integrated call to action gives interested persons the opportunity to play an active role (*self-promotion*). For all these fields, photographic material (53% of the posts) and video footage (27%) have an effect as an eye catcher and get a high reaction rate from the audience (*visualization*). The results clearly show that while there is a low number of hints and advices (26%, *suggestions*), the percentage of self-promotion of the campaigns with the attempt to mobilize the audience is much higher (61%).

This leads to the second research question **(RQ2: What are potentials to improve the impact for counter narrative campaigns in social media?**). Firstly, counter narrative campaigns should be integrated with other counterterrorism efforts. One issue is the low degree of popularity in most campaigns, so that the campaign is hardly perceived. Research indicates that reactions and interactions of the audience are much higher for other strategies, such as the approach to fight extremism with humor (Al-Rawi, 2016; Reuter et al., 2017b) in satire-based campaigns such as #TrollingDay. Furthermore, so-called *alternative narratives* are intended to paint a fact-based picture of and give suggestions related to topics discussed in terrorist propaganda (Starbird, 2017). Secondly, while social media are an effective tool to support emergency response and crisis management, this is also true for other ICT (Fischer et al., 2016; Hughes et al., 2008; Kaufhold et al., 2018b; Mirbabaie and Zapatka, 2017; Shklovski et al., 2008; Soden and Palen, 2018). Therefore, an increased cooperation with established formats could increase the coverage and gain more attention for the campaigns' work in general in such a way that the dynamics of countermeasures are not limited to social media, but that the more intensive and convincing interacting with potential target groups can be intensified in real world activities as well. Thirdly, narratives and counter narratives also occur during natural hazards, as the case of FEMA's fail and redemption during the hurricanes Sandy and Katarina demonstrate (Drennan, 2018). Thus, it might be important to integrate the concepts of narratives and counter narratives into authorities' guidelines, policies and strategies (Kaufhold et al., 2018a) in order to identify and refute harmful or wrong narratives.

Our exploratory study is subject to limitations. A large amount of data had to be excluded from further analysis due to the low reaction rate of the audience. However, it could be worthwhile examining and contrasting the characteristics of posts with low reaction rates by applying a quantitative approach on a larger and more representative data sample. Since most counter narrative campaigns address a very specific target group and do not achieve high reaction rates on their posts, it should therefore be examined whether these posts still can provide starting points to effectively place counter narrative campaigns in social media. Especially from a communicative and linguistic point of view, the posts should be further analyzed to establish a valid distinction between terrorist propaganda and alternative narrations. With regard to ICT, we assume that event detection techniques and machine learning classifiers (Imran et al., 2015) could assist in the identification of extremist content and narratives, thereby establishing starting points for counter narrative actions. Furthermore, user interfaces might support the creation of high-impact social media postings via contentual recommendations based on criteria such as these discussed within our analytical categories.

Understanding Patterns and Mood Changes through Tweets about Disasters

Liuqing Li and Edward A. Fox
Department of Computer Science, Virginia Tech
Blacksburg, VA 24061, USA
[liuqing, fox]@vt.edu

ABSTRACT

We analyzed a sample of large tweet collections gathered since 2011, to expand understanding about tweeting patterns and emotional responses of different types of tweeters regarding disasters. We selected three examples for each of four disaster types: *school shooting*, *bombing*, *earthquake*, and *hurricane*. For each collection, we deployed our novel model TwiRole for user classification, and an existing deep learning model for mood detection. We found differences in the daily tweet count patterns, between the different types of events. Likewise, there were different average scores and patterns of moods (fear, sadness, surprise), both between types of events, and between events of the same type. Further, regarding surprise and fear, there were differences among roles of tweeters. These results suggest the value of further exploration as well as hypothesis testing with our hundreds of event and trend related tweet collections, considering indications in those that reflect emotional responses to disasters.

Keywords

Disaster, Pattern, User Classification, Mood Detection, Twitter

INTRODUCTION

Disasters can appear in any area of the world, and include both natural disasters like earthquakes, hurricanes, floods, and forest fires, as well as man-made disasters such as shootings, bombings, and train crashes. Different types of disasters have distinct patterns. For example, natural disasters have dramatic effects and can bring huge loss, while man-made disasters often proceed rapidly, with long-lasting impact. Further, natural disasters have particular spatial distribution patterns (Shen et al. 2018). Since Twitter users tend to tweet about the latest developments, and convey emotional feelings in a time of disaster, the patterns found in large tweet collections can reflect public concern about disasters, and help researchers dive deeper into understanding them.

Twitter users express different moods during disasters. For instance, some users may be frightened by the aftershocks during an earthquake, some are angered by a bombing disaster, and others verbalize their sadness for the victims in a school shooting event. Their changes in mood, synchronized with the unfolding of disasters, are interesting to explore. In addition, Twitter users assuming different roles (e.g., brand/organization, female, male) behave differently. For example, preliminary work has shown that male users prefer technology and sports (Bamman et al. 2014), female users are more emotional (Rao et al. 2010), and brand users act as broadcasters by spreading information or delivering messages. The gender value can be set by a user or predicted by Twitter on the profile page, but it is unreadable to others and does not include the brand class. Since moods might vary with time among different roles of users, analyzing such changes will be helpful both academically and practically. Social scientists can conduct user-related research, while disaster assistance can help victims recover, through targeted services.

In this paper, we report on a comprehensive analysis of 12 large tweet collections, to understand tweeting patterns and mood changes of different types of tweeters about disasters. We prepared three tweet collections for each of four disaster types: *school shooting*, *bombing*, *earthquake*, and *hurricane*. We developed TwiRole, a novel hybrid model to identify role-related users, and reused an existing recurrent neural network (RNN) model to detect the moods expressed in tweets. Considering both user roles and mood scores, we studied patterns and mood changes at

both the event and role level. To help investigate patterns and changes associated with disasters, we developed the following research questions: 1) Is there any tweeting pattern behind disasters of each type? Are these patterns similar between different types? 2) How do tweeters demonstrating different roles relate to these disasters? 3) What is the major mood? Are there exceptions? 4) How does mood change along with the daily tweet count pattern in each disaster? 5) Is there any difference in mood change among roles of tweeters?

The findings of our study indicate that different types of disasters lead to different daily tweet count patterns. Regarding user participation, brand users played an essential role in tweeting, while male users were more active than female users. There were different average scores and patterns of moods (fear, sadness, surprise), both between types of events, and between events of the same type. Fear is the major feeling in most disasters, while sadness is dominant in two of the school shootings analyzed. Mood delays exist in most disasters, where sadness is more time-sensitive. Regarding surprise and fear, mood variation appears among users with different roles.

We next present related work, and then describe our methodology for data selection, user classification, and mood detection. After that, findings, followed by evaluation and discussion, are presented in detail. Our conclusions are drawn in the final section.

RELATED WORK

User Classification on Twitter

Several researchers have worked on Twitter user classification according to role. Multiple features have been considered and extracted for gender classification. (Liu and Ruths 2013) investigated the relationship between first name and gender, and took the first name as an important feature for gender prediction. Some researchers have found that female and male users may apply templates in different colors (Alowibdi et al. 2013a; Alowibdi et al. 2013b; Fortmann-Roe 2013), and so utilized color-based features in gender inference. Information in user profiles, especially the descriptions of users, may also contain gender-based terms or phrases (e.g., man, woman, actor, mother) that are good indicators (Daas et al. 2016; Vicente et al. 2015). Besides these features, a user's network and behavior (Ciot et al. 2013; Lasorsa 2012; Nilizadeh et al. 2016), external sources (e.g., personal website, Facebook) (Burger et al. 2011), tweets (Artwick 2014; Bamman et al. 2014; Li et al. 2014; Pennacchiotti and Popescu 2011a; Geng et al. 2017; Rao et al. 2010), and profile images (Levi and Hassner 2015; Wang et al. 2016), have been advocated for gender classification.

In addition to the traditional bi-classification, (Purohit and Chan 2017) categorized Twitter users into organization, organization-affiliated, and non-affiliated, while (Pennacchiotti and Popescu 2011b) classified Twitter users as either Democrat or Republican. However, there are methodological concerns regarding the evaluation of such studies, because most approaches were evaluated on self-labeled datasets, and performance is still unclear on other datasets. We developed TwiRole, that applies multiple simple features as well as some novel features for 3-way (i.e., brand, female, and male) classification of tweeters. After training and testing TwiRole on an open third-party dataset, we also evaluated its performance on our disaster collections.

Sentiment / Emotion Classification on Twitter

There has been growing interest in sentiment and emotion classification of tweets. (Schulz et al. 2013) took unigram, part-of-speech, syntactic, and sentiment information as features for sentiment analysis. (Nagy and Stamberger 2012) detected tweet sentiments during crisis situations by using sentiment words, emoticons, and a list of out-of-vocabulary words. (Caragea et al. 2014) performed sentiment classification of tweets during Hurricane Sandy, and visualized these sentiments on a geographical map. Many studies have been published on basic sentiment analysis (i.e., positive, negative, and neutral) by applying traditional machine learning techniques (e.g., Naive Bayes, support vector machine, logistic regression). (Wendland et al. 2018) applied an appraisal system to account for the interpersonal assessment of speakers and associated attitudes, which evaluated the sentiments of tweets from several aspects such as appreciation, affect, and judgment. A recent study reported in (Colneriĉ and Demsar 2018) improved the classification performance using RNN deep learning. Instead of detecting the three basic sentiments, their model predicted tweet emotions, which can better describe the feelings of tweeters. The default task is for predicting Ekman's six basic emotions (Ekman 1992), while the other two aim to identify the eight moods developed by Plutchik (Plutchik 1990), and the six mood states from the profile of Mood States (POMS) (Norcross et al. 1984). In our study, we deployed the innovative RNN deep learning model to predict the moods of users through tweets.

Empirical Study in Disasters

Regarding social media studies in crises, some researchers are focusing on single disasters, such as the 2011 Egyptian uprising (Kavanaugh et al. 2013), 2011 Japan Earthquake (Wilensky 2014), 2012 Hurricane Sandy (Caragea et al. 2014; Neppalli et al. 2016), 2013 River Elbe Flood (Herfort et al. 2014), 2016 Ghana Election (Moreno et al. 2017), or 2016 Berlin Terrorist Attack (Fischer et al. 2018). (Yang et al. 2013) designed PhaseVis, a multi-view integrated visualization tool, and applied it to Hurricane Isaac. (Lee et al. 2012) built a prototype of a digital library to detect and visualize water main breaks in disaster and other areas. (Alam et al. 2018) analyzed the multimedia content from three hurricane collections. Novel theories, models, and techniques have been developed and applied, and researchers can make further discoveries or tell exciting stories about these disasters. However, the generality of these approaches is not clear. It is uncertain how well they can work on other disasters. To the best of our knowledge, this is the first investigation of groups of disasters, carried out in a systematic empirical study, combined with both user classification and mood detection.

METHODOLOGY

Figure 1 shows the data flow of our analysis across disaster types. First, we created three tweet collections for each of four types of disasters. Second, we identified users from the cleaned tweets after preprocessing. Third, we designed and implemented TwiRole [1], a hybrid model for user classification on Twitter, which detects brand-, female-, and male-related users. Then, we applied a pre-trained RNN model to predict the moods of tweets. Finally, we carried out a comprehensive analysis of disaster patterns and mood changes, considering both user roles and mood scores.

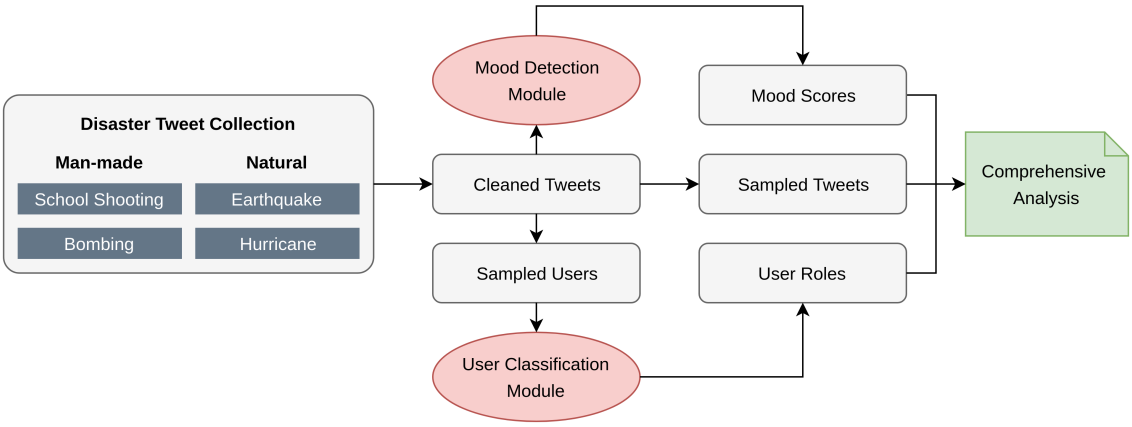

Figure 1. A data flow diagram: selection, classification, and analysis

Data Selection and Cleaning

Though we already had hundreds of tweet collections dating from 2012, we applied GetOldTweets3 (Mottl 2018) to create a dozen larger, more complete, tweet collections with four different types of disasters (i.e., school shooting, bombing, earthquake, and hurricane), three event collections per type. Each search query includes a disaster name and bound dates. The time range of each collection covers up to about one month after the corresponding disaster. For example, regarding hurricanes, we found the date they first formed, according to Wikipedia, and obtained tweets for four weeks starting on that date. Later, retweets (RTs) and non-English tweets were filtered out during cleaning to avoid muddling of results and to meet the input requirements of the mood detection module, respectively. Table 1 shows the details of our collections.

Role-related User Classification

We designed and implemented TwiRole to classify users by role. This hybrid classifier has a basic feature (BF) multi-classifier, an advanced feature (AF) multi-classifier, a convolutional neural network (CNN) model, and a final multi-classifier, as shown in Figure 2. Features for a given user include name, description, tweet, relationship, and profile image. Each classifier/model takes one or more features as input and predicts the probability of each role (i.e., brand, female, and male). Features and their details in each classifier/model are shown in Table 2. We utilized

Table 1. An overview of the twelve tweet collections, across four disaster types

Type	Collection	Starting (UTC)	# of tweets	# of cleaned tweets
School Shooting	Sandy Hook Elementary School shooting	12/14/2012 14:40:00	100,833	97,283
	Stoneman Douglas High School shooting	02/14/2018 19:27:00	22,441	22,321
	Umpqua Community College shooting	10/01/2015 17:48:00	17,930	17,821
Bombing	Boston Marathon bombing	04/15/2013 18:49:00	220,221	211,142
	San Bernardino attack	12/02/2015 18:58:00	44,359	44,224
	Manchester Arena bombing	05/22/2017 21:31:00	6,119	6,105
Earthquake	Nepal earthquake	04/25/2015 06:11:00	677,067	671,323
	Japan earthquake	03/11/2011 05:46:00	644,814	566,627
	Taiwan earthquake	02/05/2016 19:57:00	49,052	48,894
Hurricane	Hurricane Sandy	10/22/2012 00:00:00	2,528,523	2,399,334
	Hurricane Matthew	09/28/2016 00:00:00	1,092,684	1,088,212
	Hurricane Florence	08/31/2018 00:00:00	639,888	636,281

an existing third-party dataset (Kaggle 2016) to train and test TwiRole, and also evaluated it on the users extracted from our disaster collections. TwiRole performs better than other existing models on the Kaggle dataset, and its overall accuracy is about 90%.

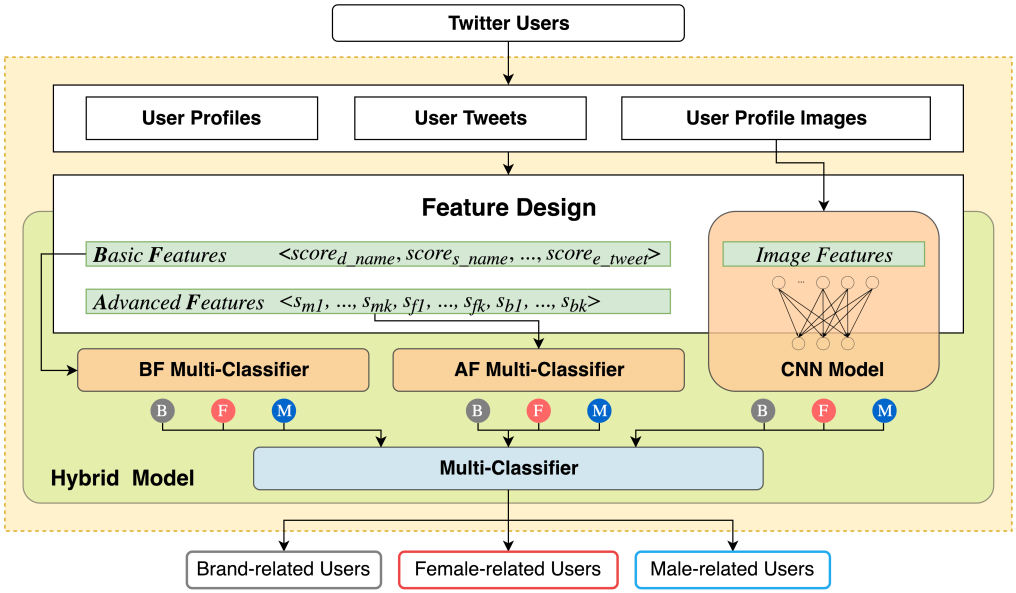

Figure 2. TwiRole is a hybrid model consisting of four components. The BF multi-classifier takes the basic features from the user profiles and tweets as input. The AF multi-classifier focuses on the k-top words in user tweets. The CNN works on the user profile images. The final multi-classifier takes the output of the above three modules as input during training and testing.

Mood Detection

We used a pre-trained RNN model (Colneriĉ and Demsar 2018) for predicting Ekman's emotions (Ekman 1992) from tweets, which outperforms several traditional machine learning methods (e.g, SVM, Naive Bayes, Random Forest). The F1 score mentioned in their paper is about 70%, leading to an approximate emotion analysis. The model takes each tweet as input and predicts the score for each of six basic emotions (i.e., anger, disgust, fear, happiness, sadness, and surprise). In our study, as a simple start, we focus on three moods: fear, sadness, and surprise. We assume these are common feelings during disasters.

FINDINGS

Disaster Patterns

For each disaster collection, we calculated the number of tweets posted per hour during the time window of the event. Then we applied min-max normalization to convert the number of hourly tweets to a scale between 0 and 1

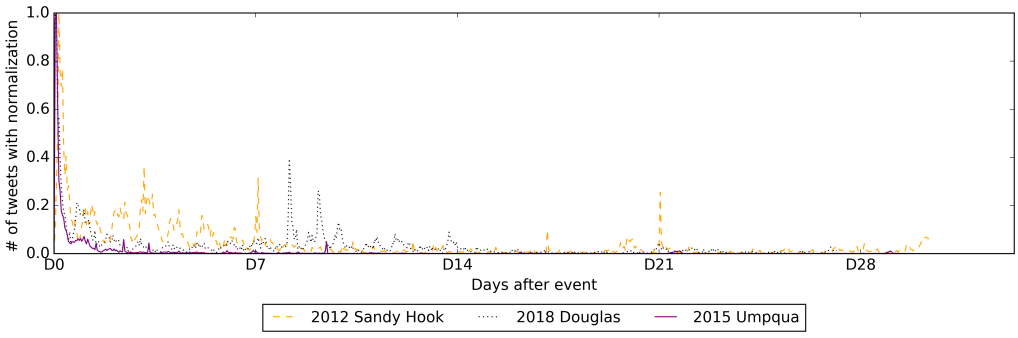
Table 2. Feature Types and Details in TwiRole

No.	Feature Type	Feature Detail	No.	Feature Type	Feature Detail
BF1	*name*	display name screen name	BF3	*relationship*	Twitter Follower-Friend score
			BF4	*profile image*	brightness
BF2	*description*	first-person score term frequency	BF5	*tweet*	first-person score interjection score emotion score
AF	*tweet*	k-top words	CNN	*profile image*	hidden in image

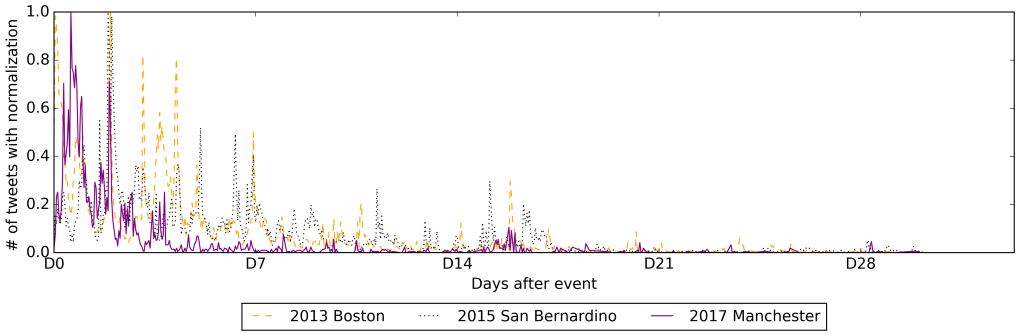
for inter-comparison. Different colors represent different collections in each disaster type. Figures 3a to 3d show the collection timelines across different disaster types.

Figure 3 illustrates that each type of disaster has a pattern that differs from the others. These patterns can also help us better understand user mood changes.

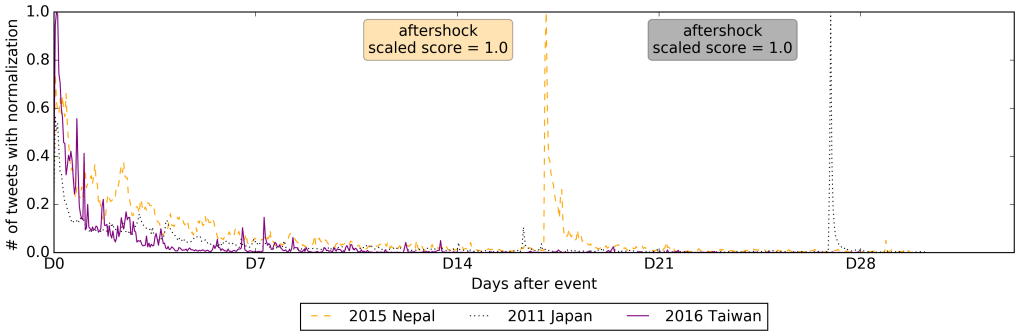
- *School Shooting*: School shootings are not as complicated, among man-made disasters, as bombings. The number of hourly tweets dropped to a low level just one or two days after a shooting. However, further along in the timeline, there are still some smaller peaks, e.g., corresponding to subsequent information releases or discoveries.
- *Bombing*: Each bombing timeline demonstrates highly variable numbers of tweets during the subsequent week. Tweets in significant numbers were posted even two or three days after the incident, which indicates that users paid close attention to information about the disaster.
- *Earthquake*: Twitter users posted many tweets, shown by a peak, when an earthquake occurred, and then the number of tweets gradually reduced over time. Later, when a massive aftershock occurred, another greater peak appeared, followed by a rapid reduction different from that observed after the original event.
- *Hurricane*: As a progressive natural disaster, each hurricane has a well-recognized timeline that approximates a normal distribution. We can roughly distinguish its stages and estimate the time when it hit land and caused severe damage. Moreover, the day-night periodicity in tweet number variations is more significant than for other types of disasters.



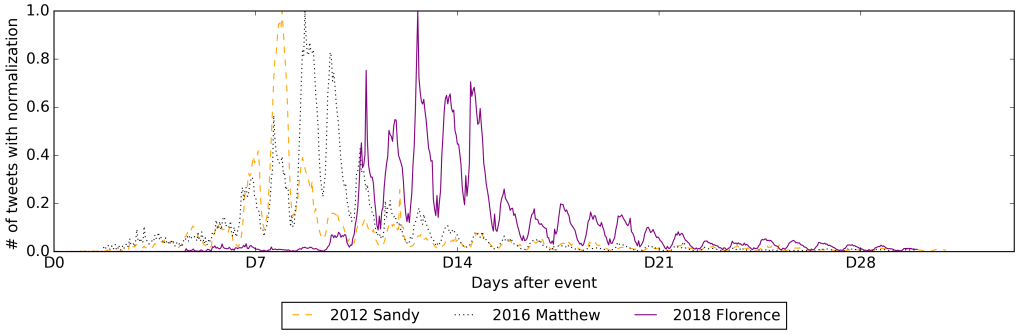
(a) School Shooting



(b) Bombing



(c) Earthquake



(d) Hurricane

Figure 3. Number of tweets (scaled) per hour for different types of disasters

User Distribution

We randomly selected at most 10,000 users from each disaster collection; the total across all collections was 107,323 users. Some accounts were deactivated or protected. Finally we utilized TwiRole to detect a user's role for 102,597 users (95.6% of 107,323 users). Afterward, we calculated the fraction of each role in each collection. The results (Brand: 0.4737 ± 0.0093; Female: 0.2124 ± 0.0098; Male: 0.3139 ± 0.0085) indicate that the distribution of users is relatively consistent among all disasters, as shown in Figure 4. Brand users are the primary group who might publish information or deliver messages, while male users participated more actively than female users in our selected disasters.

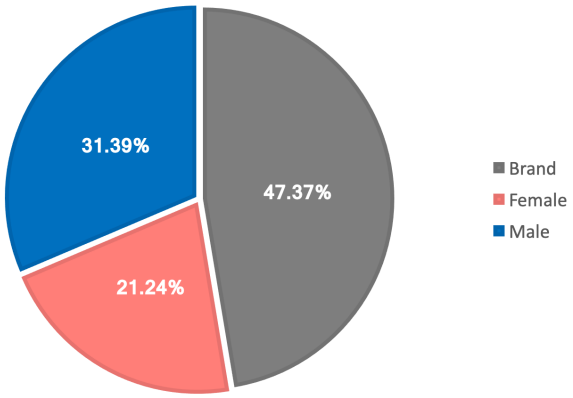


Figure 4. User distribution totals across all disasters

Bots are worth exploring and we applied Botometer for detection. Due to the rate limit, we detected 150 sampled users for each collection and calculated the percentage of bot users. The result (0.0694 ± 0.0270) indicates that only a small number of users are bots, so they have little impact on our results.

Mood Changes in All Users

We randomly sampled at most 100,000 tweets from each disaster collection and predicted the mood scores (i.e., fear, sadness, and surprise) of each tweet with the pre-trained RNN classifier. The scores of each mood were accumulated and divided by the total number of tweets in each collection. Figure 5 shows the average scores of the three moods in our collections.

Fear is the dominant feeling in eight out of the twelve disasters, which is consistent with our expectation. After the Boston bombing in 2013, users posted more fear tweets and expressed their feelings with words: *fear*, *afraid*, *terror*, *deadly*, or *scared*. During Hurricane Matthew in 2016, the fear words include *fear*, *scary*, *terrifying*, *frightening*, and *threatening*.

Twitter users show more fear and surprise than sadness in ten collections. The two counter-examples are school shootings, where sadness is the common mood. Users felt great sadness for the children and students who died or were injured in those massacres, and showed their feelings with sad words or phrases like *R.I.P*, *heart goes out*, *condolence*, *heart is broken*, and *depressed*.

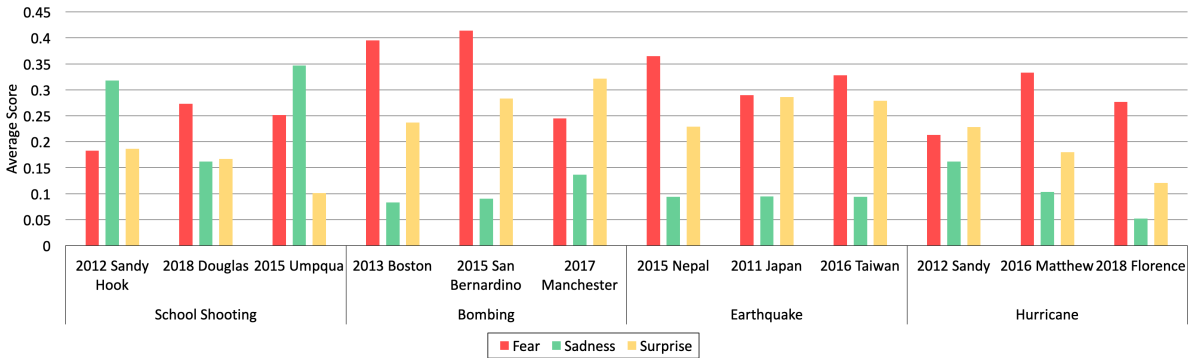

Figure 5. Average scores of fear, sadness, and surprise in different types of disasters

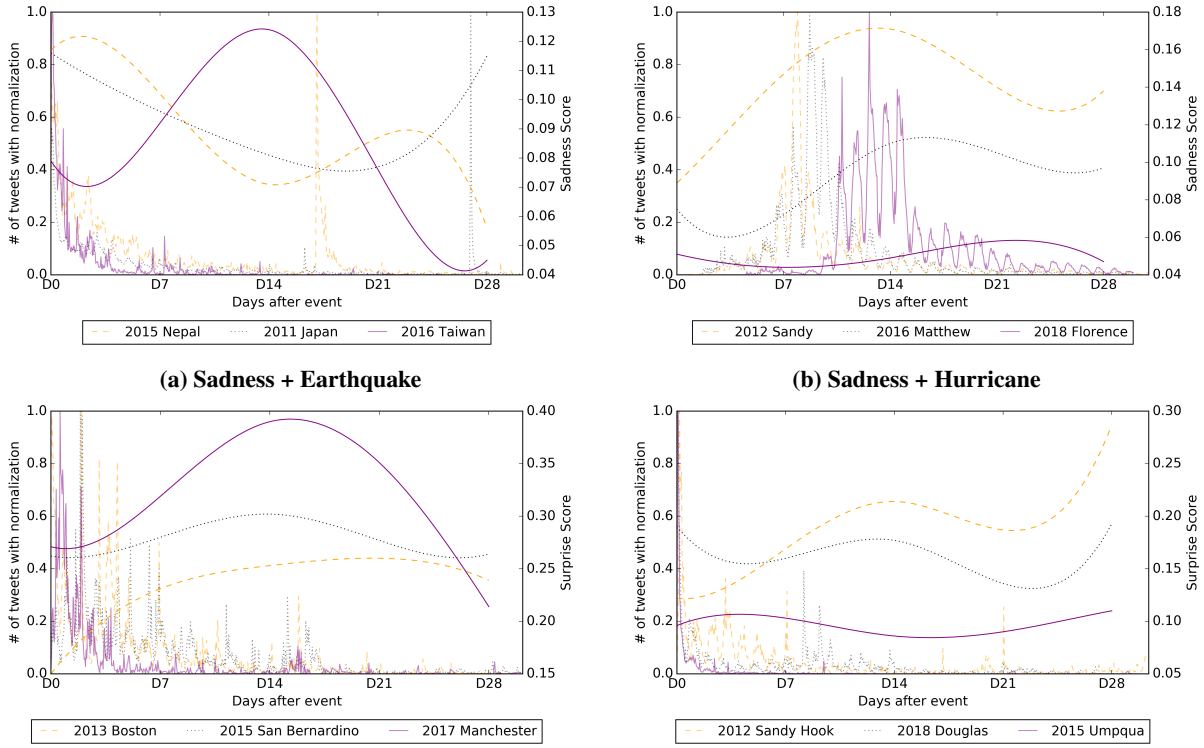
To explore further, we calculated the average score of each mood on the first day of each disaster and in every week after that. We selected two moods and two types of disasters for each mood, and showed changes over time with the corresponding tweet timelines, in Figures 6a through 6d. Figure 6a illustrates the sadness change in the earthquake disasters. The sadness score peaked two weeks after the main shock in Taiwan, while the aftershock played an important role in the Japan and Nepal earthquakes, leading to an increase in sadness. Figure 6b displays the sadness change in the selected three hurricanes. The sadness scores peaked about one week after the tweet count peaks of the three tweet timelines. Figure 6b also supports a quantitative comparison of the impacts of the three hurricanes. Users felt sadder in Hurricane Sandy, since it was the fourth-costliest hurricane in U.S. history, while Hurricane Florence made landfall as a weakened Category 1 hurricane, accompanied by a low sadness score.

The peaks in surprise were delayed by two or three weeks, for the bombing disasters shown in Figure 6c; we discuss more about mood delays below. As Figure 6d indicates, for school shootings, the scores of surprise were still increasing one month after the disasters, especially for the Sandy Hook Elementary School shooting (2012) and the Douglas High School shooting (2018). After browsing through users' tweets, we noted that users posted tweets like "*The Sandy Hook shooting was a hoax?!*" and "*I find it very odd two of the sandy hook funds were created before the shooting*" after the former shooting event, while they tweeted "*Who's Behind the Real Scandal*" about the latter event.

Mood Changes for Different Roles of Users

Based on the user and mood classification results, we enriched each tweet collection with user roles and mood scores, analyzed the mood changes among different role-related users, and carried out two case studies. Each sub-figure in Figure 7 illustrates the mood change across brand, female, and male users in one specific disaster, with its corresponding tweet timeline. Then, for each case study, we sorted the tweets according to mood score, and presented the surprise value for the k-th (k=1, 10, 20, 30) ranking tweets, for all three roles. Finally, we give the texts of some sampled tweets in Tables 3 and 4.

- *Case Study 1*: Surprise change in 2011 Japan Earthquake
  Figure 7a shows that the surprise score of male users had a significant increase after the aftershock, compared with the scores of brand and female users. The ranked k-th surprise scores also show male users were more surprised than brand users, while female users were relatively calm during that period.



(a) Sadness + Earthquake

(b) Sadness + Hurricane

(c) Surprise + Bombing

(d) Surprise + School Shooting

Figure 6. Mood changes (smoothed) for different types of disasters

Table 3. Ranked k-th surprise score comparison and sample tweets from male users in 2011 Japan Earthquake

	Surprise Score		
k	**Brand**	**Female**	**Male**
1	0.993	0.938	0.996
10	0.899	0.775	0.959
20	0.866	0.664	0.925
30	0.818	0.570	0.880

Sample tweets from male users with high surprise scores
japan had another earthquake? #idontbelieveyou
Japan just had another earthquake. WHHAAAAAAAAA?!?
Mother nature #idontbelieveyou another earthquake Japan?
Another earthquake in Japan! #wow
There was another earthquake in Japan?!?! OMG #PRAYFORJAPAN

- *Case Study 2*: Fear change in 2012 Hurricane Sandy
  Figure 7b shows the divergence of fear scores among different roles that appeared during the last week of the one-month time window. Here, brand users expressed more fear, and the fear scores of female and male users decreased at the same time. From the sample tweets, we noticed that brand users posted fear-related tweets regarding the aftermath of the destructive hurricane.

Table 4. Ranked k-th fear score comparison and sample tweets from brand users in 2012 Hurricane Sandy

	Fear Score		
k	**Brand**	**Female**	**Male**
1	0.999	0.991	0.996
10	0.875	0.720	0.848
20	0.789	0.537	0.733
30	0.728	0.441	0.635

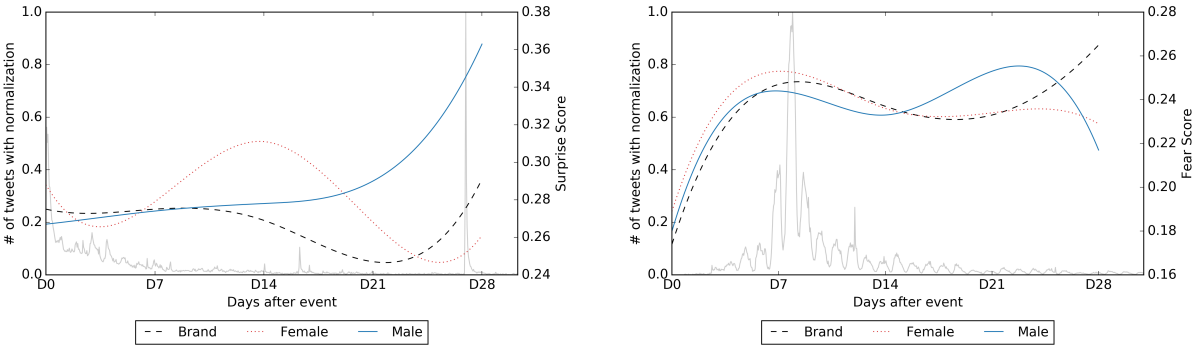
EVALUATION OF TWIROLE

Our new tool TwiRole has been used to predict the role of a Twitter user. To assuage concerns regarding the accuracy of the user classification predictions, we report on an evaluation of that tool. We utilized 10-fold cross-validation to evaluate TwiRole on an existing third-party dataset with gold standard labels. Further, we randomly selected 150 users from our disaster collections, and labeled user roles by hand, for a further evaluation of the prediction results of TwiRole.



(a) Surprise + 2011 Japan Earthquake **(b) Fear + 2012 Hurricane Sandy**

Figure 7. Mood changes (smoothed) among different roles of users in specific disasters

Metrics

We use a confusion matrix to calculate the recall (R), precision (P), and F1 score for each role. For a certain role r, the three values are computed as:

$$\begin{aligned} Recall_r &= \frac{\text{\# of users correctly identified as } r}{\text{\# of users labeled as } r}, \\ Precision_r &= \frac{\text{\# of users correctly identified as } r}{\text{\# of users predicted as } r}, \\ F1_r &= \frac{2 * Recall_r * Precision_r}{Recall_r + Precision_r} \end{aligned} \tag{1}$$

The performance of TwiRole is reflected in the overall accuracy; see Equation 2.

$$Accuracy = \frac{\sum_r (\text{\# of users correctly identified as } r)}{\sum_r (\text{\# of users labeled as } r)} \tag{2}$$

Results

First, we compare TwiRole with Ferrari et al.'s work (Ferrari et al. 2017) on the same third party dataset, since they also categorized Twitter users into the same three classes. The classification results are shown in Table 5. Their model has an advantage in identifying the male-related users, where their F1 score is 0.947 while ours is 0.903. But TwiRole performs better in detecting both female-related ($F1_{female} = 0.908$) and brand-related users ($F1_{brand} = 0.885$), and the overall accuracy ($Acc = 0.899$) is higher than with Ferrari et al.'s approach ($Acc = 0.865$). In addition, the prediction results of our model are more balanced across different roles, because the difference in F1 score is only 0.023 in TwiRole while it is 0.136 for Ferrari et al.

Table 5. Classification results of TwiRole and Ferrari et al.'s work

Tool	Brand			Female			Male			Acc
	R	P	F1	R	P	F1	R	P	F1	
TwiRole	**0.891**	**0.879**	**0.885**	**0.920**	**0.897**	**0.908**	0.885	0.922	0.903	**0.899**
Ferrari et al., 2017	0.837	0.786	0.811	0.806	0.857	0.831	**0.948**	**0.946**	**0.947**	0.865

Table 6. Classification results of TwiRole on disaster collections

Tool	True Label	# of users	Predict			Accuracy
			Brand	Female	Male	
TwiRole	Brand	50	41	6	3	82%
	Female	50	6	38	6	76%
	Male	50	10	3	37	74%

Second, using our disaster collections, we randomly chose 50 users labeled by TwiRole in each class and checked their roles manually by browsing their Twitter pages. Table 6 lists the manual checking results and the accuracy of prediction in each role. The overall accuracy of TwiRole is about 77%, which is satisfactory in our situation, where it is used to describe mood changes among tweeters.

DISCUSSION

As is mentioned in the Findings section, mood delays appear in some disasters. For instance, sadness maximum values were delayed one week after the peak counts in tweet timelines for hurricanes, while surprise score has a delay of two or three weeks for the bombing disasters. Accordingly, we examined mood changes over four weeks in all of our twelve collections, to check whether mood delay is a widespread phenomenon in disasters and is different among moods. For each mood, we compared its score on the first day with the score in each of the following four weeks. Table 7 lists the occurrences of the peaks of moods in different periods.

Table 7. Mood peak occurrences in different periods of time among all twelve disasters

Moods	Number of peaks occurred on / in					
	Day 0	Week 1	Week 2	Week 3	Week 4	Total
fear	3	2	4	0	3	12
sadness	7	0	2	1	2	12
surprise	1	3	2	3	3	12

The peaks of fear occurred on the first day in three out of the twelve collections (i.e., 2017 Manchester Arena bombing, 2015 Nepal earthquake, and 2012 Hurricane Sandy), while others can be found in the following weeks. Sadness peaks could be spotted on the first day in seven disasters, while others appeared in the next few weeks. For the surprise mood, the first-day peak only existed in one disaster (i.e., 2016 Hurricane Matthew); other peaks were distributed evenly over the weeks. Based on the mood peak distribution, we found that the sadness delay is shorter than the other two moods, which indicates that people tend to show their sadness feelings while facing a disaster right after its occurrence. In contrast, fear and surprise moods are likely to be delayed, as disasters and their reporting develop or unfold.

CONCLUSION

Focusing on patterns and mood changes during disasters on Twitter, we built twelve tweet collections with four disaster types: *school shooting*, *bombing*, *earthquake*, and *hurricane*. Then, we designed and implemented TwiRole to detect different roles of users, and used a pre-trained RNN model to predict moods (i.e., fear, sadness, and surprise) of tweets. Both user roles and mood scores were added to the data in the raw tweet collections to enrich the tweet representation.

Regarding analysis, we first investigated different types of disasters and found that each type has its own pattern. Next, based on the percentage of each role in our disasters, we concluded that brand users played an important role in disasters, while male users seemed more active than female users. Then, we worked on the mood changes at the event level and discovered that fear is the major feeling in most disasters, while sadness is dominant in two of the school shootings analyzed. By exploring each collection at the week level, we carried out a temporal analysis and discussed mood delays in disasters, where sadness is more time-sensitive than fear and surprise. Finally, two case studies illustrated that mood variation appears among users with different roles.

There are some limitations to our study that should be noted. The performance of the two classifiers might not be the best, in identifying users and moods, resulting in an approximate analysis. Three disasters in each type might not be enough for pattern analysis. We accumulated the mood scores of tweets, and it might not be the best approach to describe users' moods. In future work, we plan to add more disaster collections and improve the performance of TwiRole. We also will examine the analysis results on both local and distant populations, since the mood patterns might be different. Another improvement would be to explore the text information (e.g., frequent words, favorite topics) of tweets of users, which can assist in victim recovery in real-world emergencies.

ACKNOWLEDGMENT

Thanks go to the US NSF for its support of the Global Event and Trend Archive Research (GETAR) project, through grant IIS-1619028. We would also thank Ziqian Song and Xuan Zhang for their early work on TwiRole.

ABSTRACT

The use of social media to support emergency operators in the first hours of the response phases can improve the quality of the information available and awareness on ongoing emergency events. Social media contain both textual and visual information, in the form of pictures and videos. The problem related to the use of social media posts as a source of information during emergencies lies in the difficulty of selecting the relevant information among a very large amount of irrelevant information. In particular, we focus on the extraction of images relevant to an event for rapid mapping purpose. In this paper, a set of possible filters is proposed and analyzed with the goal of selecting useful images from posts and of evaluating how precision and recall are impacted. Filtering techniques, which include both automated and crowdsourced steps, have the goal of providing better quality posts and easy manageable data volumes both to emergency responders and rapid mapping operators. The impact of the filters on precision and recall in extracting relevant images is discussed in the paper in two different case studies.

Keywords

Rapid mapping, floods, information extraction, filtering, crowdsourcing

INTRODUCTION

During the first phases of crisis response after an emergency event such as a flood, a storm, or an earthquake, there is a need for creating awareness about the ongoing event and for providing as much information as possible to the emergency operators. Social media are considered a potentially valuable source of information to support gathering information from people living near the event location or informed about it. Several initiatives based on social media have been proposed, as well as tools to manage automatically the large amounts of data produced by social media in those cases (Imran et al. 2015), that can reach hundreds of thousands or even millions of posts related to the event within hours. It is well known that among this large amount of data, only a small amount of it consist of valuable information. For instance, in an analysis of Dresden floods in 2013 (Fohringer et al. 2015), from 15 millions of tweets in the flood period, only 5 images were considered useful to estimate water levels in the affected area.

Very recently, in (Alam et al. 2018) the extraction of relevant images from social media has been discussed with the goal of providing only relevant images about the event, eliminating duplicates and using supervised machine learning techniques to assess the damage's intensity in the area of interest. In fact, the concept of relevance is heavily dependent on the task to be performed, be it an assessment of water levels as in (Fohringer et al. 2015), or an assessment of the intensity of damage as in (Alam et al. 2018).

In the present paper, we focus on the task of extracting images which are useful for rapid mapping purposes, for a fast provision (hours-days) of geospatial information to support emergency management activities immediately following an emergency event.

The goal of this paper is to discuss how information retrieved from social media posts extracted from Twitter, can provide a visual evidence about a disaster.

In particular, we discuss how different filtering techniques can support the selection of the images which are relevant to an event from the large number of incoming social media posts. The different filtering options, which include automatic filtering and crowdsourcing, are presented and analyzed in detail, focusing mainly on two parameters: precision and recall. Precision allows us to provide the operators with images which are really relevant to the event, while recall evaluates how much a filter could result in a loss of contents, since it filters our possibly useful images.

The paper is structured as follows. First, we discuss the state of the art, then we introduce the crisis maps created in the E2mC project and how visual information can be retrieved from social media. Then we discuss possible filters to reduce the amount of irrelevant information provided to the volunteers for crowdsourcing and to emergency rapid mapping operators. The evaluation of the effect of filters in terms of precision and recall is then performed in two cases studies, discussing possible threats to validity and future work.

RELATED WORK

Information systems for emergencies have been rapidly developing since the first successful experiences with Ushahidi[1] (Goldstein and Rotich 2008) and its use in the Haiti earthquake [2].

Several other initiatives focus also on real time collection of information, such as in SensePlace, focusing on near real-time access for big streaming data (MacEachren et al. 2011; Pezanowski et al. 2018) and TWINE (Nozza et al. 2017) for real-time analysis of posts.

Many studies have been carried out in the last years regarding the extraction of relevant information through the analysis of the textual content of the posts published during disasters. On the other side, the visual contents have not been studied that much. (Peters and Albuquerque 2015) have demonstrated that the images extracted can increase awareness on the situation and that they can be indicators of the relevance of the post in which they are contained; however some authors underlined that to obtain, manage and analyze them automatically is complex (Murthy et al. 2016). They reported an analysis of how the contents of the posted images change during the different phases of the disaster, by classifying them manually. (Gupta et al. 2013) tried to filter fake images extracted from social media during hurricane Sandy in 2012. Since they noted that traditional image analysis methods were difficult to apply, they used tweet-based features to create a Decision Tree classifier that reached the 97% of accuracy in detecting fake pictures. (Chen et al. 2013) built an automated classifier utilizing text, image and social context features to distinguish visually-relevant and visually-irrelevant tweets obtaining a macro F1 of 70.5%. Another recent work from (Alam et al. 2018) shows a combined use of human and machine computing to process social media images for damage assessment during a disaster. They propose a real-time social media image-processing pipeline where unwanted images are discarded through a deduplicating passage, based on perceptual hashing, and through a relevance filter, based on Convolutional Neural Networks architectures. The images are then labelled and classified by a crowd of volunteers and used to train the automatic machine classifier to assess the level of damages in area as severe, mild or none. Their results show that this approach can help to gain situational awareness during an ongoing event. They also show that filtering the images allows increasing the precision of the classification both of the human and of the machine system.

PRODUCING CRISIS MAPS IN E2MC

The E2mC project[3] has the goal of producing crisis maps for emergency events, to support rapid mapping activities performed by operators in Emergency Mapping Services (EMS) of Copernicus[4], the European initiative to provide timely and accurate information derived from satellite data and additional sources on the ground.

As described in (Havas et al. 2017), the E2mC platform is composed of a set of tools aimed to support the analysis of social media posts, extracted from Twitter, Flickr, and YouTube. The goal is to provide EMS rapid mapping operators with timely and relevant visual information extracted from posts. The processing of posts is performed in near real-time, as the event progresses. The starting point is a crawler that collects posts through the social media APIs. As most of the posts are not natively geolocated, in particular in Twitter and YouTube, crawling is followed by a geolocation tool, called CIME (Context-based Image extraction) (Francalanci et al. 2017), that localizes the posts as precisely as possible from the textual contents of each post using OpenStreetMap[5] as a gazeteer. Only the

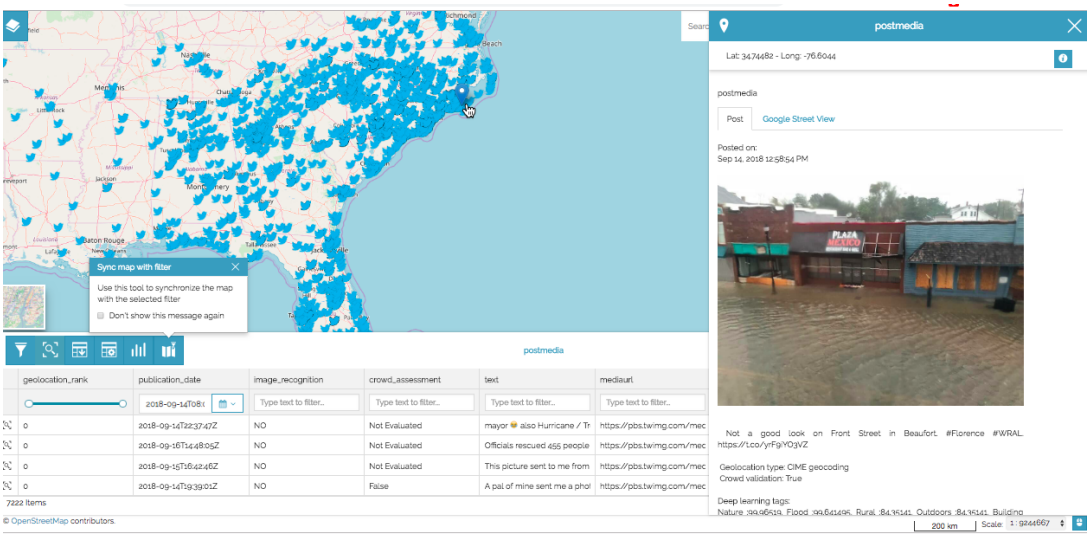

Figure 1. Witness user interface for the E2mC crisis maps

posts that contain an image or a video and are located at least at locality level (town or village) are retained for further analysis.

Figure 1 shows the webGIS interface developed in E2mC, called Witness. The Witness interface shown in the figure provides a crisis maps with located tweets (displayed in the center of their OSM location) and gives the possibility to show the contents of each tweet, accessing Twitter through its APIs. In addition, a set of possible manual filters is shown, to select localities at different levels of precision (from locality level down to precise points in the map), to examine only relevant tweets as evaluated from crowdsourcing, and to select only images detected as relevant to the specific type of event (e.g., floods).

The tweets are processed near-real time during the event, so that the classifications of the filters are incrementally populated.

In the present paper, we present different ways to reduce the number of tweets, and in particular using a set of filters which are discussed in detail in next section. Some of the filters illustrated in the following are part of the core E2mC platform, others, like the color and text filters, are proposed in the present paper and evaluated in the present work.

Two case studies are considered in the following parts of the paper, with datasets containing posts from Twitter which are geolocated at least at locality level and include an image: i) Southern England Floods in 2014 (corresponding to EMS activation number EMSR069, started on Feb. 10, 2014), consisting in 343 tweets, collected in the period February 10-14, 2014; ii) the Hurricane Florence over USA East coast in September 2018 (EMSR311), where the storm continually dumped heavy rain along coastal areas from September 13, 2018; in this case more than 28,500 posts have been crawled, of which we consider a data set of 2,940 posts collected in 24 hours on Sept. 13-14, 2018, from which we randomly sampled 301 posts for performing manual annotations for the analysis work presented in this paper. Both datasets are available on request from the authors.

FILTERS

During a disaster, the main problem is managing timeliness: for the operators it is necessary to have valuable information on the affected area in a short time. Images coming from social media can help in obtaining this information, but, on the other side, the volume of the data extracted may be too high to be managed within the short time frame they have. In addition, the data extracted is usually of low quality, since the images obtained from the crawling includes a high percentage of irrelevant information. Thus, it is necessary to send readily usable aggregated and cleaned data to the emergency rapid mapping operators and emergency responders. Consequently, many filters have been designed and analyzed to understand their potential in reducing the volume and improving the quality of the set of images available.

In the next subsections, we introduce a set of possible filters that can be applied to reduce the volume of posts with associated images to be provided to rapid mapping operators and we analyze their efficacy in improving the section of posts for rapid mapping. The following filters are considered in this work:

- Redundant information reduction
  - Duplicate reduction
  - Retweets elimination
- Image filtering
  - Colour-based filtering
  - Elimination of pre-event images
  - Face detection
  - Text detection
- Crowdsourcing
  - Crowd-sourced relevance tagging task

For each filter, a short description is provided in this section, illustrating the main characteristics, parameters, its effects, and time to be executed on a laptop HP Pavillon, with Intel Core i5 and 8GB RAM. In the following section, the filters are evaluated in the two case studies examined in this work.

Redundant information reduction

Duplicate reduction

During disasters, people use social media to post a huge amount of information, often sharing pictures they are seeing on pages of other users. Thus, the goal of this filter is to detect all the duplicates and near duplicates (that are pictures very similar to the original but with little modifications like addition of borders, colour enhancement and luminosity changes, addition of text, cropping), since they usually do not provide new information. However, it can happen that the same image is posted with different textual descriptions that may bring additional and useful information. The goal of the filter is to consider duplicate images only once in the filtered dataset.
The detection of duplicates can be implemented in different ways. The one adopted for the E2mC project provides the use of image hashing (in particular the perceptual hashing). Perceptual hashes are fingerprints of the pictures, created on the basis of the features and visual content of the images, so they are similar to each other if the images contain similar features. The perceptual hash is obtained through the Python library *phash* that is an open source software library. For all the pictures, the hash is computed and it is compared with the set of all the hashes found in the data set using the hamming distance, that is the number of positions at which the bits of the two strings of the hashes differ. If the distance between two hashes is lower than a certain threshold, then the pictures are considered duplicates. The threshold has been fixed to 15 since analyses on the data sets shown that this value guarantees the detection of a high number of duplicates while committing a low number of errors. This system has the advantage of being very fast (one second per image) since it just compares simple strings.
A modification that can be done to the previous algorithm consists in the addition of a feature detection system. A SIFT detector is used to identify the small characteristics of the pictures and compare them. These features are then compared with the feature of other images to assess if they match or not. With this improvement it is possible to detect more near-duplicates but the computation time increases 5 times.

Retweets elimination

A retweet is the re-post or the forward of the message posted by another user. During a disaster, the most impactful images or the funniest ones are retweeted several times. For the E2mC project it is important to understand if retweets bring new information or if they only increase the volume of the dataset. Retweets repost the same image and usually also the text is not changed, so they spread duplicated information. They can be identified by the initial "RT" at the beginning of the post's text, so they are easy to be recognized automatically. The goal of the analysis presented in this paper is to evaluate the impact of eliminating retweets on the resulting dataset, in terms of evaluating the loss of relevant images.

Figure 2. Examples of a white image, a black image and an image with peaks

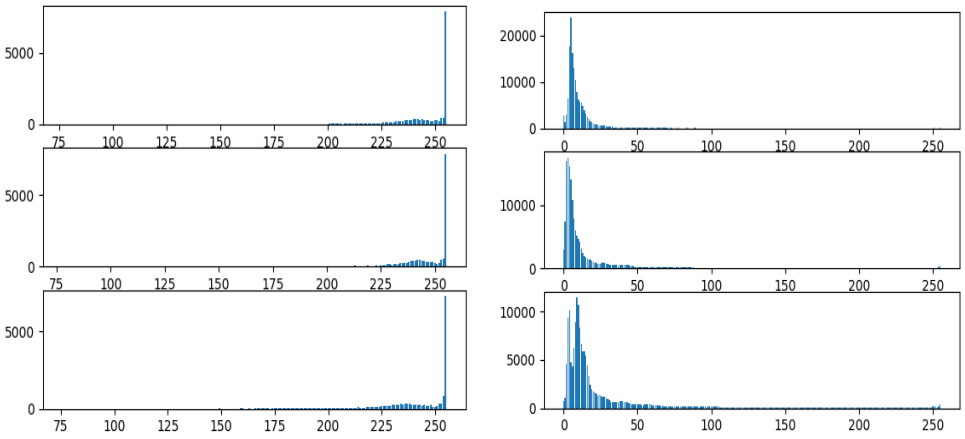

Figure 3. Histogram of a light image (left) and of a dark image (right)

Images filtering

Colour based filtering

The aim of this tool is the filtering of the images on the basis of their colours. During a disaster, pictures containing graphs, weather reports, jokes, texts are published, and they are not useful for disaster rapid mapping. This kind of images represent a huge source of noise during the analysis of the crawled posts. Therefore, three filters have been created to eliminate pictures that are too light, too dark or that contain graphs, drawings, not "taken photos". An example of these categories is reported in Figure 2.

The filter is based on an analysis of the image's intensity value histogram, that represents the distribution of the pixel values in the picture. Pictures that are very light have histograms shifted towards the higher values, while dark images have a histogram concentrated at the lower values. The difference is shown in Figure 3. There are three histograms because the levels of the RGB (red-green-blue) in the image are analyzed separately.
Pictures with graphs and drawings, that have a part of the picture of the same colour, present peaks of values in correspondence of these colour intensities. The difference between an image with peaks and a natural image can be seen in Figure 4.

For each filter a threshold is fixed to understand if the image should be discarded. The thresholds have been defined after an accurate analysis of the histogram of some test images. The thresholds for the "white" and "black" filters are based on the quartile (0,25,50,75,100 percentiles) subdivision of the histogram values. In fact, if the first quartile, that is 25, is high, it means that there is a concentration of pixel values towards the right side of the histogram, while if the third quartile, that is 75, is small, it means that values are concentrated in the left side of the histogram, meaning that a lot of pixels have a dark colour. In addition, the percentage of dark and light pixels in the image can be computed. Thus, if the first quartile is higher than 200 and the percentage of light pixels is higher than the 80% of the total values, the image is classified as 'white', while if the third quartile is lower than 35 and a percentage of dark pixels is higher than the 80% of the total values, the image is classified as 'black'. The images with peaks are, instead, identified as the images that have a total number of peaks higher than 3. A peak is found when the

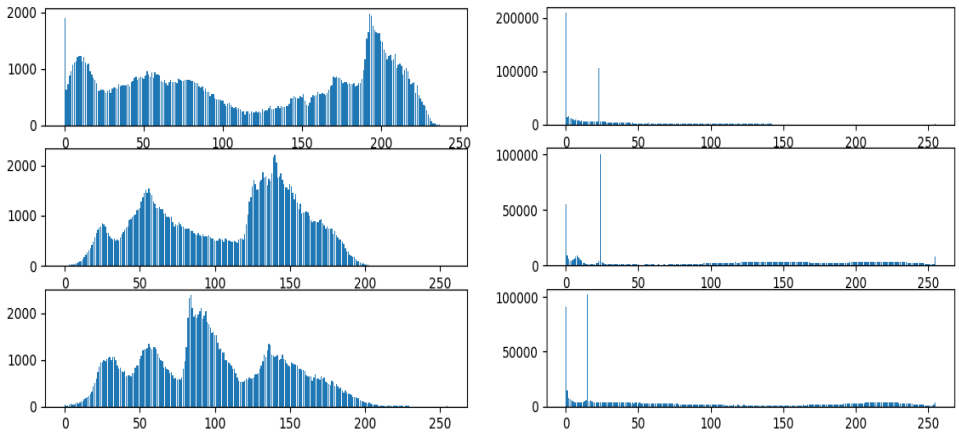

Figure 4. Example of a natural image histogram (left) and an image with peaks (right)

difference between the pixel intensity's before and after the analyzed pixel is high. This difference has been fixed to 3,500, but it can be lowered to create a filter that discards more images.
The classification of the images with these tools is fast and requires about 1 second for each picture.

Pre-event images

A problem that has been raised regarding the use of pictures posted in social media as a reliable source of information is the presence in datasets of pictures coming from previous events. These pictures can be mixed up with pictures of the current event, leading to the non-credibility of the whole dataset and to errors in the damage assessment of the affected area. The tool that has been used to face this issue is Google images[6].

This application offered by Google allows the user to search among all the pictures that have been posted on-line by keyword, by URL or uploading a picture to search all the similar ones present in the web. The parameters used to classify an image as being old are: (1) The presence in the Google results of older dates than the date of beginning of the disaster. (2) The presence in the results of pictures equal to the given one. (3) The presence of the searched image inside the website given as a result by the Google reverse image search.

Some problems limit the potentialities of this tool. There is a limitation on the call to the API that makes it necessary to add some waiting time in the process that increases the computational time of the algorithm. In addition, due to copyrights and recent policies on privacy, some pictures are no more freely available on the Internet. Because of this, some pictures coming from previous events may not be found.

Faces detection

Another kind of pictures that are present in the dataset during an emergency are the pictures with faces. These pictures often are not useful, such as jokes and selfies, but include also pictures extracted from television news reports, that in some cases could report useful information. Because of that, this filter should be used in case of overload of incoming pictures and when there is the need of reducing the dataset.
The tool, that exploits a built-in face classifier and detector, OpenCV[7], finds each face in the picture and draws around it a rectangle. Checking the number of faces found and the total area of the rectangle (or rectangles), it is possible to understand if the faces occupy the biggest part of the picture, thus meaning that it is not useful. A threshold value is needed to specify how many possible "face features" each candidate rectangle should have to consider it a face. In the current implementation, the threshold has been fixed to 8. This tool requires 0.5-1 seconds to evaluate each picture and it is very reliable. The limitation of this algorithm is related to the built-in cascade XML provided by OpenCV for the face recognition that is able to detect only frontal faces.

Text detection

Text detection can be used to reduce the volume of relevant images that arrive to geolocation crowdsourcing volunteers and to emergency rapid mapping operators, to provide a set of images easier to geolocate, an important characteristic when dealing with rapid mapping. In fact, the presence of words in an image can be related to road signs, license plates, shop signboards which are features that can help to find the place where the picture was taken.

[6]https://images.google.com/
[7]https://opencv.org/

Figure 5. Examples of relevant images with words detected in them

It is useful, in particular, in case of big datasets, since volunteers and emergency rapid mapping operators, that are overloaded with work, would prefer to see only the most relevant pictures.
The filter is a text detector created with the Python OpenCV's EAST text detector. The parameter that changes its performance is the probability that the area analyzed in the picture contains words. An area contains text if the probability is higher than a certain threshold, that has been fixed to 0.99 to ensure a reliable result in the finding of words. The time required to evaluate each picture is less than 2 seconds. Time can be reduced making the dimension of the picture under analysis smaller, but this operation would also decrease the precision of the tool.

Examples of the images extracted are reported in Figure 5. The EAST text detector has a limitation for the images with metal grills or meshes. In fact, it confounds tiny metal grills with words.

Crowdsourcing

Crowdsourcing is used in E2mC to both identify relevant posts and to validate and improve the precision of the geolocations generated by the CIME algorithm, with the help of volunteers. In the present paper we focus on crowdsourcing used for relevance tagging of the posts.

Crowdsourcing relevance tagging task

The selection of the pictures useful for creating disaster maps can be performed manually by a crowd of volunteers that evaluates the relevance of each image. Volunteers are asked to decide if a picture is relevant or not in a platform specifically created for the E2mC project, where the image and the related post are shown, as shown in Figure 6. The relevance value can be 1, when the image is considered useful and 0, when it is considered not useful. Each picture should be evaluated at least by 5 people to reduce the possibility of a wrong result by comparing the answers given by all the volunteers. In some cases of lack of time, the minimum number of results can be reduced, to process all the pictures in less time. The quality of the result given by the crowd, in this case, will decrease. Then the mean answer value is computed, and, if it is higher or equal to 0.8 (i.e. 4 out 5 volunteers considered the image relevant), the image is considered relevant. The time required to evaluate each picture is short, but the number of pictures that can be processed with this tool is not predictable, because it depends on the number of volunteers that participate in the project. From the case studies, each volunteer in the crowdsourcing can evaluate approximately 500 images per hour, however the effects of fatigue should also be considered, as discussed in (Purohit et al. 2018).

EVALUATION

In the present section we evaluate the illustrated filters, considering their effects on the goal of providing the rapid mapping operators with an informative set of images. Each filter can be considered a binary classifier that, depending on the value of a threshold, marks the images as 'negative' when they are classified as pictures to be eliminated because they are not relevant, or 'positive' if they should be kept, because they are useful for mapping purposes.

The result of the classification produced by each filter is then compared with the manual classification of relevance of each picture evaluated by two experts, to create confusion matrices that present the numbers of True Positive, True Negative, False Positive, False Negative. Thus, the filtering performance is evaluated in term of *precision*, i.e., the fraction of relevant posts among the retrieved posts, *recall*, i.e., the fraction of relevant posts that have been

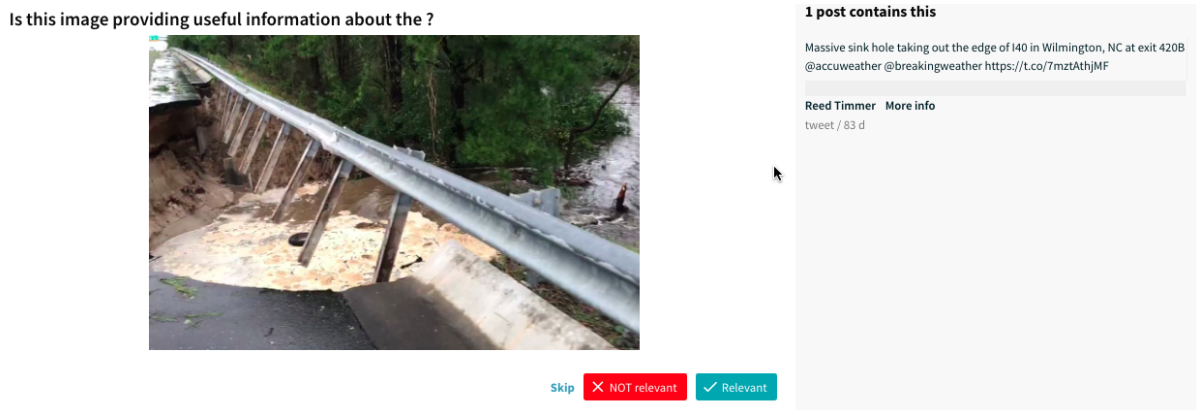

Figure 6. Crowd4EMS tool developed in E2mC

Table 1. Initial datasets expert evaluations

	UK flood		*Hurricane Florence*	
	Number of images	*Percentage*	*Number of images*	*Percentage*
Relevant	176	51.31%	38	12.62%
Not relevant	167	48.69%	263	87.38%

retrieved over the total amount of relevant posts, and the *percentages of relevant and non-relevant images discarded*. For each filter the mean percentage of reduction of the initial dataset and the precision gain after filtering is reported. The filters have been tested on two case studies, the floods that affected the Southern region of United Kingdom in 2014 and the Hurricane Florence in September 2018, which hit the North America East Coast. The first case study dataset is composed by 343 images that have been manually annotated, while for the second dataset a subset of 301 images has been used for the following analysis, manually annotating the relevance of the images by experts. For the analyses presented in this paper, random samples of the posts where manually annotated by two experts with the relevance of the images to the rapid mapping activity, as a basis for comparing the results obtained applying the different types of filters. Post selection is detailed in the following. The initial precision of the two datasets as evaluated by the experts and considered as ground truth are reported in Table 1.

Evaluation of redundant information reduction filters

Duplicates

Duplicated pictures have been detected in the two datasets with the *phash* technique. The algorithm shows limitations for both rotated and cropped images, which are not recognized as near duplicates. Duplicates are spread both between the relevant and non relevant images. The reduced precision of the final dataset in the set of hurricane Florence is due to the high percentage of duplicates between the relevant images. Table 2 summarizes the results.

Table 2. Duplicate filter results

	UK flood	*Hurricane Florence*
Precision	55.74%	9.70%
Recall	77%	60.53%
Relevant eliminated	23.00%	39.47%
Non relevant eliminated	35.33%	18.63%
Dataset reduction	28.86%	21.26%
Precision gain	+8.63%	-23.13%

Table 4. Colour filters results

	Filter white		*Filter black*		*Filter peaks*	
	UK flood	*Florence*	*UK flood*	*Florence*	*UK flood*	*Florence*
Precision	52.69%	13.38%	51.03%	12.50%	56.11%	14.81%
Recall	100%	100%	99.42%	97.37%	96.59%	84.21%
Relevant eliminated	0%	0%	0.58%	2.63%	3.41%	15.79%
Non relevant eliminated	5.39%	6.46%	1.78%	1.52%	20.36%	30.04%
Dataset reduction	2.62%	5.65%	1.17%	1.66%	11.66%	28.24%
Precision gain	+3.88%	+6.02%	+0.60%	-0.95%	+9.35%	+1.41%

Retweets

The filtering of the retweets has been applied on both datasets.The differences in the results on the two cases are due to the fact that hurricane Florence's dataset is characterized by a high percentage of retweeted posts, while for UK flood case they are less (see Table 3).

Table 3. Retweet filter results

	UK flood	*Hurricane Florence*
Precision	52.10%	6.86%
Recall	91%	32%
Relevant eliminated	9%	68%
Non relevant eliminated	11.38%	38.02%
Dataset reduction	9.91%	41.86%
Precision gain	+1.54%	-45.64%

Evaluation of image filters

Colour based

In Table 4 the results of the application of the three filters on the colour are reported. The low percentage of relevant images eliminated shows that they can be applied without discarding too many relevant pictures. The slightly higher value of relevant images eliminated by the "peak" filter on the hurricane Florence dataset is related to the scarce amount of relevant images in this dataset. Applying them one after the other can improve the quality of the final datasets and can eliminate high percentages of the non relevant images.

Images from previous events

The filter has been used on both the datasets. For the UK flood case study the algorithm was able to detect only one image considered relevant coming from a previous event. 11 not relevant images have been found that where posted from 2007 to the end of January 2014. In the case of hurricane Florence, no relevant images and 15 non-relevant images coming from previous events have been found.
This technique is not perfect and paid APIs would be needed to further improve it. Thus a faster and easier way to detect images from past events would be to create a database that collects the hashes of the viral and more repeated images of each event, to compare them with the new-coming images. This database could be implemented and tested when more case studies will be available.

Faces detection

The filter has been used on both the dataset showing that is useful to eliminate a part of the unwanted images without eliminating relevant ones (see Table 5.

Text detection

The filter has been applied to both the case studies' dataset to see how many images are discarded and if the images selected to be kept can be useful. In Table 6 the percentage of relevant and non-relevant images containing words

Table 5. Faces filter results

	UK flood	*Hurricane Florence*
Precision	53.66%	13.52%
Recall	100%	100%
Relevant eliminated	0%	0%
Non relevant eliminated	8.98%	7.60%
Dataset reduction	4.37%	9.63%
Precision gain	+4.58%	+7.13%

Table 6. Texts filter results

	UK flood	*Hurricane Florence*
Relevant with text	17.20%	9.97%
Non relevant With text	30.32%	62.46%
Reduction of the set of relevant	49.57%	21.05%

with respect to the whole dataset is reported to show that non-relevant images contain words more frequently than the relevant ones. Thus the last line of the table shows how much the set of relevant images would be reduced with this tool.

Evaluation of crowdsourcing activities

Crowdsourcing relevance tagging task

A crowd of volunteers has been used to evaluate both data sets. In the case of the Southern England floods dataset, the images have been evaluated five times by different members of the crowd, while in the case of hurricane Florence only once. This provokes a higher number of relevant images eliminated and lower number of non-relevant images discarded in this second case study (see Table 7). Anyhow the crowd filtering gives recall and precision values higher than any other filter for both case studies. The limitation of the tool is related to the human factor, since not always a sufficient number of persons are available to do these tasks when a disaster strikes.

Table 7. Crowdsourcing filter results

	UK flood	*Hurricane Florence*
Precision	96.93%	39.24%
Recall	88.76%	81.58%
Relevant eliminated	11.24%	18.42%
Non relevant eliminated	97.01%	81.75%
Dataset reduction	52.48%	73.75%
Precision gain	+88.91%	+210.94%

Evaluation of filters combinations

Some initial experimentation has been performed on the combination of the tools, in particular considering the configuration currently chosen in the E2mC project, which at the moment is adopting retweet filtering and crowdsourcing. The results have been evaluated using as ground truth an expert evaluation of the posts.

From the first experimental analyses, we gathered the following evidence:

- with the current E2mC configuration, retweets are filtered out and then a relevance task is performed by the crowd. We obtain an 80.11% recall and 2.99% False Positives in the UK flood case study and 69.92% recall and 9.09% False Positive rates in the case of Hurricane Florence, maintaining recall at a good level and with a limited number of false positives while reducing the manual effort. i.e., the resources needed to produce the images which are sent to the mapping operators for rapid mapping.

- Some filters appear to be highly correlated. For instance, black vs white filters are not correlated, while retweets and duplicates are highly correlated. Further investigation is needed to assess filter correlation in general.

THREATS TO VALIDITY

While for some of the filters, e.g., the colour filters, the recall and precision values have comparable values in the two case studies, in other cases they appear to be largely different, such as for instance for retweets. In future work, an estimation of these values could be derived case by case during different events, to study how to adapt thresholds and to estimate precision and recall accordingly.

Another aspect to be considered when combining different filters is that some of them are strongly correlated (e.g., the duplicates and the retweets filters). In those cases, the probability of joint occurrences for the two filters has also to be estimated, in order to be able to estimate the final precision and recall values for the combined filters. Ongoing work is analyzing the relationships between filters, to assess which ones are independent (such as for instance, it appears to be true in the pair white filter - duplicate filter) and the correlations patterns in correlated filters.

Finally, thresholds need to be fixed for each filter. They have been empirically estimated on the available case studies, therefore the values can not be considered valid for every kind of disaster. Also in this case further work is needed to be able to dynamically evaluate the appropriate thresholds for each filter given the type of emergency event and the number of available posts to be processed in real time.

CONCLUDING REMARKS

In this paper we have proposed a general approach for reducing the amount of irrelevant information extracted from social media during an emergency to support the activities of rapid mapping operators. As the quantity of posts can be variable in different events, due to their severity, their location, the availability of infrastructures after the event and the diffusion of social media, the aim is to support the choice of the best combination of filters depending on the characteristics of the on-going event. In future work, as the focus of this work has been on image analysis, we plan to analyze more in detail other types of filters, including also filters based on automatic image classification, being developed within the E2mC project. An adaptive tool combination and selection is also going to be studied in the future, to facilitate the rapid mapping operators activities, avoiding manual selection of filtering criteria, and aiming to generate a good combination of precision and recall in image selection. The aim of this work is to create an adaptive platform to select dynamically the filters and their thresholds, with an adaptive approach suited to the specific ongoing event.

ABSTRACT

In this paper, we will discuss a system design for simulating social media data based on historical datasets. While many datasets containing data collected from social media during crisis have become publicly available, there is a lack of tools or systems can present this data on the same timeline as it was originally posted. Through the design and use of the tool discussed in this paper, we show how historical datasets can be used for algorithm testing, such as those used in machine learning, to improve the quality of the data. In addition, the use of simulated data also has its benefits in training scenarios, which would allow participants to see real, non-fabricated social media messages in the same temporal manner as found on a social media platform. Lastly, we will discuss the positive reception and future improvements suggested by 911 Public Service Answering Point (PSAP) professionals.

Keywords

Twitter, Simulation, Crisis Response, Social Media

INTRODUCTION

Does it work? This is a question asked by many software and application developers when designing and developing new tools. This question however becomes much more complex when examining tools and applications designed to work in real time. Furthermore, when the application is designed to be used to support critical decision making that could affect lives of others, it has to work. With this in mind the software development cycle can be broken up into the five stages of; requirements analysis, design, implementation, testing and evolution or iteration.

Unfortunately, the world of software development is one that seems boundless, with each application having different requirements and goals. In order to provide focus to our research, we have chosen the domain of crisis response. In particular, we investigate software development tools for crisis response that look at how to best gather, filter, and curate data produced by citizens such as that found on social media. With people turning to social media to both disseminate and gather information, there is an abundance of information. For example, if we take the social media platform Twitter, infamous Hurricane Sandy during 2012 in which over 20 million tweets were posted over a five-day period (Halse et al. 2016). Next, as crisis responders only require actionable information with a high degree of veracity, much work as looked at how to improve the quality of this data through tools applying advanced filtering and machine-learning algorithms (Halse et al. 2016)(Caragea et al. 2011).

Due the nature of crisis response, the implementation phase of the software development cycle can be a particularly challenging one. Previous work has shown the value of tools for social media analysis for crisis responders along with the desire to use such tools (Alexander 2014). However, it is not without difficulties associate with deployment in the crisis response domain (Jin, Liu, and Austin 2011). These include difficulties in increasing the workload of the responders, especially during a crisis, along with providing adequate training tools

that are based on actual, non-fabricated datasets similar to those that would be seen during and event.

The next two crucial steps in the software development cycle, is that of implementation and testing. It is within these steps that we face two primary challenges in developing tools for crisis response. The first is the unpredictability of certain crisis. Some slow onset crisis, such as hurricanes, floods, and fires, provide enough time for researchers and end users to deploy and monitor software application for data. However fast onset crisis, earthquakes, bombings, and other manmade crisis may require advanced techniques for detection and identification. Furthermore, fast onset crisis also require the users of applications to have active ongoing data collection and analysis. The second issue regarding development of crisis response application is that of the temporal nature of the data collected during a crisis. While many discoveries and tools have been created through the analysis of full datasets, they are difficult to test and improve within a real time environment.

It is these last two steps in the software development cycle, which this paper will address. This is done through presenting a simulation tool designed to allow testing of software used for gathering, filtering and analyzing social media data. We discuss the system architecture, features and the results of a small workshop with crisis response professionals. Additional avenues, such as training, in which a simulator can be implemented, are also discussed.

RELATED WORKS

Social media contains a vast amount of data, be it a community or people sharing information about every day, to large organizations attempting to disseminate time sensitive critical information to the public. This makes it an ideal candidate for data collection and analysis, especially during emergencies when traditional avenues of information gathering and sharing may not be available. It has also become an important tool to reach those impacted by a crisis event (Kavanaugh et al. 2012). While there can be an overabundance of information found within social media sites, many previous research studies have been able to parse out particular information related to a given event. For example, work has shown that through using given keywords and machine learning algorithms, earthquakes events and information can be detected through messages found on Twitter (Crooks et al. 2013)(Sakaki, Okazaki, and Matsuo 2013). Likewise, social media has also been used to capture data for fires, shootings, hurricanes and building collapses (Palen 2008).

Furthering this frameworks, tools have also been developed to allow dynamic detection and capturing of data during a crisis (Bruns and Liang 2012). With many frameworks and analysis methods available, tools have been developed for use by crisis responders. Some of these tools include; Earthquake and reporting system (EARS) (Avvenuti et al. 2014), Tweet4act (Chowdhury, Chowdhury, and Castillo 2013), SensePlace (MacEachren et al. 2011) and TweetTracker (Kumar et al. 2011). Unfortunately, despite the availability of these tools, social media remains a "white whale" for crisis responders. A solution to social media adoption by crisis responders can be addressed through examining two primary concerns; the first is identifying which of the tools are most effective and identifying areas in which they can be improved, with the second being developing simulated training environments for the top performers. This has been approached in previous work which investigated how data can be used to design, develop and improve tools the emergency responders (Hampton et al. 2017). However, this work utilizes data that is fabricated artificially. In this work, we utilize previously collected corpuses from real messages posted on Twitter.

With the first concern in mind, and with the use of simulations in crisis response shown to be an effective method by which to improve the quality of software applications and algorithms used in crisis response (Walker and Giddings 2011), we can begin to standardize the testing environments. Through standardizing the simulation inputs and outputs with the same datasets, we can reduce any additional confounding variable during testing. Previous research has shown that valuable information in system design can be gained, especially through incorporating user centered design (Kluckner and Wendt 2014). This is done through presenting end users with a simulated environment to determine what information they feel is most relevant. Likewise, through incorporating the results of studies into a simulated environment, software developers have an ability to compare one iteration and design to another based on user feedback. Standardizing the simulated environment also opens avenues in which policies and procedures can be created.

In addition to testing, and with respect to the second concern, standardizing simulation environments allows for the development of training protocols. Training for crisis responders with games and simulations has had much success in previous literature (Heldal and Wijkmark 2017) (Parush et al. 2016). These two examples describe how through simulations, training is both reduced in cost and increased in effectiveness. This combats the problem of users being unfamiliar with the system during times of crisis. It is through training that the user can develop a better understanding of the system and learn the limitation or advantages within (Schaefer et al. 2014). Additional works have also stressed the importance of training, especially when the system be utilized is novel and the user is unfamiliar with it (Abbasi and Kumar 2012)(Baumgart et al. 2006). Rather than having to wait for a particular event to occur in real time, simulations within a training environment provide the ability to control which data set and corresponding event is being used. In addition to this, with data collected during previous crisis, crisis

responders can identify particular keywords, search tactics and analysis strategies. This is particularly important when the data used for the simulation has been localized to their area of interest.

SIMULATOR SYSTEM DESIGN ARCHITECTURE

The goal of this simulator is not to create new social media messages, but instead is to take messages that have been collected from previous datasets. These messages would then be sent in the same temporal pattern as they were originally posted. Rather than send a fully collected dataset to a software application, the basic premise of this simulator is to read in the data one message at a time, detect the timestamp for that message and then send the data after a given amount of time has passed. That is, once the simulator has begun running it starts at a predetermined historical timestamp such as 1 hour before the event had occurred. It would then calculate the delay between this time and the timestamp found from the Twitter message. After the simulator had been running for this delay, it would then send that message. For example, if we set our simulators start time to 11:00, and had an event such as a shooting, where the first message about the shooting was posted at 11:57, then it would take 57 minutes for that message to be shown (assuming a timescale of 1:1). This emulates the temporal nature that would be seen from data gathered during a crisis event. Figure 1 below shows how the simulator is connected to existing tools with the minor addition of a data adapter.

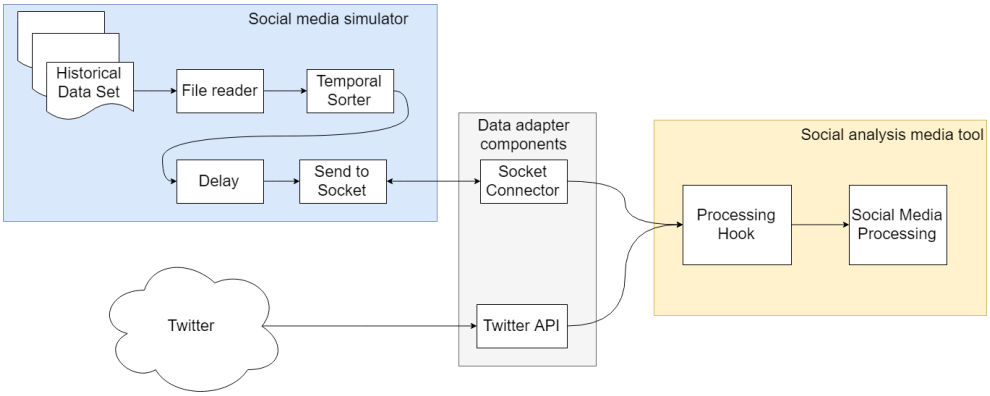

Figure 1 - Overview of system usage

From Figure 1 we can see that the social media simulator is implemented in place of collecting data directly from Twitter. The concept here is to allow developers to leverage previously collected datasets, that are crisis related, to test and improve their designs. The goal of the simulator is not to replace data collected from Twitter, however there is not always a crisis occurring that can be used for development purposes. It is through the adapter component that the source of the data would be selected. In the diagram above we have shown the adapter as a separate component however it can be easily incorporated into the existing social media analysis tools. This way the developers can choose if they would prefer live data, (assuming a crisis is ongoing) or simulated data based on a selected dataset.

Data

In order to create a tool that leverages historical datasets to produce a simulated social media stream, historical datasets are needed. The datasets used for testing in our case was those publicly available from crisislex.com and described in the works of (Olteanu et al. 2014). This collection contains data collected on over 30 different crisis events. As each data set has the potential to contain many different data points, we began by defining some of the fields that would be required to create a simulation stream. As the simulator's main purpose was to deliver tweets from these datasets in the same temporal nature to how they were originally found, the first required data point is that of a timestamp. Next, the simulator detects one of two possible conditions: data containing a messageID, and data with no messageID but does have message context. In some cases, the creators of a dataset did not collect additional information concerning a message, but instead only a timestamp and a messageID were collected. If no messageID is available then only the message content data field is used. While it is possible for the datasets to contain additional informational fields, our simulator is primarily concerned with displaying each of the tweet's message in the same temporal order originally seen. Each of the data points are explained in more detail in the following sections.

Timestamp (Required)

The timestamp for the data is required as this serves as the basis for when to send or show the data. This tool looks for the timestamp with the earliest value and uses this as the simulators start time (startTimestamp). It then

calculates the value (in milliseconds) between the earliest timestamp and the next timestamp (nextTimestamp). This is done using the following formula deltaTime = nextTimestamp – startTimestamp. One the value for how much time exists between the start time and corresponding tweet's timestamp (deltaTime) has been calculated, a delay of deltaTime is implemented before displaying the message data. For example to increase the speed at which messages are displayed we can divide deltaTime by the scale factor. The pseudo code snippet looks like this:

```
Loop for each message in dataset
deltaTime =   nextTimestamp – startTimestamp;
        timePassed = nowTime – codeExecutionStartTime;
        if(timePassed > deltaTime/timeScaleFactor)
                Show/Send message
endLoop
```

It is important to note that while the simulator is designed to present messages found in a dataset at the same speed they were originally displayed, a timeScaleFactor was added to allow for accelerated testing. For example, if we wanted to test the performance of an analysis algorithm in pseudo realtime, a time scale factor could be used as some of the datasets were collected over a period of many days. However, if the timescale is changed it is important to adjust the parameters of any tools that expect data in real time. Furthermore, by using a timeScaleFactor variable, we provide two features of the simulator. The first is to allow computational tools to be tested at an accelerated rate, whereas the second feature offered is the ability to provide end user the ability to slow or speed up the data. In training scenarios it may be necessary to pause or slow the data stream down to allow for explanation and topics to be discussed.

MessageID (Required if no message content)

Some datasets do not contain information beyond a timestamp and a messageID. This is particularly true with Twitter datasets that require a process knowns rehydration. Rehydration occurs when only as some situations Twitter do not allow the message contents of a tweet to be shared but instead only allows the sharing of the tweet's timestamp and its tweet ID. In these cases, the simulator connects to the Twitter API and requests information for the given messageID. If the contents of a message are not available, the simulation tool connects to the Twitter API to retrieve the relevant message data. As such, the message ID for each message within a data set is required if there is no corresponding content. In addition, with messageIDs other Meta data can be collected for further analysis such as number of retweets, likes, media links and poster's information.

Message content (Optional)

Message content is a field found in some of the datasets and is essentially the body or message of a tweet that contains only the text portion of a Twitter message. The simulator is designed to use this message field if it is found in the corresponding dataset. As the primary interest of the researchers in this paper was to present message content to a separate analysis tool, this field was used when found. If however the dataset did not contain the contents of messages, the rehydrating process described above was used.

Other Information (Optional)

As mentioned previously the datasets that we used for testing the Twitter simulator contained many different data fields. With this in mind, we limited the required fields to only that of a timestamp and a MessageID. However, additional fields such as coding fields for each tweet can easily be added. This in turn would then be added to the output to be used later by other applications.

Input data

Due to the similarity of the datasets used during testing, a comma separated (.csv) file structure was used for the input file. This is not however a limitation but rather a design choice as most of our test datasets were contained within the csv files. In a similar manner, any delimited file could be used as the input to the simulator with minor modification. Furthermore, while not implemented in the current vision of the simulator, additional data input formats could be added in the future such as database connections or JSON and XML formats.

Data handling

The simulator is responsible for parsing data from a given input file, selecting the appropriate fields, analyzing the time sequence of tweets, creating a connection endpoint and outputting the data to that connection endpoint. The code for the simulator was written in Java. As we are using .csv dataset file the first step of the simulator is to read each file in. it then parses out fields such as timestamps, messageID, message content and any additional fields contained. Furthermore, if additional information is required, the simulator would query the Twitter API using the messageID as a reference to request information about the respective message. After this, a time sequence is calculated using the earliest tweet as a reference, delays are calculated using the formula described in

the Timpstamp section. After the delay has occurred (amount of time between first tweet's timestamp and current timestamp) the data from a particular tweet is converted into a JSON format and sent to the endpoint. Any tools connected to that endpoint would then be responsible for processing the data.

Output data

The output data is sent via a connected socket. The simulator begins by opening a listening port and then sends the processed data to any applications connected to that socket for the given tweet's timeline. The format of the output of the simulator uses Javascript Object Notation (JSON). This entails that any application wishing to leverage the simulator should be capable of handling this format. However, this format could be replaced or additional formats added in future releases.

TWITTER SIMULATOR USE CASE

In order to test the effectiveness of our Twitter simulator we deployed a simple prototype in an active 911 public service answering point (PSAP). This center was located in a city with a population over 100,000 people. The first visit took place in May of 2018, with the primary goal on initial discovery. That is, during this visit we were interested in gaining a better understanding of how 911 centers operate and if social media could provide value to the existing processes. The primary goals of the first visit was to conduct observational research, interviews and workshops in order to discover what tasks and procedures were used. In addition, we also investigated how social media is currently used, and the possible future avenues of its use within the 911 environment. Lastly, challenges involving communicating data obtain from social media and potential other sources were discussed. These interviews shed light on how the data from social media should be displayed and presented for use by the center. It also helped us understand the importance of specific pieces of information, in particular the following categories emerged: what was the location or "where" was the person making the tweet, what was the timeline of the incident or "when" did it occur, "who" was involved in the incident, "what" was the nature of the incident, where there "weapons" or use of weapons mentioned and "why" had the incident occurred. These information points were referred to as the 6w's.

We then conducted an in person, informal workshop. This involved simulating data using the 2013 airport shootings in Los Angeles USA dataset found in the CrisisLexT26 dataset from crisislex.org (Olteanu, Vieweg, and Castillo n.d.). As the airport shooting occurred at 9:24 am only the hours of 8am – 12pm were used. A timescale of 15 was used meaning that the total simulation took 16 minutes. The first reference to LAX and shooting did not occur until the fifth minute of the simulation. This was used across three different participant groups. In addition to monitoring and examining how the prototype was used, we also observed the interaction between the participants to determine how the data from social media may be integrated into the existing process and if any disruptions had occurred.

In order to mimic the PSAP's existing procedures, sets of three participants were used, one as a traditional call taker, one as a social media analysist and one as a dispatcher. Each of these participants were 911 professionals working in the call center with multiple years' experience. All participants had access to the social media prototype interface user interface.

The social media prototype GUI was built on the ELK stack. The ELK stack is an open source software platform consisting of three primary components (https://www.elastic.co/). The first is a mechanism to import data from one format into another. In our case this was the role of the simulator tool, which imported data from the T26 LAX shooting dataset into the stack. The second mechanism is the elastic search analytics engine, which performs similar to a database. The third component was Kibana which is a user interface designed to display information from the elastic search environment. This allows you to create custom dashboards and interfaces. An example of this interface can be seen in Figure 2.

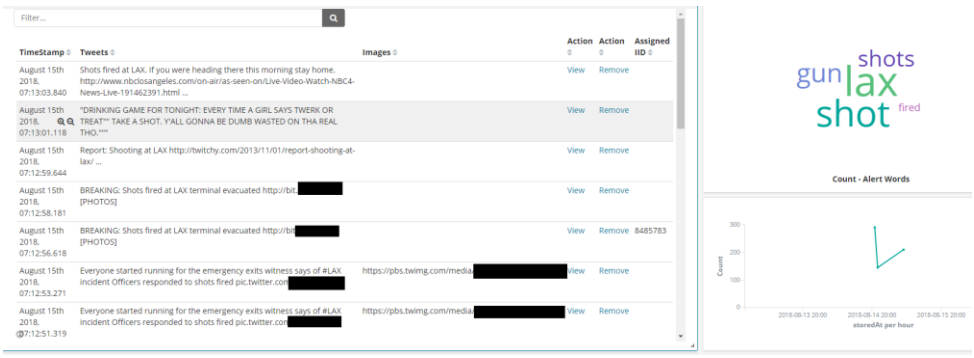

Figure 2 - Example Interface

Figure 2 illustrates a simple user interface developed using Kibana. While there is much room for improvement the goal of this work was to develop a tool capable of simulating Twitter data collection in real time. From the figure we have three primary data points displayed. The first is a table containing a list of tweets (which updates in real time) along with the associate timestamps, and image links. The other columns, action (view), action (remove) and assign incident id (iid) were used in conjunction with our prototype. The first action (view) allows the user to view the details of the tweet with second action (remove) allowing the user to remove a particular tweet from the database (Elasticsearch). Lastly, assigned IID allowed users to connect a tweet to a particular incident within their system. The assig IID was for display purposes only.

Overall, the participants were impressed with the ability to present previous data in a real-time format. Unfortunately, they did say that there was too much data being presented to fast. It was then explained that the data they were seeing was at an accelerated rate. Two recommendations to combat this issue were discussed and presented. The first was to narrow down the data further to show 10-15 minutes before the incident and 30-40 minutes after that. This was suggested, as they (crisis responders) would only really be interested in the event onset and possibly any victims. Once the suspect had been apprehended, further data would not necessarily be required. While we only used the airport shooting data during our workshop it is highly suggested that further work is done to test slow onset crisis such as floods, and hurricanes.

The second recommendation was to filter out more noise and allow for custom searches. As the tweets shown to the users were based on the dataset, no further filtering was implemented. Note that the datasets were collected using various keywords and collection methods originally. While this could be a side effect of the rate at which the tweets were been shown, allowing custom filtering to be setup within the simulator would allow users to fine tune the data that is shown during training exercises.

The last recommendation was to use a localized dataset. While the LAX dataset did have some clear useful information in it, those who were unfamiliar with the lingo of area may not be able to identify points of interest. This was found to be especially true when images were presented, as the PSAP was not located in the LAX area, they were unable to identify where the picture may have been taken. Additional examples of images were presented in another session to which the crisis responders were quickly able to identify where the picture was taken.

CONCLUSION

Previous research done on datasets has mostly looked at datasets as a whole in identifying patterns within the messages. These patterns are then used in the design of new methods for data collection and analysis. While this technique has been somewhat successful, two primary issues still exist. The first is that when messages are collected in real-time access to the overall picture, or the full dataset, is not available until after the event has occurred. The developers of these tools must then examined how each of them performed iterate the design and then wait for another event to occur to test the changes. Secondly, with respect to training, Twitter contains a vast amount of information, with many unique ways of sharing information. Unfortunately, developing a tool that attempts to create these messages for training purposes becomes less than ideal as different areas or languages may report things in different ways. Lastly, by involving the 911 operators in the design the prototype we can discover key data points and information that they would use within the existing process.

In order to address these issues, this paper describes the design and creation of a tool to present and simulate Twitter message from previously collected datasets. By doing this, the first issues is combatted the tweets are presented based on their timestamp meaning that tools connected to the simulator would not be able to analyze the full dataset at once and instead only receive data up to a given time point with new data flowing in as time progresses. This temporal delivery can also serve as a method for testing a systems robustness and assist in discovering the limits or requirements of an analysis application. A Twitter simulator can also assist as an input to existing training tools. Because we are leveraging existing datasets, actual tweet messages are used. This means that the issues of tweet fabrication can be overcome as the tweets are written by humans and not auto generated.

In being able to test this simulator with actual crisis response professionals, we gained valuable insight into the design. The following design recommendation were discovered

- If training or humans are being used to analyze data, a timescale for accelerated tweet delivery should be used very cautiously
- The timescale feature should be used only for computational analysis and tool testing
- Crisis response professionals would only need to see a very time limited margin of tweets to assess the value of the data depending on the dataset
- Consider incorporating custom filtering into the simulator for training purposes
- When at all possible use localized datasets

The design and development of this Twitter simulator is still ongoing, with many features to be added in the future. First with respect to the data input, this system would benefit from the ability to connect to databases as

well as accept input files in different formats besides the .csv datasets used. Likewise, datasets from social media platforms other than Twitter would need to be incorporated into the design depending on the availability of their APIs. Next, while intentionally left out of our design, incorporating filter methods could also be added for those wishing to use the simulator without needing to connect it to an existing application. Lastly, while we selected the JSON format as our output due to familiarity, additional output formats would be needed including; database connection, REST calls and raw file outputs.

ABSTRACT

Nowadays, micro-blogging sites such as Twitter have become powerful tools for communicating with others in various situations. Especially in disaster events, these sites can be the best platforms for seeking or providing social support, of which informational support and emotional support are the most important types. Sympathy, a sub-type of emotional support, is an expression of one's compassion or sorrow for a difficult situation that another person is facing. Providing sympathy to people affected by a disaster can help change people's emotional states from negative to positive emotions, and hence, help them feel better. Moreover, detecting sympathy contents in Twitter can potentially be used for finding candidate donors since the emotion "sympathy" is closely related to people who may be willing to donate. Thus, in this paper, as a starting point, we focus on detecting sympathy-related tweets. We address this task using Convolutional Neural Networks (CNNs) with refined word embeddings. Specifically, we propose a refined word embedding technique in terms of various pre-trained word vector models and show great performance of CNNs that use these refined embeddings in the sympathy tweet classification task. We also report experimental results showing that the CNNs with the refined word embeddings outperform not only traditional machine learning techniques, such as Naïve Bayes, Support Vector Machines and AdaBoost with conventional feature sets as bags of words, but also Long Short-Term Memory Networks.

Keywords

Refined Word Embedding, Deep Learning, Machine Learning, Sympathy Tweets Detection

INTRODUCTION

Sympathy is an expression of one's compassion or sorrow for a difficult situation that another person is facing. Expressing sympathy for people who are facing disaster situations is one way of caring for people emotionally. S. Kim et al. (2012) discovered that the expression of certain emotions, including sympathy "influences" other people in Twitter to become more positive. Moreover, Froyum (2018) discussed that if an emotional connection between helper and helped exists, e.g., sympathy, helpers are more eager to give assistance in various kinds of formats. According to Baberini et al. (2015), there is a higher chance that people who express sympathy could potentially provide monetary helping hands since they are emotionally inclined to people who are encountering disasters status. Donations are very important to people in crisis circumstances for restoring their lives.

Since micro-blogging social media sites such as Twitter are widely used nowadays, people get real-time information by using these sites. Not only limited to personal use for acquiring knowledge, exploiting social media as information sources in groups has shed light on earning valuable resources. For example, for building "post-disaster" programs,

Table 1. Examples of Sympathy Tweets and Non Sympathy Tweets

non-profit organizations can use Twitter as information roots. More specifically, in emergency situations like earthquakes, floods and typhoons strike, Red Cross can use Twitter as a source of big-data analysis for figuring out long-term donors. According to Han et al. (2013), identifying long-term donors is crucial because they need to plan longstanding programs such as fund-raising campaigns. However, Han et al. (2013) reported the fact that when a disaster happens, one-time donations usually spike sharply. Twitter, which is a real-time posting platform, can be a good resource for extracting valuable information since we can easily notice this sharply increasing one-time donation phenomenon in real-time.

Thus, our goal in this paper is to identify Twitter postings (or tweets) that have sympathy related contents. This can be used not only for designing improved features in Twitter for providing emotional support, but can also be used for identifying users that can be candidate donors. Consequently, we learn supervised models to automatically detect sympathy in Twitter data. Our labeled Twitter data comes from a series of diverse disasters that happened during 2013 to 2015 world-wide. Examples of tweets that contain and do not contain sympathy are shown in Table 1.

Many natural language processing approaches for short text or sentence classification use Convolutional Neural Networks (CNNs) (Y. Kim 2014) and Long Short-Term Memory Neural Networks (LSTMs) to reduce the burden of feature engineering. In text processing, deep learning approaches are predominant in terms of feature detection since humans do not need to intervene in a detailed way. Deep learning approaches have achieved substantial success over traditional machine learning techniques in disaster contexts as well (V. K. Neppalli et al. 2018; Nguyen et al. 2017; C. Caragea, Silvescu, et al. 2016; Ben Lazreg et al. 2016). For example, Nguyen et al. (2017) used CNNs to classify tweets into categories related to situational awareness and showed improvements over traditional algorithms. Ben Lazreg et al. (2016) used a different deep learning approach, specifically a Long Short-Term Memory (LSTM) network, to learn a model from crisis tweets and used this model to generate snippets of information summarizing the tweets. In addition to these, V. K. Neppalli et al. (2018) reported that CNNs outperform Naïve Bayes that exploit Twitter specific features and conventional linguistic features in Twitter informative posting classification.

In this paper, we focus on sympathy detection of Twitter disaster data using Convolutional Neural Networks. Conventional word embeddings such as pre-trained word2vec, Glove, FastText, and a domain-specific word2vec trained on CrisisNLP data (Imran, Mitra, et al. 2016) are used to test the performance of our proposed model. We observe that even if two different words look similar or are semantically related, conventional word embeddings based model may not consider them as tightly correlated, and hence, return a low similarity value. For example, when we use the CrisisNLP word embeddings for measuring the similarity of words "pray" and "prayer", the similarity value that implies how much they are alike is significantly low. In order to mitigate this problem, we design a refined word embedding technique based on word stemming, where semantically similar words become closer in the vector space. Our technique is inspired from Yu et al. (2017) who used a sentiment lexicon for generating polished word embeddings. By using refined word embeddings, we achieve an F1 score of approximately 76% as compared with approximately 74% achieved by conventional word embeddings. In experiments, we also contrast CNNs with two other deep learning models, LSTM and Bi-LSTM. In summary, our contribution can be organized as follows:

- We explore CNNs with various word embeddings (pre-trained and fine-tuned on domain specific data) for sympathy detection of Twitter disaster data. Moreover, we design a word stemming based refinement model to improve word representations in vector space.

- We show that the CNNs with refined word embeddings outperform the CNNs with conventional word embeddings. In addition, we contrast the CNNs with LSTMs and Bi-LSTMs and show that the CNNs (with and without refined word embeddings) have better performance in most cases.
- Our CNN models outperform traditional approaches such as decision tree and SVM on sympathy detection task. The F1 score of proposed model is 3.63% higher than SVM, which has the best performance in traditional classifiers.

RELATED WORK

Substantial progress has been made in extracting, processing and classifying messages posted in social media during disaster events, using natural language processing and machine learning techniques (C. Caragea, Squicciarini, et al. 2014; Verma et al. 2011, Sarda and Lal Chouhan 2017, Rudra, Sharma, et al. 2018). For example, Ashktorab et al. (2014) used a combination of classification, clustering, and extraction methods to identify actionable information for disaster responders. Imran, Elbassuoni, et al. (2013) classified tweets into situational awareness categories, such as caution and advice, casualties and damage, donations, people missing, using unigrams, bigrams, POS tags, presence of URL/hashtags, tweet length, etc. Yin et al. (2012) used similar features to identify tweets related to a disaster, identify disaster type and assess the impact of a disaster. Rudra, Ghosh, et al. (2015) used lexical features to extract situational information in disasters. More recently, researchers started to explore deep learning techniques, and in particular Convolutional Neural Networks and word embeddings, for classifying disaster social media data into diverse categories such as situational awareness, informational tweets, and actionable tweets (Alam et al. 2018; Derczynski et al. 2018; V. K. Neppalli et al. 2018; Nguyen et al. 2017; C. Caragea, Silvescu, et al. 2016).

Sentiment analysis and emotion detection have also been explored in disaster contexts. For example, Nagy and Stamberger (2012) focused on sentiment detection in Twitter during the San Bruno, California gas explosion and fires from 09/2010. They used SentiWordNet together with dictionaries of emoticons and out of vocabulary words, and a sentiment-based dictionary to identify the basic sentiment of a tweet. Schulz et al. (2013) focused on the classification of human emotions into six classes: anger, disgust, fear, happiness, sadness, and surprise, from tweets related to the Hurricane Sandy. As features, they used bag of words, part of speech tags, character n-grams (for n=3,4), emoticons, and sentiment-based words compiled from the AFINN word list (Nielsen 2011) and SentiWordNet (Baccianella et al. 2010). Mandel et al. (2013) performed a demographic sentiment analysis using Twitter data during Hurricane Irene. K. Neppalli et al. (2017) explored the concept of *emotional divergence* and analyzed how likely a tweet is to be retweeted with respect to its emotional divergence value, using Twitter data from the Sandy Hurricane. *Emotional divergence*, first introduced by (Pfitzner et al. 2012), measures the diversity of the emotions expressed in a text.

Social support is one important aspect for which people join social networks, and hence, researchers investigated the types of social support (e.g., emotional support and informational support) and their benefits in these networks. For example, Bautista and Lin (2015) studied social support in tweets posted during a terrorist manhunt in Philippine, in which 44 elite policemen died, and found that informational support was more frequent compared with emotional support. Among the sub-types of informational support, the authors found that a large fraction of the posted tweets contained news-related pictures and articles. Similarly, during the Great East Japan Earthquake of March 2011, the city lost electricity and water and communication became inaccessible. Smartphone became the primary device to obtain information and communicate with each other. The author found that Twitter has the potential to disseminate important information, which is greatly beneficial during the disaster (Kaigo 2012). When the massive floods happened in Queensland, Australia, during December 2010 to January 2011, the social media platforms provided valuable information to the public. Not only for this, social media was also used as communication channels to people who were facing emergency disaster situations (Bunce et al. 2012). Emotional support in Twitter shows benefits on people's moods and behavior. Generally, when people feel emotionally supported, they tend to feel better. For example, in a study on social aspects of emotions in the general Twitter, S. Kim et al. (2012) showed that the expression of certain emotions, including *sympathy*, "influences" others to become more positive. More precisely, the authors discovered that changes in emotional states from negative to positive are influenced by topics such as greeting, sympathy and recommendation, whereas changes from positive to negative are influenced by topics such as worry, teasing, and complaint (S. Kim et al. 2012).

Against this background, we explore and contrast deep learning models, Convolutional Neural Networks (CNNs) and Long Short-Term Memory Networks (LSTMs), and refined word embeddings for *sympathy detection* in disaster-related Twitter data. Imran, Mitra, et al. (2016) presented results on a multi-class classification task for classifying disaster-related tweets into situational awareness categories of which sympathy and emotional support represents one such category. However, unlike Imran, Mitra, et al. (2016), we present a thorough analysis of sympathy detection and propose a word embedding technique that produces more suitable embeddings for our task.

METHODS

Nowadays, CNNs perform well on many text classification tasks. For example, Y. Kim (2014) showed that a CNN with a convolution and pooling layer can produce good performance on several classification tasks including sentiment analysis and question classification. Zhang and Wallace (2017) conducted extensive experiments of CNNs on sentence classification task. The authors concluded several useful suggestions that are helpful for applying CNNs to sentence classification. Aipe et al. (2018) developed a CNN model for multi-label classification of disaster dataset. Specific linguistic features are extracted from tweets to augment the original CNN model.

Based on these previous works, we use a CNN model for the classification of tweets as containing sympathy or not. Figure 1 shows our proposed architecture which is inpired from Y. Kim (2014) and Aipe et al. (2018). The CNN models generally work better when the input is given as word embeddings.

Word embeddings are trained from a very large corpus to generate effective representations for words with similar meanings. This method contributes to the progress of word representations and thus has been widely used in text classification and machine translation areas. Nowadays, it is very convenient for people to apply pre-trained word embeddings(e.g., GoogleNews and Glove) to their applications and get satisfying results. In our paper, we mainly discuss four word embeddings: CrisisNLP, GoogleNews, Glove and Fasttext. Different from the others, CrisisNLP is a word2vec embedding trained in a smaller dataset, which can be regarded as domain embedding.

A common problem existent in current word embeddings is that semantic consistency is hard to maintain in vector space, which means the most similar words of a target word in word space are irrelevant to the target word in some cases. And meanwhile, the synonyms of target word are far from the location of target word in the vector space. This problem is clearly illustrated in Figure 2a. The red numbers in this figure are cosine similarities between the target word and its synonyms and all other words are top 20 most similar words of target word 'pray'. Target word 'prays' is far from its synonyms and thus has low cosine similarities with those words. Therefore, it restricts potential improvement of some fine-tuned classifiers.

In order to address similar problems in sentiment analysis, Yu et al. (2017) proposed a refinement model to converge sentimentally similar words by using sentiment lexicon. The results show that it has good performance in both binary and fine-grained sentiment classification tasks. However, this model is only designed to improve the sentiment embedding or conventional embedding applied in sentiment analysis. Therefore, inspired by this model, a more general refinement method of conventional word embedding is proposed in this section. The procedure for refining word embeddings can be divided into three stages. First, Snowball stemmer is used to cluster words with similar meanings, which means that words with same stem are regarded as one cluster. Second, words in each cluster move close to each other in the vector space to get better representations, following the approach described below. Finally, the refined embedding is fed as the input of CNN model and yields better performance in sympathy detection task. As we can see in Figure 2b, the synonyms of the target word move much closer to the target word in the vector space with refinement model, which brings better word representations in sympathy detection.

Snowball stemmer is by far the most popular stemmer and performs better when compared with original Porter stemmer. The comparison between original Porter stemmer and Snowball stemmer is shown in Table 2. We can clearly observe that Snowball stemmer is more precise than Porter stemmer. For all selected vocabulary words in conventional word embedding, we have over 40,000 clusters in total after running Snowball stemmer and these clusters are used to improve the word representations in vector space. After we obtain the word clusters for original

Table 2. Porter stemmer vs. Snowball stemmer

Stemmer	Word cluster
Porter stemmer 'gener'	'general', 'generation', 'generator', 'generous', 'generations', 'generate', 'generally', 'generated', 'generals', 'generic', 'generously', 'generators', 'generating', 'generates', 'gener', 'generational', 'generalize', 'generalizing', 'genere', 'generalizations', 'generalization', 'generalized', 'generics', 'generative', 'generalities', 'generou', 'generality', 'generically'
Snowball stemmer 'generat'	'generation', 'generator', 'generations', 'generate', 'generated', 'generators','generating', 'generates', 'generational', 'generat', 'generative'

word embedding, we'd like words in each cluster to move closer to each other in vector space and meanwhile not too far from their original locations. An objective function is presented to minimize the total distance among each cluster, which is defined as

$$\Phi(V) = \sum_{i=1}^{n} \sum_{j=1}^{k} w_{ij} dist(v_i, v_j) \quad (1)$$

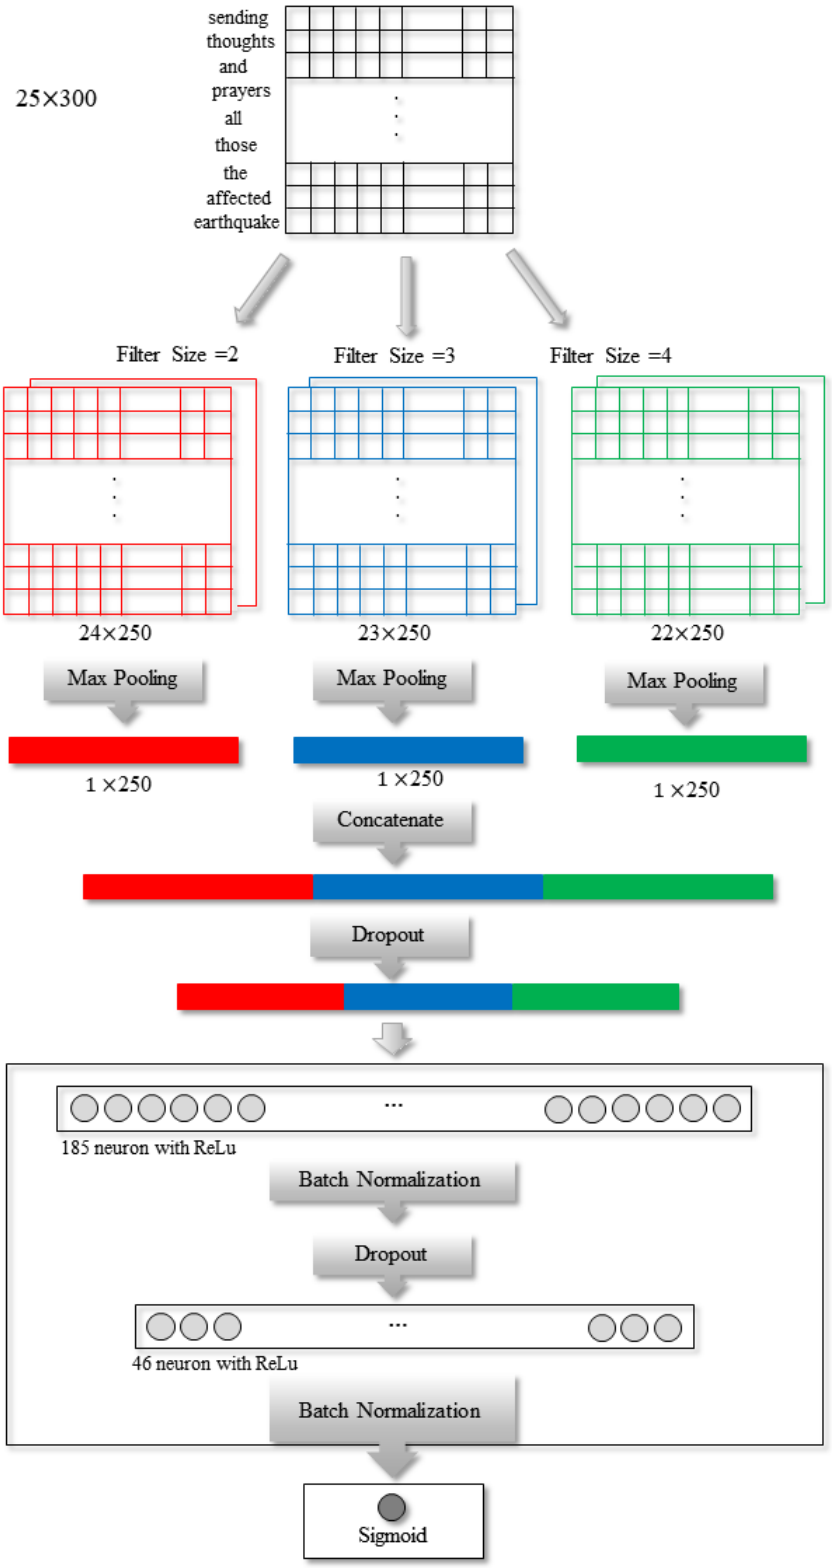

Figure 1. CNN Model

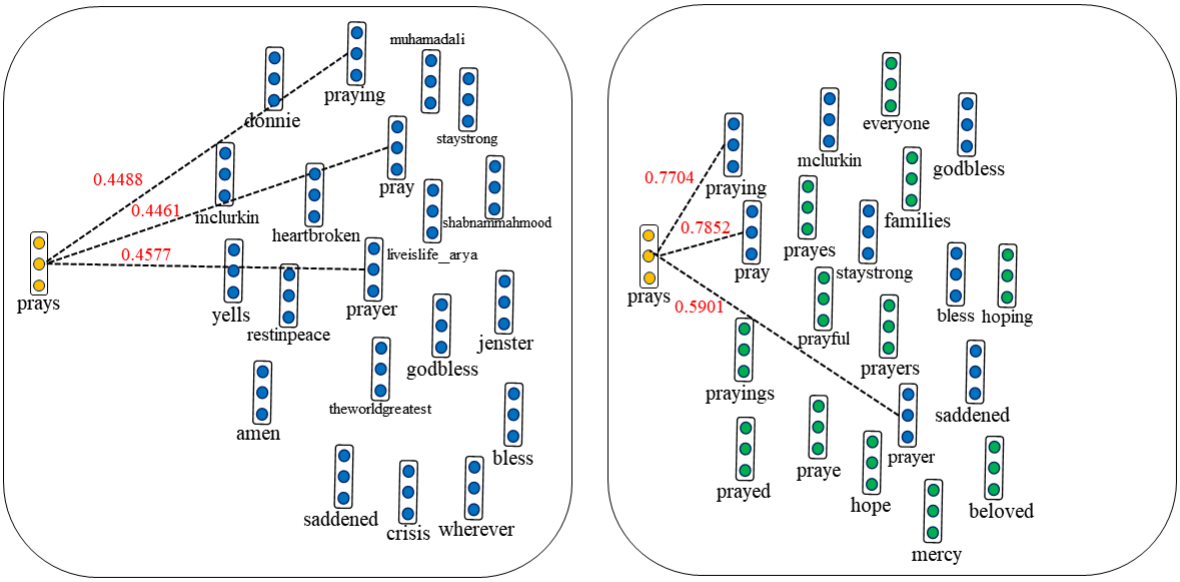

(a) Word embedding without refinement model

(b) Word embedding with refinement model

Figure 2. Conceptual diagram of word space for CrisisNLP embedding

where n denotes total number of clusters and k denotes the size of each cluster, dist(v_i,v_j) denotes the distance between target word v_i and similar word v_j, w_{ij} denotes the weight of each similar word related to target word. Each target word v_i has k-1 similar words within one cluster and the number of k may vary due to different size of clusters. Square Euclidean distance is used to calculate the distance between the target word and its similar words, defined as

$$dist(v_i, v_j) = \sum_{d=1}^{D} (v_i^d - v_j^d)^2 \tag{2}$$

where D is the dimension of pre-trained word embedding and w_{ij} is defined below

$$w_{ij} = \frac{1}{order_j} \tag{3}$$

where $order_j$ denotes the order of word in each cluster. Once we finish the word stemming, we have a fixed order for words in each cluster. In order to avoid putting weights on specific word in cluster, we randomly shuffle the order of each cluster when we run refinement model. To prevent refined model from destroying good word representations, a constraint, which is defined as the first part of objective function, is added to make sure the target word can only move with small steps in vector space. The objective function is defined as

$$argmin\Phi(V) = argmin \sum_{i=1}^{n} \left[\alpha dist(v_i^{t+1}, v_i^t) + \beta \sum_{j=1}^{k} w_{ij} dist(v_i^{t+1}, v_j^t) \right] \tag{4}$$

where v_i^{t+1} denotes word vector of target word in t+1 step, parameter α and β determine how far the target word can move away from its original location in vector space. To minimize the objective function, we set $\frac{\partial \Phi(V)}{\partial v_i^{t+1}}$=0 and target word vector is updated by

$$v_i^{t+1} = \frac{\alpha v_i^t + \beta \sum_{j=1}^{k} w_{ij} v_j^t}{\alpha + \beta \sum_{j=1}^{k} w_{ij}} \tag{5}$$

We need to tune three parameters: the number of iterations, α and β. The number of iterations controls the degree to which words converge in the vector space. α and β determine how far the target word can move for each iteration. In our experiments, iteration number=1, α=10 and β=1.

Table 3. # of Tweets for each label in CrisisNLP Data

Class	Train(70%)	Val(20%)	Test(10%)	# of Tweets
Sympathy and Emotional Support	1,378	394	197	1,969
Caution and Advice	743	212	107	1,062
Displaced People and Evacuations	442	126	63	631

Not Related or Irrelevant	1,642	469	234	2,345
Other Useful Information	4,004	1,144	572	5,720
# of Tweets	13,367	3,818	1,910	19,095

DATASET

The dataset used in experiments comes from CrisisNLP (Imran, Mitra, et al. 2016). The dataset consists of tweets posted during 11 different disasters that happened during 2013 to 2015. Each tweet is annotated by paid CrowdFlower Workers using situational awareness categories. The disasters in this collection can be classified as two categories: natural disasters and medical disasters. First category has 8 labels and second category has 7 labels. In this paper, we only used natural disasters data since medical disasters data does not contain sympathy labeled tweets.

As a result, we use 9 different disasters and the total number of tweets is 19,095. The detail information of the dataset labels/categories and the number of tweets in each category are shown in Table 3. All tweets are posted only in English. Since we have a purpose of extracting sympathy tweets, we mainly focus on Twitter postings that have label of "sympathy and emotional support" and treat this as positive class. All other labels are considered as the negative class. The number of tweets containing sympathy is 1,969 and the number of non-sympathy tweets is 17,126.

EXPERIMENTS AND RESULTS

Preprocessing

This step contains removing Twitter ID, hashtags, special characters and URLs. Moreover, OOV dictionary is used to process slangs and abbreviations. Lastly, we remove words and sentences with length smaller than 3.

CNN performance

The proposed CNN model, which is shown in Figure 1, is based on Y. Kim (2014) and Aipe et al. (2018). The CNN model consists of a convolutional layer followed by a max-pooling, concatenation and two fully-connected layers with batch normalization. More specifically, with regard to convolutional layer, there are 250 feature maps for each kernel size {2,3,4} and these feature maps are then max-pooled and concatenated as the input of fully-connected layer. Two dropout layers are added to reduce overfitting of neural network and drop rate is 0.5.

In experiments, the proposed CNN model, as well as the LSTM and Bi-LSTM models, are implemented on the disaster dataset described earlier. Ten different random seeds (from 5 to 50 with interval 5) are selected to split the pre-processed dataset and the final result is the average score of the 10 experiments. The proposed refined word embedding method is implemented in four different pre-trained word embeddings and tested on all deep learning frameworks. As we can observe from Table 4, all refined models outperform original models. More specifically, for example, refined CNN improves original CNN model with word embedding CrisisNLP, word2vec (GoogleNews), Glove and Fasttext by 0.25%, 0.57%, 0.48% and 1.21% respectively. Overall, CNN is generally the best performing algorithm with or without refinement model. It produces the best performance on word2vec, Glove and FastText embedding. Even though the refined Bi-LSTM model has the best result (75.08%) in CrisisNLP embedding, however the refined CNN with FastText embedding yields a better result (75.78%).

From our experimental results, we can also conclude that there exists at most 0.95%, 1.23%, 1.44% and 1.21% increase in CrisisNLP, word2vec, Glove and FastText embedding, respectively. Table 4 also shows that FastText word embedding generally performs better than other word embeddings. Four out of six models with FastText word embedding yield better performance over the others. To conclude, the refined CNN model with FastText embedding achieves the highest F1 score, which shows that the CNN architecture has the ability to solve specific text classification tasks such as sympathy detection and sentiment analysis.

Table 4. Performance of CNN and other frameworks on sympathy detection(F1 Score)

Model	CrisisNLP	word2vec	Glove	Fasttext_Crawl
Refined CNN	74.26	**75.39**	**75.42**	**75.78**
Refined LSTM	74.64	74.07	75.15	74.38
Refined Bi-LSTM	**75.08**	75.18	74.48	75.33
CNN	74.01	74.82	74.94	74.57
LSTM	74.03	72.84	73.71	74.38
Bi-LSTM	74.13	74.03	73.44	74.44

CNN vs. Baseline Classifiers

We compare our proposed refined CNN model with baseline machine learning algorithms such as Logistic Regression, Decision Tree, Stochastic Gradient Descent(SGD), AdaBoost , Support Vector Machine(SVM) and CNN-non-static model (Kim, 2014) with word2vec embedding in Table 5. In order to guarantee the correctness of comparisons, for each baseline model, the same training and testing samples are used and the final result is the average of 10 experiments.

From Table 5, we can see that the refined CNN model performs best in recall and F1 measure, which achieve 70.79% and 75.78%, respectively. We also observe that CNN-non-static model has the best result among baseline classifiers, followed by SVM and AdaBoost. Even though Logistic Regression has the highest precision score, it performs the worst in recall due to imbalanced data distribution. In general, CNN has better precision and recall score and thus it can be applied to detect sympathy sentences in highly skewed data.

Table 5. CNN vs. Baseline Classifiers

Model	Precision	Recall	F1-Score
Refined CNN	81.83	**70.79**	**75.78**
Logistic Regression	**95.2**	43.55	59.58
Decision Tree	64.44	66.67	65.47
SGD	90.69	55.77	68.96
AdaBoost	82.9	59.31	69.09
SVM	80.17	65.66	72.15
CNN-non-static (Kim, 2014)	87.99	64.60	74.40

CONCLUSION AND FUTURE DIRECTIONS

In this paper, we explore neural networks (e.g., CNNs, LSTMs) with different word embeddings for sympathy detection from Twitter disaster data. As a starting point for finding candidate donors, we successfully achieve the task of sympathy contents tweets detection using deep learning techniques. Moreover, we present a word stemming based refinement model to improve the existing pre-trained word embeddings. Instead of training new word embeddings, we can easily integrate the proposed refinement model into conventional word embeddings and improve the F1 score of text classification task such as sympathy detection. Experiments on disaster dataset show that proposed refined CNN model produces the best performance when compared with CNN and other deep learning frameworks. The performance of our model is significantly better than traditional classifiers.

In future work, it would be interesting to test our proposed model on various classes of disaster datasets, e.g. ‘donation needs or offers’. Also, it would be very interesting to see if our refinement model can improve text classification under different backgrounds. Moreover, an exciting direction to explore is the relations between sympathy and donations. An inspection of the CrisisNLP dataset reveals that there are many tweets that contain both sympathy and donation related contents. Several tweets that show a potential relationship between sympathy and donations are provided in Table 6. Based on this, our refinement model can also be extended as adding donation encoded features in the last layer of CNN and determine whether the performance of sympathy detection changes.

Table 6. Tweets containing 'Sympathy' and mentioning 'Donations'.

RT@RealLouisAndre: Sending out all my support for all people in #Chile all the prayers are with you, also u can donate @RedCross #PrayForChile
@justinbieber thanks for the challenge but I'm not able to do it so I just donated 30$ do the #ASL hope that makes up for it

ABSTRACT

Social Media contain a wealth of information that could improve the situational awareness of Emergency Managers during a crisis, but many barriers stand in the way. These include information overload, making it impossible to deal with the flood of raw posts, and lack of trust in unverified crowdsourced data. The purpose of this project is to build a communications bridge between emergency responders and technologists who can provide the advances needed to realize social media's full potential. We are employing a Delphi study survey design, which is a technique for exploring and developing consensus among a group of experts around a particular topic. Participants include emergency managers and technologists with experience in software to support the use of social media in crisis response, from many countries. The topics of the study are described and preliminary, partial results presented for Round 1 of the study, based on 33 responses.

Keywords

Social media, emergency management, crisis informatics, software requirements, Delphi method

INTRODUCTION

Social Media (SM) contain a wealth of information that could improve the situational awareness of Emergency Managers (EMs) during a crisis (Power et al., 2014; Palen and Hughes, 2018) but agencies are often reluctant to use SM, especially to gather unverified crowdsourced data (Plotnick et al., 2015; Plotnick and Hiltz, 2016). There is also a disconnect between the technologists who design and build automatic data processing systems to analyze SM data and the EMs who could benefit from using them. EMs do not know what is technically possible while technologists do not know what EMs want. Moreover, most existing systems rely only on a single SM data source (e.g., Twitter or Facebook). However, combining informative signals from multiple SM data sources could be useful in several ways e.g., determining the trustworthiness of SM data (Sherchan et al., 2013; Panteras et al., 2015), obtaining missing information (Mahmud et al., 2012), etc. Furthermore, these diverse SM data sources produce different content types. For instance, Flicker is best for images, YouTube for videos, whereas Twitter and Facebook are good for both text and images. Diversity in content types not only brings complementary information (Panteras et al., 2015), it is also useful to gain contextual understanding (Bontcheva et al., 2014). Despite the fact that complementary information in the form of either images or videos is readily available on many SM platforms, many past efforts to build automated systems for disaster response and management only focused on the textual content available on SM.

The purpose of this project is to build a communications bridge between emergency responders (for both governments and NGOs) working in Emergency Management and technologists who can provide the advances needed to realize SM's full potential. Moreover, we aim to solicit software requirements beyond the use of a single SM data source and single content type. To build this bridge, we employ a Delphi study, which is a technique for exploring and developing consensus among a group of experts around a particular topic (in this case, SM use in emergency management). Our study includes emergency responders and technologists from many domains and nations. The final product of the study will be a set of software requirements to better enable EMs to gather organized information from SM that is rated for trustworthiness and usable for decision making. Our overarching goal is to inform technologists of EM needs and to help EMs understand the feasibility of, and possible solutions to, meeting those needs.

In the sections that follow, we review the prior literature on software to support the use of social media by emergency managers, and briefly describe the Delphi method. We then describe the methods used in the Delphi study that is underway as of November 2018.

LITERATURE REVIEW

Social Media (SM) have become ubiquitous and are often used by emergency management organizations to disseminate information (Plotnick and Hiltz, 2016). However, prior studies (Hughes and Palen, 2012; Plotnick and Hiltz, 2016) suggest that there is great hesitation by emergency management (EM) organizations to use SM to collect data from the public during an emergency. This hesitation can create missed opportunities to improve situational awareness. Additionally, the public expects EMs to respond to their SM queries (Petersen et al., 2017) which cannot be done if EM agencies do not accept and use public SM posts.

Software Enhancements for Social Media Use in Emergency Management

There are many barriers to the use of social media (SM) for emergency management (EM), both technical and organizational. Social media are examples of "socio-technical" systems; meaning that their use and effectiveness are determined not only by the features and quality of the systems themselves, but also by social context factors such as user attributes (e.g., skills and training, or the lack of them), and by organizational norms and policies and resources (Power and Kibell, 2017). This is especially true of the use of SM as part of an emergency response management system, when the information that could be retrieved and used is generated by the public and communicated via a public commercial system, rather than by trusted information systems under organizational control (Plotnick and Hiltz, 2016). Some of these barriers can only be overcome through organizational changes, but others, especially those having to do with issues of information overload (thousands to millions of tweets and posts on a specific disaster; too much information arriving too fast and in a disorganized manner) and trustworthiness of SM posts (Tapia et al., 2011; Plotnick et al., 2015; Hughes and Shah, 2016), could be dealt with through software pre-processing systems.

Many studies describe possible software enhancements and systems that could improve the usability and usefulness of social media for disaster management. See (Imran et al., 2015) for an extensive survey of these technologies as of about four years ago. A great many of these new technologies for processing social media data incorporate both human efforts (e.g. crowdsourcing to create training sets for machine learning) and automated tasks (Imran, Mitra & Castillo, 2016). The multiple challenges facing software developers include real-time parsing of brief and informal messages, determining information credibility, and prioritizing useful information (Imran et al., 2018).

In a survey of 477 U.S. county-level EMs (Plotnick and Hiltz, 2018), several of the specific potential software enhancements described in (Imran et al., 2015) that could help overcome the limitations of SM for EMs were rated with the result being that they are perceived as highly useful. These enhancements included the ability to view SM data as generated by geographical location on a map-based display, and categorization of SM data by sub-events (e.g., rescue issues). However, that study had several limitations: participants were limited to U.S. county level EMs and many potential enhancements that have subsequently appeared in the literature were not included. The current study aims to overcome these limitations by including software developers and researchers related to SM in EM, from many countries and types of organizations, and adding features from systems described in recent studies and proposed and vetted by the study participants.

The Delphi Method

A Delphi study consists of two or more rounds of structured written exchanges between anonymous experts with different types of expertise relevant for a topic (Linstone and Turoff, 1975, 2011). It was developed in the 1950s to obtain expert input on a particular problem while allowing the participants to remain anonymous. The

expert panels are given questionnaires (mailed or online) and answer them at a time and place convenient to them. The technique is particularly useful in cases where the expert panel is dispersed over a wide geographic area, and for complex, multi-disciplinary problems (Hendela et al., 2017).

The Delphi method utilizes a series of questions over two or more rounds where each participant may suggest additional items for consideration in subsequent rounds. An important aspect of a Delphi is that experts are generally asked not only to rate various alternatives or issues or items, but also to explain their rating in comments. The comments often surface the underlying reason for disagreement on ratings, such as one person assuming that a related development is likely, while another expert assumes that it is not. After each set of questionnaires is completed, a facilitator summarizes the experts' inputs and then distributes the summary with another round of questions. The results are annotated to show which category(ies) of expert provided each feedback item. Thus, although anonymity is maintained, expert participants know the domain of the person providing feedback. This is helpful when the experts evaluate the feedback. The experts can then revise their answers from the first round in light of the ratings and comments of others, and add ratings of newly surfaced items or issues.

RESEARCH METHOD

Our objective is to foster a dialogue and exchange of knowledge among software developers, emergency managers, and researchers on SM, from different nations and types of organizations. Thus, we aim to obtain a representative "spread" of diverse opinions from different types of stakeholders, rather than a random or representative sample of any particular population.

Expert Recruitment

In recruiting possible participants, we cast a wide net, using our professional networks. This included sending invitation messages to researchers who had published papers in the social media tracks of recent ISCRAM-sponsored meetings; sending emails to lists of U.S. emergency managers; posting on Linked In discussion boards for EMs; personal messages to software developers; and requests for those initially invited to suggest other experts.

Following approval of the study by the New Jersey Institute of Technology Institutional Review Board (which included the consent form, screening questionnaire, and Round 1 questions of the Delphi), the initial invitation to participants was to complete a screening questionnaire. We used email to send the prospective participants a link to a Recruitment survey to build our expert panel prior to the actual Delphi. The Recruitment survey asked for information such as years of experience in EM and in software development for SM in EM, to make sure the volunteers qualified as "experts." We had hoped to obtain funding for the study, and the consent form stated that if we did obtain funding, those who completed both rounds would receive a $200 honorarium, payable to themselves or to a disaster-related charity, such as Doctors Without Borders. The screening questionnaire asked if they were willing to participate with or without such funding; it was reassuring that all but one of those who responded said they would participate "with or without" the funding, especially because we did not receive the funding. Since it was stated that the Delphi rounds of the study may take between 30 minutes and two hours per round, depending on how many comments a participant makes, this might have affected the response rate. There were 48 valid respondents to the Recruitment survey who indicated they were willing to participate out of over 400 prospective participants who received invitation messages or may have seen one on a discussion board.

We reviewed the responses to the Recruitment survey to confirm that the respondents were qualified by their expertise and experience to participate as members of the Delphi panel of experts. Those few respondents (N=9) to the Recruitment survey who were deemed unqualified either failed to complete the survey beyond the consent or did not have experience as a researcher, practitioner, and/or academic in the focus area of use of social media for emergency management. We maintained a list of the qualified respondents and then sent email to only these respondents with the link to the Round 1 Delphi questionnaire. The Recruitment survey took, on average, four minutes for the respondents to complete.

Delphi Questionnaires

Once the panel was formed, our Delphi process consisted of two rounds of surveys with feedback to the experts from each. This paper reports on the results of the Round 1 questionnaire.

The Round 1 questionnaire was a mix of qualitative and quantitative questions focused on four broad topic areas of participant demographics and experience, social media platforms, tool features, and recommendations. These topic areas were determined from the literature survey (particularly Imran et al., 2015 and Plotnick and Hiltz,

2016) and through iterative discussion within the research team. Once these broad topic areas were determined, they were refined and expanded into the specific survey questions, again through iterative discussion. In Round 1, we asked participants to rate the desirability and feasibility of a list of possible tools and features (provided by the research team) as well as to suggest others and to comment on software requirements. We were mindful of the trade-off between obtaining comprehensive answers from respondents and the time taken for them to complete the survey. With this in mind, the questions were structured as a mix of closed questions (using rating scales) and optional open-ended questions to provide further detailed information about the reasoning behind each rating. The Round 1 questionnaire is included as Appendix 1. We deployed the questionnaires using the Survey Monkey® system. Round 1 took place in late November 2018 through January of 2019. The Round 1 questionnaire took respondents an average of 36 minutes to complete.

For the second round, to occur in early 2019, the results will be fed back, including new suggestions and re-ratings, to try to reach a greater agreement. Data will be analyzed using SPSS® and a system that supports collaborative text content analysis, such as Dedoose®.

PRELIMINARY RESULTS OF ROUND 1

Characteristics of the Expert Panel Respondents

As of the end of January 2019, 33 of the invited and referred experts had responded to Round 1 of the Delphi study. The participants are diverse and well balanced among different types of background experiences, as shown below in Tables 1 and 2. A little less than half (16) are from the U.S., with 5 from Spain, two each from Germany and New Zealand, and one each from several other countries in Europe, Asia, the Middle East, and Canada.

Table 1. Work experience is in the domain of (check all that apply)

Software Design	NGO EM	Local gov't EM	State gov't EM	National gov't EM	Research
17	5	10	6	6	20

Note that participants could choose more than one domain. To further explore these work domains, we created mutually exclusive categories by first grouping participants as Practitioners if they were the EM for local, state, or National levels or an NGO. Then we coded as shown below:

Table 2. Work Experience Domains

	Frequency	Percent
Software Design only	2	6.1
Research only	6	18.2
Practitioner only	7	21.2
Software design and practitioner	4	12.1
Software design and research	7	21.2
Practitioner and research	3	9.1
Software design, practitioner and research	4	12.1
Total	33	100

In terms of relevant years of work experience related to social media use for EM, only 3 had 2 years or less; 10, 3-5 years; 12, 6-10 years; and 7, over 10 years. Given the recency of the emergence of this field of expertise, this is a very experienced set of experts. They are about 2/3 male, which reflects the gender makeup of the field.

Selected Preliminary Results

Systems to be Included

Many of the existing prototype systems for collecting, categorizing, and analyzing Social Media posts for disaster work with only one Social Media platform, most often Twitter or Facebook. The feasibility of creating systems for a single platform thus has been repeatedly demonstrated. However, it is not reasonable to expect EMs to use different software aids for different social media platforms and somehow integrate this information; 61% of the experts say it is not useful to have a system that uses only one SM platform. However, if the

software analysis system could handle both Facebook and Twitter, then the majority say it would be useful, as shown below:

Table 3. How useful to an EM would a system be that handles both Facebook and Twitter posts, but not other systems?

	Frequency	Percent
Not useful	0	-
2	1	3.0
3	3	9.1
4	2	6.1
5	4	12.1
6	9	27.3
Very useful	13	39.4
Cannot say	1	3.0
Total	33	100

Perceived as most useful would be a real-time system that handles all "major" SM platforms, customized for a particular country, as shown in Table 4.

Table 4. How useful would it be to have a real-time system that handles and integrates information from "all major" SM platforms customized for a particular country?

	Frequency	Percent
Not useful	0	-
2	0	-
3	0	-
4	1	3.03
5	4	12.12
6	4	12.12
Very useful	24	72.73
Cannot say	0	-
Total	33	100

What are these "major" platforms that should be included? They do vary by country of the respondent, but after Twitter and Facebook, mentioned by almost all, Instagram was checked by 21 out of the 33 participants, WhatsApp by 14, YouTube by 12, Flickr by 9, and several other platforms suggested by one to three.

Though this design requirement, to include all major SM platforms, is considered very important, the feasibility of doing so is questioned by many of the experts, as shown in Table 5. Thus, the panelists have identified in the first round, an important design challenge for the research community.

There were many comments from participants that highlighted the types of challenges posed, of which the following two quotes reflect frequent themes:

> "*There are several aspects to developing the SM platform that integrates multiple social platforms. One of the primary issues that I struggle with is the restrictions applied on the data – while Twitter is one of the best options, Facebook has a lot of content that is more promising – however, accessing FB is a massive struggle given the platform restrictions. Most often, creating public FB pages that many people 'like' and contribute to is one of the very few means of getting data but is highly restrictive, time consuming and potentially biased.*"

> "*I think it would be incredibly useful to have a system that integrated multiple social media platforms, especially if it could be tailored to a local area. However, there are a lot of challenges. First, one has*

to identify the most commonly used platforms (which is in flux). Second, there are many interoperability issues. Each social media platform has a different API, different types of data (and associations between those data), different privacy settings, different terms of services, and different ways of representing user data and messages."

Table 5. How feasible is it to implement a real-time system that handles and integrates information from "all major" SM platforms customized for a particular country?

	Frequency	Percent
Not feasible	0	-
2	2	6.06
3	3	9.09
4	3	9.09
5	6	18.18
6	2	6.06
Very feasible	4	12.12
Cannot say	13	39.39
Total	33	99.99

In analyses of the completed research, we will also present results for the desirability and feasibility of many specific features or capabilities that could or should be included in the ideal SM analysis system for the future. These were rated on 1 to 7 semantic differential scales; the scales are from 1 (not useful/not feasible) to 7 (very useful/very feasible). In the preliminary and partial results shown below in Table 6, the means for some of the most highly rated design options are reported with the "cannot say" responses removed.

Table 6. Desirable and Additional Features – MEANS

	Mean	Std Dev
Usefulness of viewing SM data as classified by geographic location with map-based display	6.74	0.682
Usefulness of viewing SM data as generated by categories of users	6.68	0.599
Usefulness of filtering incoming SM data for relevancy using NLP and expert ratings	6.68	0.599
Usefulness of a system that can automatically process SM images to identify relevant ones	6.55	0.675
Usefulness of a system that could dynamically extract emerging/unanticipated types of information	6.53	0.681
Usefulness of a system that can automatically process SM images to identify whether or not an image shows damage	6.48	0.890
Usefulness of a system that can identify the location of SM posts even without GPS tagging	6.44	1.162
Usefulness of the ability to view SM data as categorized by sub events	6.42	0.958
Usefulness of having a way to automatically integrate SM data into any major IS system currently used by EMs	6.38	1.264
Usefulness of a system that can automatically process SM images to identify injured, trapped, or displaced people	6.32	0.871

There is a clear pattern that the usefulness of features is rated higher (over 5.5 for all listed, including several not included in Table 6) than the feasibility of developing or having the features (not shown). Statistical significance is not calculated but it appears that while there is enthusiasm for the features, there is less confidence that they can be implemented.

Future analyses will look at how ratings of usefulness and feasibility of the various potential software tools vary by the nature of the work experience/background of the participants (practitioners vs. technologists and U.S. vs. other nations).

CONCLUSION

In this paper, we share preliminary findings from a Delphi Study designed to understand how software can better support the SM needs of emergency managers. Already experts in the study have identified many useful and desirable features for managing SM, but it seems that at least some of these features may be difficult to develop. Completion of the Delphi study and more analysis is needed to fully understand the feasibility of developing these features. Additionally, several of the experts who volunteered for the study noted its potential for providing needed information to guide the future of software development for social media use in emergency management. For instance, one emergency manager said, "Thank you for your work. We rely on SM as a primary means of public information and warning. Any improvements would have significant social benefit for our rural communities." Another Delphi participant exclaimed, "Excellent area of study! Much needed!" With the cooperation of the experts to complete the two rounds of the Delphi study, we hope to fulfill these expectations.

ACKNOWLEDGMENTS

Authors are listed in alphabetical order. We are grateful to all of the participants in this study, who gave generously of their time.

APPENDIX 1

The Round 1 questionnaire consisted of 64 questions organized into eight sections focused on the themes of: consent (2 questions), participant emergency management experience (1), social media platforms (9), desirable features (2), additional features (14), other features (28), recommendations (3) and participant demographics (5). There were 39 mandatory and 25 optional questions with a mix of 28 free text responses, one check box for multiple responses, three check boxes that also included a free text "other" option and 32 radio buttons for a single response. A full copy of the questionnaire is available from the authors upon request.

The questionnaire begins with details of the co-investigators and references the principle institution conducting the research before asking for the participants name as shown below.

Then an overview of the research and participant instructions are provided, as shown below, followed by a question to obtain explicit consent from the participant as shown in Figure 1 below.

PURPOSE:

The purpose of our project is to build a communications bridge between emergency responders for both governments and NGOs (non governmental organizations) working in Emergency Management and technologists and researchers who can provide the advances needed to realize SM's (social media) full potential. This will create a synergy that will lead to a set of software requirements to better enable EMs (emergency managers) to gather an organized set of information from SM postings that is rated for trustworthiness and usable for decision making.

DURATION:

My participation in this study will last for approximately 4 months (2 surveys several months apart), each requiring 1-2 hours to read background material and then answer thoroughly.

I have been told that my participation in this research is important for the success of the research and that the results of this research study are expected to produce the following benefits to society and for me as a subject.

BENEFITS FOR SOCIETY AND THE SUBJECT:

I have been told that the benefits are:

For society: recommendations and software requirements that will lead to more effective use of social media in crisis management, thus better protecting lives and property.

For you: opportunity to exchange information and ideas with peers about future needed software systems related to social media and emergency management.

PROCEDURES:

I have been told that, during the course of this study, the following will occur:

1. Potential participants will be asked to answer a short questionnaire indicating their interest and describing their relevant expertise.
2. From these applicants, a balanced panel of experts will be invited to participate in two rounds of online questionnaires (known as a "Delphi" design of a study, which consists of two or more rounds of structured written exchanges between anonymous experts with different types of expertise relevant for a topic.) Our topic is the desirability and feasibility of a number of software enhancements for managing social media input to emergency managers. Our 8 categories of experts include software developers, researchers, government emergency managers, and NGO emergency managers, from the U.S. and internationally.
3. Results of Round 1 will be fed back to participants, with Round 2 asking for re-ratings.
4. Participants will receive a draft report of findings prior to public release and invited to comment.

PARTICIPANTS:

I will be one of about 50 participants in this study.

EXCLUSIONS:

I will inform the researcher if any of the following apply to me:

1. You must be at least 18 years of age.
2. You must be fluent in written English.

RISKS/DISCOMFORTS:

I have been told that the study described above may involve the following risks and/ or discomforts:

As an online participant in this research, there is always the risk of intrusion by outside agents (i.e. hacking) and, therefore the possibility of being identified exists.

There also may be risks and discomforts that are not yet known.

I fully recognize that there are risks that I may be exposed to by volunteering in this study which are inherent in participating in any study; I understand that I am not covered by <redacted>'s insurance policy for any injury or loss I might sustain in the course of participating in the study.

CONFIDENTIALITY:

I understand that confidential is not the same as anonymous. Confidential means that my name will not be disclosed if there exists a documented linkage between my identity and my responses as recorded in the research records. Every effort will be made to maintain the confidentiality of my study records. If the findings from the study are published, I will not be identified by name. My identity will remain confidential unless disclosure is required by law.

Note 1: You will be assigned an ID based on this form; the file that matches the names and ID number will be kept separately and in a secure location; thus the data file that contains your answers will not be identifiable by name.

Note 2: If you agree, the final report on the study will list your name in a list of expert participants; if you do not explicitly agree, your name will not be included as a contributor to the research.

RIGHT TO REFUSE OR WITHDRAW:

I understand that my participation is voluntary and I may refuse to participate, or may discontinue my participation at any time with no adverse consequences. I also understand that the investigator has the right to withdraw me from the study at any time.

INDIVIDUAL TO CONTACT:

If I have any questions about my treatment or research procedures, I understand that I should contact the principal investigator at: <redacted>

If I have any additional questions about my rights as a research subject, I may contact: <redacted>

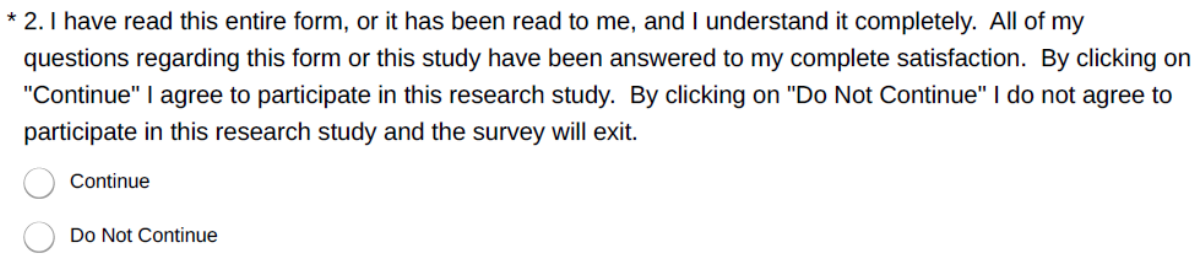

Figure 1: The Consent question.

The figures below show a selection of questions from the survey instrument. The question in Figure 2 corresponds to the results shown in Tables 1 and 2 above. Note the asterisk (*) next to the question number (3 in this case) indicates that the question is mandatory. This is an example of a check box question where the participant can select multiple responses.

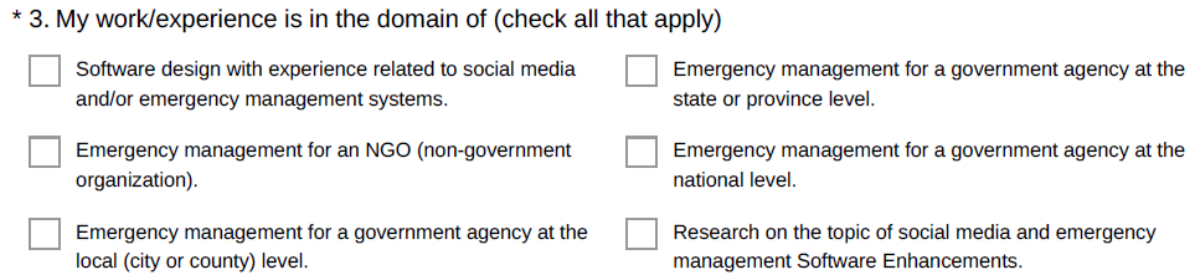

Figure 2: Participant work/experience.

Figure 3 shows the first four questions in the social media section of the survey where each is a radio button allowing only a single response. This section is preceded by an introduction describing the purpose of the survey in terms of identifying software enhancements as follows:

Our overarching goal is to make social media more usable for emergency managers (EMs) to gather and assess information from the public, to aid in "situational awareness" and decision making. In the research literature, there are many systems described that take the form of gathering information from social media (SM) posts during a crisis and processing it by organizing it, displaying it, and/or assessing its validity, etc. The purpose of this study is to gather expert wisdom about the potential usability and feasibility of a number of such possible software enhancements, in order to arrive at a set of requirements to guide future developments. We begin in this round with your ratings of an initial set of possible improvements that are already specified in the current literature, and then ask you to add additional improvements you think will help EMs more effectively use SM. Please supply as many comments as you can in the text boxes, in terms of additional ideas or reasons for your ratings.

If you do not have experience with software engineering, you should check "cannot say" when estimating feasibility of a possible enhancement

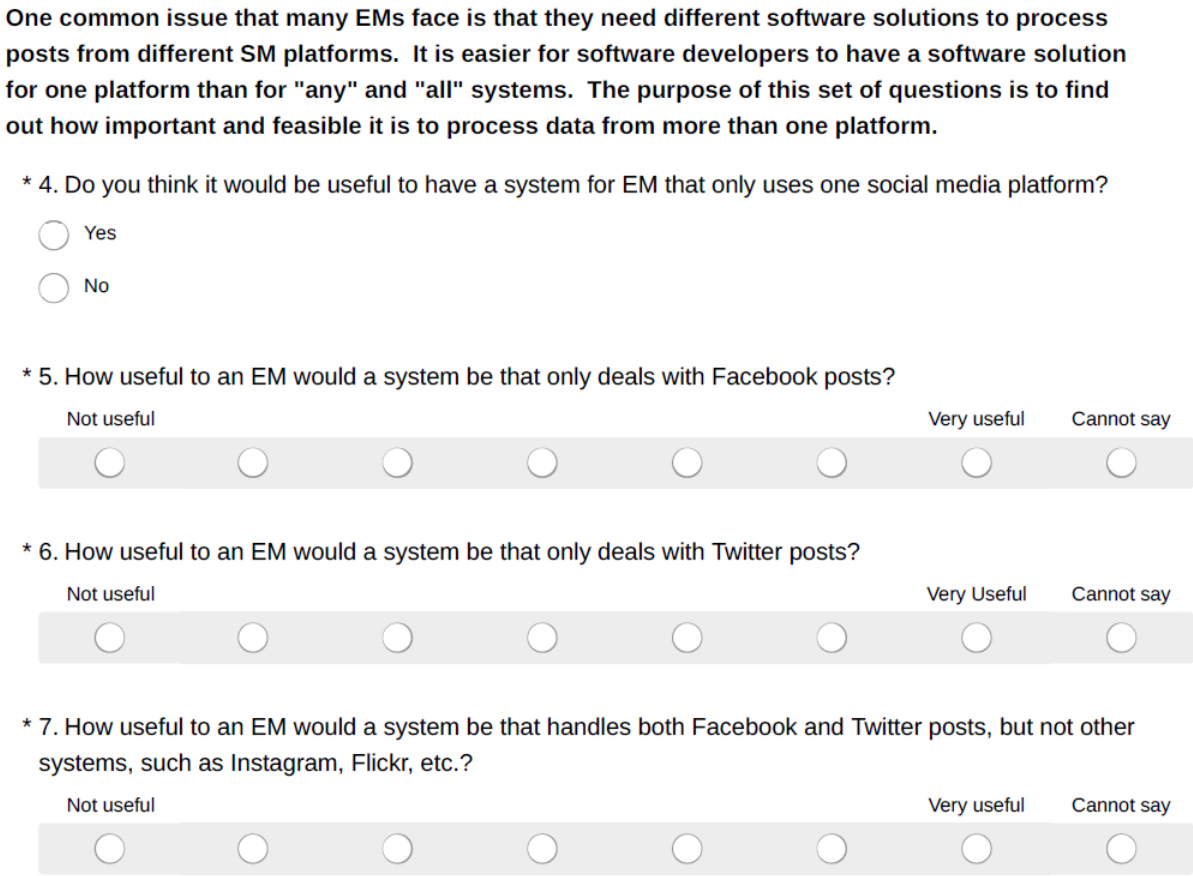

Figure 3: Example Social Media Platform questions.

ABSTRACT

Social media enables fast information exchange and status reporting during crises. Filtering is usually required to identify the small fraction of social media stream data related to events. Since deep learning has recently shown to be a reliable approach for filtering and analyzing Twitter messages, a Convolutional Neural Network is examined for filtering crisis-related tweets in this work. The goal is to understand how to obtain accurate and robust filtering models and how model accuracies tend to behave in case of new events. In contrast to other works, the application to real data streams is also investigated. Motivated by the observation that machine learning model accuracies highly depend on the used data, a new comprehensive and balanced compilation of existing data sets is proposed. Experimental results with this data set provide valuable insights. Preliminary results from filtering a data stream recorded during hurricane Florence in September 2018 confirm our results.

Keywords

Filtering, Convolutional Neural Networks, Natural Disasters, Twitter, Model Transferability.

INTRODUCTION

Several studies and use cases have demonstrated the great value and importance of analyzing social media streams, e.g. for rescue and helping activities in case of natural disasters and technical accidents (Reuter and Kaufhold 2018). Due to the huge and higly active user community distributed over the world, the ability to post messages from many sources as well as the accessibility of data streams via official APIs, research mainly focuses on Twitter. Furthermore, various labeled Twitter data sets related to crises and natural disasters are available.

As tweets posted during disasters are extremely varied, an automatic system needs to start by filtering out messages that do not contribute valuable information (Imran, Elbassuoni, et al. 2013). Existing approaches for filtering are keyword- or location-based, or utilize methods of natural language processing (NLP), visual analytics, or machine learning (Imran, Castillo, et al. 2015). An emerging availability of various labeled data sets recently enabled the successful application of deep learning to the problem of filtering (Burel and Alani 2018) as well as categorization of tweets into crisis-related information classes (Burel, Saif, et al. 2017, Nguyen, Al-Mannai, et al. 2017).

In this work, the robustness and accuracy of deep learning models is investigated for the task of filtering disaster-related tweets. Formulating filtering as a, preferably unambiguous, binary classification problem allows for experiments related to the impact of training data on the model quality. As investigated in (Stowe et al. 2018), a careful definition of thematic classes in filtering and classification is a crucial step. The authors distinguish between *related* and *unrelated* tweets, where the first class represents messages that are somehow related to disasters, and the

*corresponding author
†http://DLR.de/dw

latter class contains all off-topic posts. Since inter-annotator agreements around 92 % were obtained for this binary classification problem, this definition is also used here.

To develop robust filtering models, we compiled a new comprehensive and balanced dataset, which is one of the main contributions. More specifically, we are interested in performance differences of models covering various different event types (e.g. hurricanes, floods, earthquakes etc.) compared to models exclusively trained on one specific event type. The goal is to understand how to obtain accurate and robust filtering models and in particular how model accuracies tend to behave in case of new events. In contrast to other works, the application to real data streams is also investigated here.

In the first step, a balanced training data set covering several disaster types and containing approximately 66,000 tweets for both classes is compiled from several existing sets. Various event-specific and unspecific subsets of this training data set are then used to train and test a state-of-the-art Convolutional Neural Network (CNN). The experimental results show that the filtering task in case of new events can be tackled by global models covering several event types with acceptable F1-scores of 0.8 and better, while the standard deviation tends to be slightly higher than for models specifically trained for single event types. Preliminary results from filtering a data stream recorded during hurricane Florence in September 2018 further confirm the observed model behaviors.

RELATED WORK

It is easier than ever to search the web for information about disasters, but filtering out off-topic discussions from the ocean of online content remains difficult (Landwehr and Carley 2014). A potentially huge fraction of messages collected for the purpose of deriving information related to a given crisis will not be related to the considered event. This fraction depends on the specific collection method used and on other factors, such as the presence of off-topic messages using the same tags or keywords as the on-topic ones (Imran, Castillo, et al. 2015).

The official Twitter streaming API provides filtering by location, keywords, author, and others. An alternative for real-time stream filtering is the use of tools based on location or keywords, for example TweetTracker (Kumar et al. 2011). Following the approach of keyword-based search, a lexicon of crisis-related terms (*CrisisLex*), intended to be used for collecting and filtering microblogged communications in crises, was developed (Olteanu, Castillo, et al. 2014). Since also unrelated messages containing the keywords will be retrieved, this approach usually requires post-filtering, for example using human labeling, crowdsourcing or automatic classification (Imran, Castillo, et al. 2015). Furthermore, a significant fraction of relevant data might mistakenly be discarded if the keywords are not appropriate, e.g. when the event is new or has changed over time. In location-based filtering, a large percentage of tweets will be discarded because only a small fraction of around 2 % is usually geo-referenced (Burton et al. 2012).

In order to mitigate the aforementioned problems of keyword-based approaches, methods for analyzing the information contained in tweets have been investigated in several studies. Analyzing tweets using traditional NLP approaches is known to be challenging, for example because of the limitation to 280 characters, abbreviations, misspellings, emoticons, informal language with grammatical errors and varied vocabulary, improper sentence structure, and mixed languages (Ramachandran and Ramasubramanian 2018). In (Win and Aung 2017), the tasks tweet filtering, feature extraction and classification using a LIBLINEAR classifier are addressed. In case of training and testing tweets from the same event, maximum accuracies of around 91 % were obtained. For test tweets from unseen events (cross-domain experiment), significantly lower accuracies around 75 % were reported. In (Parilla-Ferrer et al. 2014) Naïve Bayes (NB) and Support Vector Machines (SVM) were used to automatically detect informative disaster-related tweets. While NB outperformed SVM in precision, SVM yielded a higher average F-measure (87.3 %) than NB (62.1 %). Even though methods from the area of NLP offer a wide range of possibilities for systematically and efficiently searching, filtering, sorting and analysing huge amounts of data, their application to social media data is a relatively new topic of research and confronts researchers with many questions and challenges (Gruender-Fahrer et al. 2018).

In (Kim 2014), CNNs were applied to the general task of sentence classification. Compared to 14 machine learning methods, a superior CNN performance was achieved for four of seven data sets, indicating a good model transferability. The approach of Kim was adapted to the problem of rapid classification of crisis-related data in (Nguyen, Al-Mannai, et al. 2017). The results demonstrate that classifying tweets in case of new events, i.e., when no event-specific data is available, is still possible with a decrease of AUC-scores in a range of 5 – 19 %. In (Burel and Alani 2018), Kim's CNN was applied to tweets for tackling the problems of filtering (*related* vs. *unrelated*) as well as classifying event types and information categories using data from the *CrisisLexT26* dataset (Olteanu, Vieweg, et al. 2015). F1-scores in the range of 80 – 84 % were obtained for the filtering task.

The results of recent works in the deep learning domain confirm the importance of high-quality data for training, also identified as one of the major challenges in social media analytics in (Stieglitz et al. 2018). Furthermore,

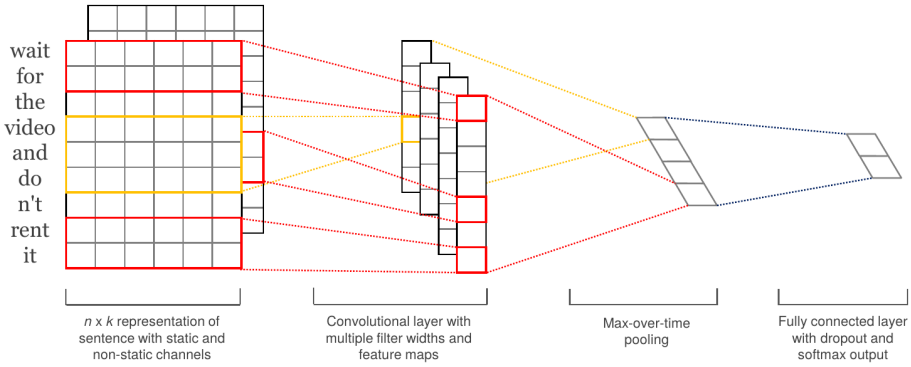

Figure 1. CNN for text classification as proposed in (Kim 2014)

the problem definition as well as other factors, like thematic class overlaps (Stowe et al. 2018) and the coverage of multiple event types (Periñán-Pascual and Arcas-Túnez 2018) may significantly affect model accuracy and robustness as well as its transferability to new events. Results of the studies discussed in this section only partially confirm these observations. With a focus on applying deep learning filtering models to real Twitter streams, the above-mentioned dependencies on data used for training is comprehensively and systematically investigated in this work. Since the CNN proposed by Kim has shown a great potential for crisis-related tweet filtering and classification, this model is utilized in our experiments.

CONVOLUTIONAL NEURAL NETWORKS FOR TWEET FILTERING

Motivated by the promising results in (Burel and Alani 2018) for tweet filtering (*related* vs. *unrelated*), per-tweet event type categorization and per-tweet information type classification, the same CNN architecture (Kim 2014) is utilized in this work (see figure 1). The approach was specifically developed for classifying sentences into diverse categories, e.g. question types or sentiments. At first, each message is pre-processed by applying a set of commonly used standard operations, i.e., lowercasing, multiple space replacing, normalizing URLs, usernames and hashtags, removing special characters, normalizing digits as well as tokenization. Each word of a tweet is then transformed into a real-valued vector of 300 elements.

Commonly used pre-trained embeddings are based on *word2vec* (Mikolov et al. 2013). In contrast, we use the embedding proposed in (Imran, Mitra, et al. 2016), which was specifically trained on 52 million crisis-related twitter messages. Hence, each tweet is represented as a matrix of size $n \times k$, where n is the maximum number of words occurring in the training data and $k = 300$ is the embedding vector length. In case the number of words is lower than n, zero padding is applied. Then, a convolutional layer applies m kernels of different widths w in parallel to the input matrix. We use standard values $m = 128$ and $w = (3, 4, 5)$, because parameter variation did not affect the results significantly. Global max-pooling is performed after each of these convolutional layers, and the results are concatenated. This new embedding is then fed into a fully connected layer with a dropout rate of 0.5 to determine the final class.

DATASET

Various comprehensive labeled crisis-related Twitter data sets are available, enabling the application and evaluation of machine learning methods. Besides a categorization of event types and information classes, labels for relatedness, relevance or informativeness are usually provided or can be derived from the data, for example by merging all information class labels to a *related* class. However, from a machine learning point of view, a significant imbalance of available class instances in nearly all datasets can be observed. Since crisis-related tweets are often pre-selected by using specific keywords or hashtags, the number of related tweets is usually higher than the number of unrelated tweets. Furthermore, not all common types of disaster events are covered by all data sets. To overcome these issues, we compile a new comprehensive and balanced training data set for filtering tweets related to disasters of different types. In this work, the labels from five common data sets are transformed to comply with our definition (*related* vs. *unrelated*). To increase the low number of *unrelated* tweets, the *Events2012* (McMinn et al. 2013) data set is utilized. This set contains relevance judgments for 150,000 tweets covering more than 500 non-crisis events from a broad range of topics. An overview of the resulting data set is provided in table 1.

Table 1. Composition of the proposed data set

Data set	*Tweet count related*	*Tweet count unrelated*	*Covered event types*
Events2012 (McMinn et al. 2013)	3,612	48,531	Disasters and accidents, 500 other topics, like sports, arts, culture and entertainment
CrisisLexT26 (Olteanu, Vieweg, et al. 2015)	24,581	3,352	Earthquake, flood, wildfire, meteor, typhoon, flood, train crash, explosions, building collapse, bombings
CrisisNLP (Imran, Mitra, et al. 2016)	22,381	-	Earthquake, hurricane, flood, typhoon, cyclone, ebola, MERS
CrisisMMD (Alam et al. 2018)	11,524	-	Hurricane, earthquake, wildfire, flood
Epic (Stowe et al. 2018)	4,578	14,809	Hurricane
Sum	66,692	66,692	

According to our definition, the *CrisisLexT26* classes *related and informative* as well as *related - but not informative* are merged to the target class *related*. From *CrisisMMD* (Alam et al. 2018), only tweets labeled as *informative* are used as *related*. Since tweets from class *not informative* may or may not be related to crisis events, they are not used here. This also applies to *CrisisNLP* (Imran, Mitra, et al. 2016), where the class *not related or irrelevant* might still contain crisis-related tweets. *Epic* (Stowe et al. 2018) uses the same problem definition as this work. From *Events2012*, tweets related to disasters and accidents are used for the target class *related*. In order to achieve perfect class balance, randomly sampled tweets from all other non-crisis topics of this data set are used for the class *unrelated*.

EXPERIMENTAL RESULTS

In this section, the goal is to evaluate the impact of the proposed data set compared to other related works as well as to investigate the performance behavior and robustness of models covering a broad range of event types (in the following denoted as "global models") compared to models specifically trained on single events (in the following denoted as "local models"). Local models individually trained on hurricane or flood event data sets are evaluated and compared to global models trained with the complete data set. Hurricanes and floods are chosen because of the their frequent occurence as well as the availability of data. Furthermore, the transferability of local and global models to new events is investigated.

The following experiments are conducted: First, global model performances are compared to a benchmark method as well as to local models trained for specific event types. In contrast to other studies, where accuracy measures obtained during cross-validation are reported (e.g. in (Burel and Alani 2018)), we use independent test data excluded from cross-validation. Model transferabilty is evaluated by using test data from unseen events. Secondly, we investigate how well local models perform in case of other event types. To this end, local flood models are applied to hurricane data and vice versa. Third, since available labeled data sets usually represent a pre-selected subset, we evaluate the transferability of our models to new Twitter data streams. First results for filtering ~1,120,000 geo-located tweets from the impact area during hurricane Florence (September 12-19, 2018) as well as after the event (January 08-15, 2019) are presented.

Flood events: Global versus local models

The five data sets listed in table 1 cover the following six flood events: Phillippines 2012, Alberta 2013, Manila 2013, Queensland 2013 (all from *CrisisLexT26*, ~ 1,000 tweets per event), Pakistan 2014 (*CrisisNLP*, ~ 2,000 tweets) and Sri Lanka 2017 (*CrisisMMD*, ~ 800 tweets). Whereas global models are trained by using the full proposed data set, local models are trained solely based on the above-mentioned flood data sets. Perfect class balance is achieved by randomly sampling the required amount of *unrelated* tweets from the *Events2012* data set. In addition to typically used 10-fold cross-validation (CV), we exclude 10 % randomly sampled tweets from CV for independent testing. In order to test the the models' transferability, each of the events is successively excluded for training local and global models, and is instead used for testing. Hence, a total number of 120 models is trained and evaluated in this experiment, where for each omitted flood event 10-fold CV for a local and a global model is conducted. Besides commonly used averaged results for precision, recall and F1-measure, the standard deviation of these scores is analyzed here as well.

In figure 2, the obtained results for the local and global models averaged over all CVs as well as the six flood events are presented. In case of local model validation with randomly excluded data (figure 2a), F1-scores around 0.92 are obtained. As expected, with test data from unseen events, the local models perform slightly worse (figure 2b). Nonetheless, the average F1-scores are 0.88 and 0.90 for the classes *related* and *unrelated*, respectively. In contrast, the global models yield F1-values between 0.82 and 0.85 and therefore perform worse than the local models. Furthermore, the standard deviations for global models tended to be higher. In table 2, the results are compared to those reported in (Burel and Alani 2018), where the same model and problem definition with *CrisisLexT26* data were used (CNN_{base}). To the best of our knowledge, this represents the best results obtained for filtering (*related* vs. *unrelated*) up to now.

Figure 2. Averaged results of local and global models tested with randomly excluded and new flood event data

Hurricane events: Global versus local models

The data sets listed in table 1 cover the following five different hurricane events: Sandy 2012 (*Epic*, ~ 20,000 tweets), Odile 2014 (*CrisisNLP*, ~ 2,000 tweets), Harvey 2017, Irma 2017, Maria 2017 (all from *CrisisMMD*, ~ 4,000 tweets per event). A total number of 100 models is trained and evaluated in the same manner as described above in this experiment. According to figure 3 and table 2, local and global models tested with randomly excluded data behave similarly to flood-related models. Testing with different unseen hurricane-related data sets results in F1 drops between 0.007 and 0.12. An intersting observation is that global models yield higher F1-scores than local models in case of unseen events.

Local model transferability to other events

Even though local models tend to be more accurate and robust in our experiments, a practical application might be challenging. Models trained on specific event types would have to be applied to a data stream in parallel. The per-tweet model votes can then be used for filtering as well as a decision regarding the relatedness to specific

event types. Even though this would provide valuable additional information, a decision cannot be made in case of ambiguous model votes. In this context, the cross-event performance of local flood and hurricane models is investigated in this experiment. Averaged results and standard deviations for all local models applied on other event types are shown in table 3. Compared to the results of local models applied to data from the same event type,

Table 3. Scores for cross-event application of local flood (F) and hurricane (H) models

	Related			*Unrelated*		
Model→ Event	*Precision*	*Recall*	*F1*	*Precision*	*Recall*	*F1*
F→ H	0.907±0.124	0.491±0.146	0.629±0.139	0.710±0.081	0.975±0.017	0.819 ±0.050
F→ F	0.989±0.007	0.789±0.094	0.875±0.054	0.830±0.069	0.990±0.007	0.901 ±0.038
H→ F	0.809±0.101	0.785±0.165	0.779±0.092	0.807±0.106	0.791±0.113	0.789 ±0.062
H→ H	0.755±0.013	0.802±0.273	0.747±0.181	0.895±0.048	0.753±0.112	0.811 ±0.038

obtained F1-scores are up to 0.25 lower, where hurricane models applied to flood data perform better than vice versa. For *related* tweets, especially in case of flood models applied to hurricane data, the recall drops significantly.

Hurricane Florence: Global model transferability

Analyzing the tweet content without preliminary keyword-based filtering, as proposed in this work, implies a significantly higher occurence of unrelated tweets, which is usually not represented in labeled data sets. We therefore acquired $\sim 600,000$ tweets during hurricane Florence from September 12th to 19th, 2018, using the Twitter API. In order to avoid effects of keyword-based filtering, we applied location-based filtering by defining an area of interest (AOI) as shown in figure 4a. Forecast services estimated that this would be the mainly affected area for which heavy rainfall was expected as well (figure 4b).

Since only a fraction of all tweets is known to be geo-referenced, this approach might again introduce bias. However, we assume that sampling geo-referenced tweets provides a more representative subset of all tweets than sampling by keywords. Another advantage of this approach is that tweets from directly affected individuals are collected, whereas tweets from users who are not directly involved, but contribute to discussions are discarded.

The results of our global model applied to the Florence data allow for several further analyses. As a first result, the temporal distribution of *related* and *unrelated* tweets binned into intervals of two hours is shown in figure 5. A daily tweet activity pattern with maximum values of $\sim 10k - 12k$ until around midnight can be observed. 14.9 % of all tweets are classified as *related* to a disaster event. Due to the current lack of labels for this data set, the results are analyzed qualitatively in order to gain first insights (see discussion).

The same model is applied to a second data set acquired for the AOI in figure 4a during a non-disaster period (January 08-15, 2019). The corresponding histogram shown in figure 6 has a similar pattern as the one generated for the event period. During the disaster, $\sim 88,400$ tweets were identified as *related*, whereas in the second period around half of this amount was detected ($\sim 43,700$ tweets). With a total number of $\sim 526,000$ tweets recorded in January 2019, 8.3 % of these are classified as *related*. Selected examples are listed in table 4. The highest-ranked

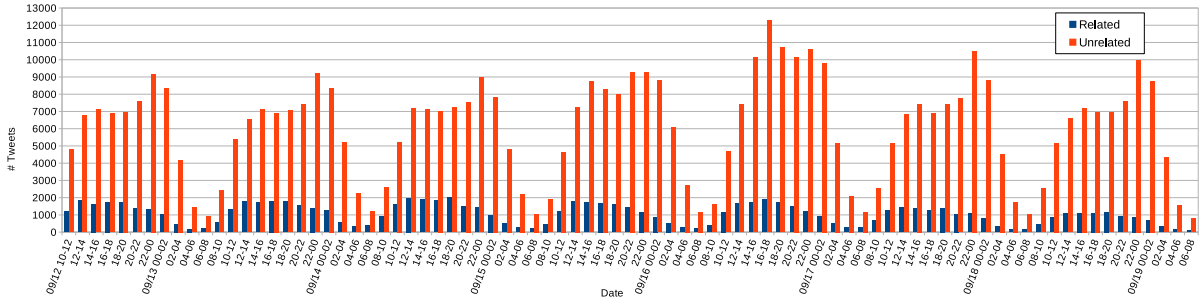

Figure 5. Filtering results during hurricane Florence, September 12-19, 2018

related tweets demonstrate that even though Florence seemed not to be a huge topic during January, other general crisis-related aspects as well as the heavy 2018 California wildfires are discussed. The *related* examples with a likelihood of 0.9 indicate that many *unrelated* tweets might be misclassified. Classification examples for class *unrelated* with softmax values between 1.0 and 0.5 in turn indicate a large likelihood that these are correctly classified.

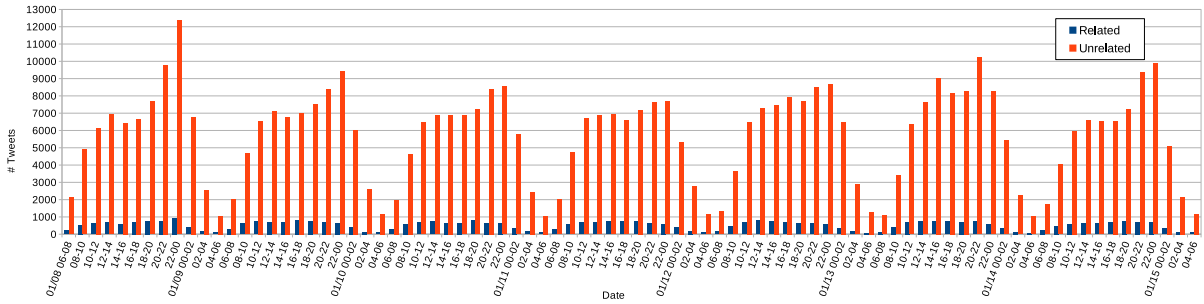

Figure 6. Filtering results during a non-crisis period, January 08-15, 2019

DISCUSSION

In this study, our comprehensive and balanced data set leads to better results for tweet filtering compared to other studies, in which the same CNN architecture and similar hyperparameters were used. We choose a binary and objective classification problem without further semantic interpretations, like the informativeness or usefulness of related tweets. Taking into account that inter-annotator agreement of around 92 % was obtained for this definition in (Stowe et al. 2018), our F1-scores in a range of 75 – 92 % for local models as well as 80 – 86 % for global models are satisfying.

Event type-specific differences of model accuracies can partially be explained by the complexity of disaster types. The fact that flood events represent one of several different sub-event types typically occuring during or after hurricanes might be the main reason for lower scores and higher standard deviations for hurricane models.

According to figures 2a-2c, the flood-related local and global models show a general accuracy pattern, in which recall is lower than precision for class *related* and vice versa for class *unrelated*. A high precision for *related* tweets indicates a low percentage of *unrelated* misclassified tweets. A lower recall for *related* tweets indicates that misclassifications for *related* tweets are more likely. An interesting observation is that the relations are intensified for local models tested with unseen event data, i.e., precision and recall for *related* are around 0.99 and 0.80, respectively, and vice versa for *unrelated*. F1 standard deviations of $0.03 - 0.05$ for the local flood models indicate a high robustness. Furthermore, the averaged scores are higher compared to the baseline model.

For the corresponding hurricane-related models (figures 3a-3c, table 2), other relations as well as lower scores and higher standard deviations can be observed, where the latter two can be explained by the aforementioned heterogeinity of possible sub-events in case of hurricanes. Compared to a baseline value of 0.84 for precision, recall and F1, corresponding average values of 0.90, 0.81 and 0.85 for models tested with randomly excluded data and 0.77, 0.83 and 0.78 for models tested with data from new hurricane events were obtained. This indicates a good performance if test data from the same event is used and slightly worse results for unknown hurricane events. Class-related patterns for precision and recall can be observed with respect to the data used for testing. Whereas the pattern is similar as described for flood models, a difference is observed for testing local models with new events, i.e., a lower precision and higher recall for *related*.

For the global models tested with unseen event data (figures 2d and 3d, table 2), the same pattern with lower precision and higher recall for *related* can be observed. This means that we can expect more false negatives and fewer false positives. A reason for this similar trend in both global models might be the fact that training is done using a large set of tweets from various event types, where only a very small fraction (a single new event) is used for testing. As expected and similar to results, for example reported in (Imran, Elbassuoni, et al. 2013; Win and Aung 2017), a drop of accuracies in case of new events can be observed. However, F1-scores between 0.81 and 0.86 indicate good accuracy compared to our baseline. Note that the scores discussed here were not obtained by testing with data excluded during CV, but by using data from completely different events. With respect to the 92 %

inter-annotator agreement reported in (Stowe et al. 2018), these results are quite satisfactory, even though higher performance variations can be expected with increasing event complexity.

Hypothetically, the application of local models to data from other event types should result in lower scores. The results in table 3 partially show a different behavior. Applying flood models to hurricane data results in 0.49 recall for *related*, indicating a higher complexity of hurricane events covering various sub-events. On the other hand, a high recall of around 0.78 in case of hurricane models applied on flood data reflects the fact that floods are sub-events of hurricanes. We therefore apply a global model trained with our proposed balanced data set to the Florence data.

Regarding the Florence data, we investigate whether our global models tend to provide the same accuracies as reported in the preceding experiments. According to figures 2d and 3d and table 2, we expect more false negatives than false positives as well as F1-scores of 0.80 ± 0.19 and better. This should result in a high percentage of correctly classified *unrelated* tweets. The $\sim 502,000$ tweets recorded during Hurricane florence that are classified as *unrelated* are therefore quantitatively analyzed by searching for crisis-related keywords (e.g. flood, hurricane, thunderstorm, tornado, and florence), as well as by manually evaluating random samples. A small fraction of $\sim 10,000$ wrongly classified tweets identified with this approach provides a hint that the model tends to behave as expected. A further indicator for this is the observation of a significantly higher percentage of *unrelated* tweets misclassified as *related*. A thorough review of randomly sampled tweets classified as *related* indicates a strong relationship between the CNN softmax outputs and misclassifications. In case of softmax values between $0.6 - 1.0$, the percentage of wrong classifications seems to be low and increases with decreasing softmax values below 0.6. The results obtained for the second data set from 2019 provide further evidence for these trends.

CONCLUSIONS AND OUTLOOK

In this work, the task of filtering crisis-related tweets is investigated. A strong dependency on chosen keywords for filtering motivates an approach for analyzing full tweet content with CNNs. Since this is intended to be the first analysis step for several crisis-related applications, a binary classification (*related* vs. *unrelated*) is used here.

In order to cover a broad range of different crisis event types as well as to overcome the often-observed problem of imbalanced training data, a new data set is compiled based on existing sets. Compared to other works, in which the same CNN was utilized, we obtain robust and even better results. In terms of model transferability to six flood and five hurricane events, our event-specific models are able to obtain F1-scores of $0.75 - 0.90$. However, since the usage of models for single event types may be ambiguous in case of similar events (e.g. floods often occur during hurricanes), we recommend to use models covering a broad range of event types. For new hurricane and flood events, an average F1-score of 0.83 ± 0.13 is obtained for these models.

However, our main focus is the application of models to real data streams. We are therefore currently investigating if the model behavior for data representing a realistic Twitter stream is similar to our experimental results reported in this work. First qualitative results with with a data set recorded during hurricane Florence indicate strong similarities. For a non-crisis period, only 8.3 % of all tweets were classified as *related*, further confirming the promising results.

In future works, we plan to (partially) label the Florence data set for further quantitative analyses. With the goal of model enhancement in case of new events, methods for domain adaptation, such as those proposed by (Li et al. 2018) for NB classifiers or online deep learning as proposed in (Nguyen, Joty, et al. 2016) could be further investigated.

ABSTRACT

Social media sources can be helpful in crisis situations, but discovering relevant messages is not trivial. Methods have so far focused on universal detection models for all kinds of crises or for certain crisis types (e.g. floods). Event-specific models could implement a more focused search area, but collecting data and training new models for a crisis that is already in progress is costly and may take too much time for a prompt response. As a compromise, manually collecting a small amount of example messages is feasible. Few-shot models can generalize to unseen classes with such a small handful of examples, and do not need be trained anew for each event. We show how these models can be used to detect crisis-relevant tweets during new events with just 10 to 100 examples and counterexamples. We also propose a new type of few-shot model that does not require counterexamples.

INTRODUCTION

Social media is an interesting source of information during disasters that has become a topic of research in recent years. Twitter users, as an example, write about disaster preparations, developments, recovery, and a host of other topics (Niles et al. 2018). Retrieving this information could lead to significant improvements in disaster management strategies. According to a Red Cross study, 69% of Americans think that emergency response agencies should respond to calls for help sent through social media channels (American Red Cross 2010). The crux of this matter lies in the retrieval and classification of such messages. Twitter users generate 5,800 tweets per second on average[1]. Even with hashtag- or location-based pre-filtering, sophisticated automatic methods are necessary to detect disaster-related messages in acceptable timespans. Approaches published so far have mainly had the generalized detection of any disaster-related tweet as their objective (Burel and Alani 2018), or have focused on specific types of disasters (Caragea et al. 2016). Designing models specific to a certain event could potentially yield much more exact results, but training such dedicated models would require large amounts of already available data and take up critical time in a disaster.

In this paper, we present a first approach that facilitates the detection of Twitter messages (tweets) pertaining to a specific event on the basis of example tweets. These models can be trained well in advance, and then require as few as ten examples against which new tweets are compared. We test few-shot networks that either require both "pro" examples and counterexamples of the event, and a new type that only requires "pro" examples. These approaches obtain F_1 meaures of 75 – 76% on tweets from unseen events opposed to tweets from other events. The paper is

organized as follows: In the next two sections, we will present an overview of related work and the data sets used in our experiments. The sections afterwards describe the proposed approaches and our experimental results. In the last section, we give a conclusion of our work so far and make suggestions for future experiments.

RELATED WORK

As described above, users generate huge amounts of data on Twitter every second, and finding tweets related to an ongoing event is not trivial (Landwehr and Carley 2014). Several detection approaches have been presented in literature so far.

The most obvious strategy is the filtering of tweets by various surface characteristics as shown in (Kumar et al. 2011), for example. Keywords and hashtags are used most frequently for this and often serve as a useful pre-filter. Olteanu et al. developed a lexicon called *CrisisLex* for this purpose (Olteanu, Castillo, et al. 2014). However, this approach easily misses tweets that do not mention the keywords specified in advance, particularly when changes occur or the attention focus shifts during the event. It may also retrieve unrelated data that contains the same keywords (Imran, Castillo, et al. 2015). Geo-location is another frequently employed feature that can be useful for retrieving tweets from an area affected by a disaster. However, this approach misses important information that could be coming from a source outside the area, such as help providers or news sources. Additionally, only a small fraction of tweets is geo-tagged at all, leading to a large amount of missed tweets from the area (Sloan et al. 2013). To resolve these problems, several other strategies were developed, starting with crowdsourcing platforms. On these platforms, a large amount of users hand-selects and labels incoming tweets in disaster situations. Examples include *Ushahidi*[2] and *CrisisTracker* (Rogstadius et al. 2013). Some of them already integrate "traditional" machine learning models, e.g. *AIDR* (Imran, Castillo, et al. 2015).

In recent years, approaches based on deep learning techniques have come to the forefront of research. On a more general level, the problem falls under the umbrella of event detection as shown, for example, in (Chen et al. 2015; Feng et al. 2016; T. H. Nguyen and Grishman 2015). Caragea et al. first employed Convolutional Neural Networks (CNN) for the classification of tweets into those related to flood events and those unrelated (Caragea et al. 2016). In many of the following approaches, a type of CNN developed by Kim for text classification is used (Kim 2014), such as in (Burel and Alani 2018). This method achieves an accuracy of 80% for the classification into related and unrelated tweets. In the same publication as well as in (Burel, Saif, et al. 2017) and (D. T. Nguyen et al. 2016), this kind of model is also used for information type classification. For comparison purposes, we also tested the relatedness model from (Burel and Alani 2018) on our test data set (*CrisisNLP*, see below) and obtained an F_1 measure of .86 and an accuracy of .77, although the data in this case is strongly unbalanced as there are few tweets in that data set that do not belong to any crisis.

All of these approaches aim to generalize to any kind of event without any *a priori* information. A real-world system may not need to be restricted in this way; in many cases, its users will already have some information about the event, and may already have spotted tweets of the required type. This removes the need to anticipate any type of event. It also directs the system towards a specific event rather than any event happening at that time. Alam et al. (Alam et al. 2018) propose an interesting solution to this: Their system includes an adversarial component which can be used to adapt a model trained on a specific event to a new one (i.e. a new domain).

We propose a system that does not assume an explicit notion of relatedness vs. unrelatedness (or relevance vs. irrelevance) to a crisis event. These qualities are not easy to define, and might vary for different users or different types of events. Additionally, as in (Alam et al. 2018), we are interested in a method that is specific to an event rather than attempting to detect any kind of crisis-related tweet. In this paper, we demonstrate how to implement a system that is able to determine whether a tweet belongs to a class (i.e. crisis event) implicitly defined by a small selection of example tweets. We employ few-shot models to for this purpose; an overview over work related to this topic is given later.

DATA

We employ two widely-used collections of disaster-related tweets to train and test our models: *CrisisLexT26* and *CrisisNLP*.

Table 1. Hashtags chosen for the *CrisisLexT26* data set. (Two events did not contain frequent hashtags and were therefore excluded.)

CrisisLexT26

CrisisLex was first published by Olteanu et al. in 2014 (Olteanu, Castillo, et al. 2014) and expanded later to *CrisisLexT26* (Olteanu, Vieweg, et al. 2015). It contains tweets collected during 26 crises, mainly natural disasters like earthquakes, wildfires and floods, but also human-induced disasters like shootings and a train crash. Amounts of these tweets per disaster range between 1,100 and 157,500. In total, around 285,000 tweets were collected. They were then annotated by paid workers on the *CrowdFlower* crowdsourcing platform[3] according to three concepts: Informativeness, information type, and tweet source. In this work, a balanced set containing 1,100 English-language tweets per event is used. Two events were excluded as no frequent hashtags for them were found (see below).

CrisisNLP

Similar to *CrisisLexT26*, the team behind *CrisisNLP* collected tweets during 19 natural and health-related disasters and published them for research (Imran, Mitra, et al. 2016). Collected tweets range between 17,000 and 28 million per event, making up around 53 million in total. Out of these, around 50,000 were annotated both by volunteers and by paid workers on *CrowdFlower* with regard to information type. In this work, only the tweets with *CrowdFlower* annotations were utilized. These tweets come from a subset of 11 English-language event sets, summing up to around 23,000 in total. There is no overlap between the events in both data sets.

Experimental data composition

In order to train and test our few-shot models, sub-sets of positive and negative supports for a class (examples and counterexamples) plus an either positive or negative query are necessary. As an example from a different domain, a positive support set for cat classification may consist of a number if images showing cats, while the negative support set may show other animals or completely different content. Analogously, positive and negative queries would consist of unseen images of cats or other animals respectively.

In few-shot models, training steps performed on such sets are called “episodes”. For our purposes, tweets are considered to belong to the same class if they are associated with the same event. The annotations provided with the *CrisisLexT26* and *CrisisNLP* data sets are not used, apart from filtering out tweets that were tagged as unrelated or irrelevant. Event selection for each episode is performed in such a way that all events are equally likely. To generate

Table 2. Hashtags chosen for the *CrisisNLP* data set.

episode data packs, tweets for an event containing a specific hashtag are selected randomly to create the positive support set. Upper- and lower-case versions are equalized, and this hashtag is removed in a pre-processing step so as not to bias the classifier towards it. For positive queries, tweets without the hashtag, but coming from the same event are picked randomly. For negative supports and queries, random tweets from other events are used. Hashtags were chosen manually according to their prevalence in the event's tweets. An overview is given in tables 1 and 2. The practical reasoning for this is that during an ongoing event, a user could quickly search for example tweets by a certain hashtag, then use the found examples to detect more event-related tweets without this hashtag using the models proposed by us. (Of course, a user may just as well use any other method for selecting examples of the class they are interested in).

In the few-shot experiments, *CrisisLexT26* is used to generate the training episodes, and *CrisisNLP* is used for the validation episodes. In this way, we ensure that our results represent the generalization ability of the models rather than their ability to adapt to a set of specific events.

PROPOSED APPROACHES

We propose three approaches for detecting event-related tweets. In the first approach, we train models explicitly on tweets related to one single event, then use these models to determine whether other tweets also belong to this event or a different one. The second and third approach both focus on few-shot models, meaning that we train models to determine whether unseen tweets belong to the same event as a small number of support examples specified at testing time (instead of training time). This means that models are also able to perform this distinction for events not seen in the training data, providing a flexible method for detecting related tweets during a new event. The difference between the second and third approach lies in the concrete employed methods. In the second approach, we train matching networks, one of the first types of few-shot-models proposed. For classification by event-relatedness, such models require both positive support examples (i.e. belonging to the event) and negative ones. In the third approach, we go one step further by training a new type of few-shot model that only requires positive support examples, so-called one-way prototypical networks.

Dedicated event models

As an anchor experiment, we trained event-wise models directly on all tweets containing the event-related hashtag plus random tweets from other events. We then tested them on tweets from the same event without the hashtag, and random tweets from other events.

The architecture used in this experiment is a Convolutional Neural Network (CNN) as proposed by Kim (Kim 2014). A visualization is provided in figure 1. This approach was originally developed for classifying sentences into semantic categories, e.g. question types or sentiments. In a pre-processing step, each tweet is padded with empty units or shortened to contain exactly 25 words. At the input, these words are transformed into word embeddings using pre-trained weights, which we keep static througout training. We use the pre-trained, crisis-specific *word2vec* embeddings described in (D. T. Nguyen et al. 2016). Then, several convolutional layers with different kernel widths are applied in parallel. Global max-pooling is performed for each of these layers, and the results are concatenated. This new embedding is then fed into a 128-dimensional fully connected layer with dropout and a subsequent softmax layer to determine the final class. We set all hyperparameters as suggested by Kim. This type of model has successfully been used for crisis-related data (Burel and Alani 2018; D. T. Nguyen et al. 2016).

We expect these models to perform very well as they are dedicatedly adapted to a certain event. However, this is almost never an option in a real-world situation because it would require the collection of a large amount of related data in advance, which is not possible until social media users have been discussing the event to some extent. Additionally, a new model has to be trained from scratch (or at least finetuned from a generic model), which uses up even more valuable time during an event. The resulting model is also not very flexible; if discussion topics within the event shift, it may not perform well anymore. For these reasons, this experiment serves merely as an upper boundary for the accuracy of a model trained on event-specific hashtags.

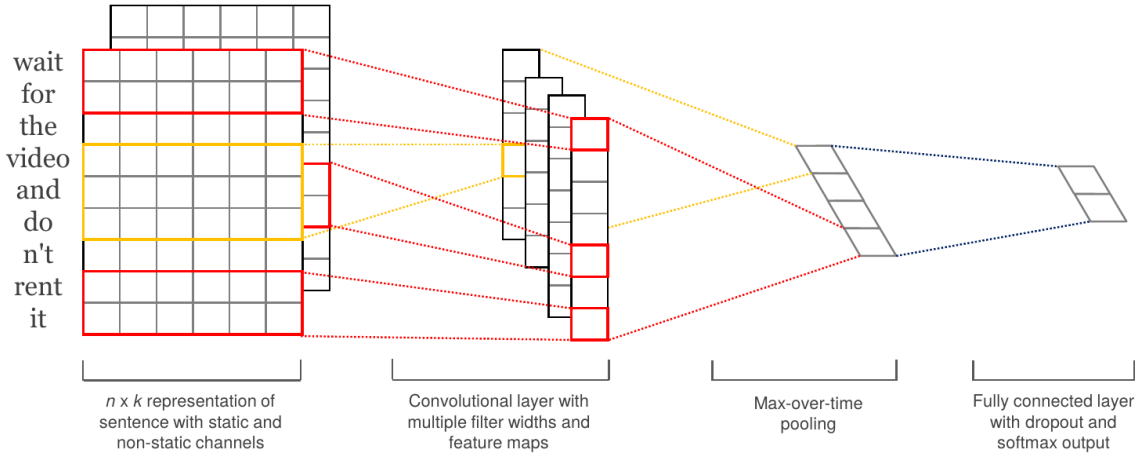

Figure 1. CNN for text classification as proposed by Kim (Kim 2014).

Matching networks for few-shot learning

Matching networks which implement one-shot learning were first introduced by Vinyals et al. in 2016 (Vinyals et al. 2016). The concept of one- or few-shot learning is motivated by human learning: If human subjects are presented with examples of a new class of objects, they usually only require very few to be able to match new instances to this class (e.g. when children are shown an animal not encountered before). This ability is, among other factors, informed by general world experience, which teaches humans to set boundaries between object classes. Matching networks are thus trained on sets of support examples for a subset of possible classes plus a query example belonging to one of the classes in so-called episodes. These episodes are generated for a wide range of class permutations. In the one-shot case, only one support example is given for each class, while there are multiple ones in few-shot models.

An example of the basic structure of one-shot matching networks is shown in figure 2. The network has two input branches: One for the support examples, and one for the query example. In both branches, the inputs are run through a sub-network which performs an embedding (expressed as embedding functions g and f). The embedding networks may or may not share their weights. The query's resulting embedding is then compared against the supports' resulting embeddings using a pre-defined distance metric. This results in likelihood measures for each input class, commonly implemented with a softmax. The over-all comparison metric for the task is learned implicitly as the network learns an appropriate embedding.

In the few-shot case, multiple support examples per class are treated independently of each other throughout the network. Example-related likelihoods are then summed into class likelihoods at the output. In this way, matching networks essentially implement a weighted nearest-neigbor classification. Few-shot learning has been used for short-text classification in (Yan et al. 2018). The architecture is slightly different, employing a CNN-based Siamese network with hinge loss as the distance metric and a subsequent SVM classifier. Support examples for one class are combined into a prototype (also see next section). The approach is tested for sentiment classification of tweets, among other tasks, where it outperforms other deep learning models.

For our experiments, we employ a relatively straightforward matching network architecture, which is illustrated in figure 3. The network has one input branch for a number of support examples for each class, and another for one query example. The subsequent CNN is identical to the one described in the previous section with all hyperparameters set to Kim's suggestions, except that there is only one 512-dimensional fully connected layer

without a softmax function after the max-pooling layers. Its outputs are used as the internal embeddings in the further processing. They are fed into a distance metric layer, where the query embedding is compared to each support embedding. As proposed in (Vinyals et al. 2016), we use the cosine distance as our metric here. The resulting distances are then processed by a softmax layer and summed up for each class, generating the final class scores.

Because we are applying matching networks to a binary problem (a query tweet is either related the considered event or not), we need support examples for two classes: Positive examples of tweets concerning the event, and random other tweets. Semantically, this amounts to a workaround, as there are no two comparable classes. Instead, one of them merely consists of counterexamples (a sort of "garbage" class). Examples in this class will have a much wider feature distribution. This makes selecting random examples difficult, as they should still be representative of this distribution, particularly when only a small number of support examples is used.

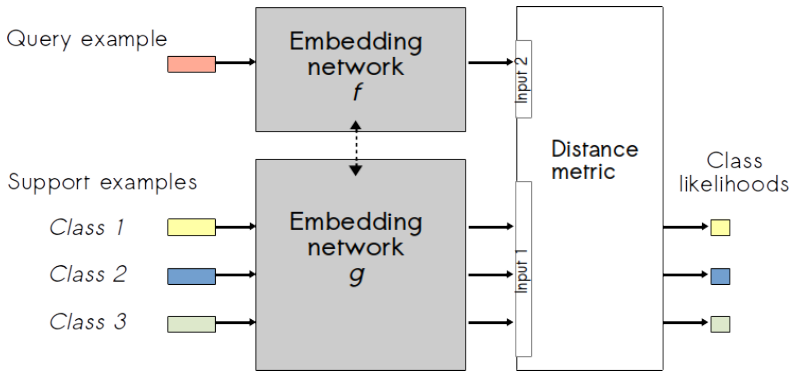

Figure 2. Matching network architecture as proposed by Vinyals et al. (Vinyals et al. 2016).

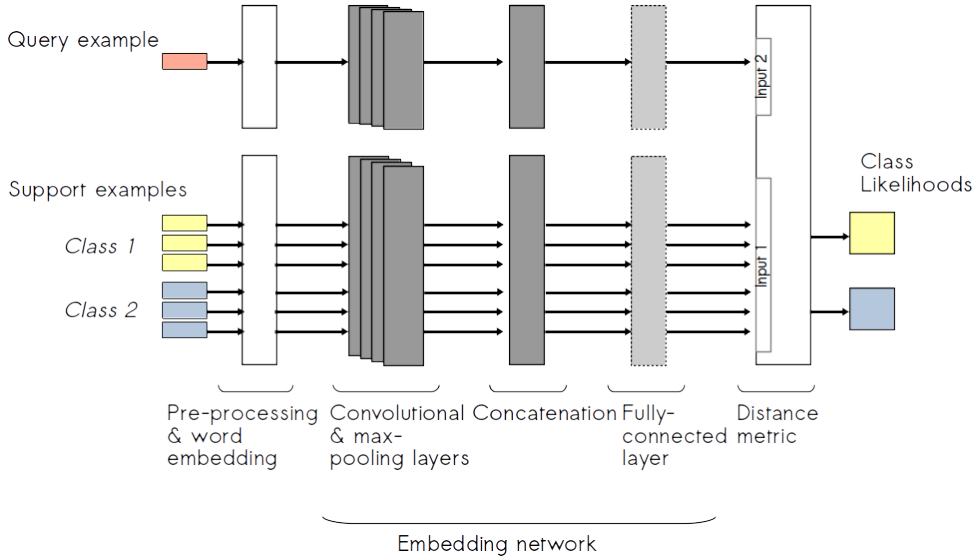

Figure 3. Matching network architecture used in our experiments.

One-way prototypical networks for few-shot learning

Prototypical networks are an extension to matching networks and were proposed by Snell et al. in 2017 (Snell et al. 2017). Instead of treating all of a class' support examples independently in the few-shot case, they compute a so-called "prototype" of the class after the embedding network. This prototype is commonly the mean of the class; a visualization is provided in figure 5. When the squared Euclidean distance is used as the metric, this implements a linear classifier (as opposed to the nearest neighbor classifier produced by matching networks).

We take this approach one step further. As described above, using counterexamples as one class in a binary few-shot problem presents some difficulties. We therefore construct a prototypical network that only requires positive support examples, from which it generates an internal embedding of the whole class. The query embedding is then compared

to this, and judged to belong to the same class or not. We call this type of network a "one-way prototypical network". The sub-network for generating the internal embeddings is the same as before. An illustration is shown in figure 4.

This approach presents a challenge for the distance metric: Because Cosine or Euclidean distances are not bounded, we cannot set a threshold for class belonging. We solve this by substituting a novel Gaussian probability layer. In this layer, Gaussian distributions are fitted over the support embeddings for each embedding dimension. Then, the probability of each of the query embedding's dimensions is calculated and normalized. The average of these probabilities is used as the final result, i.e. the likelihood of the query belonging to the supported class.

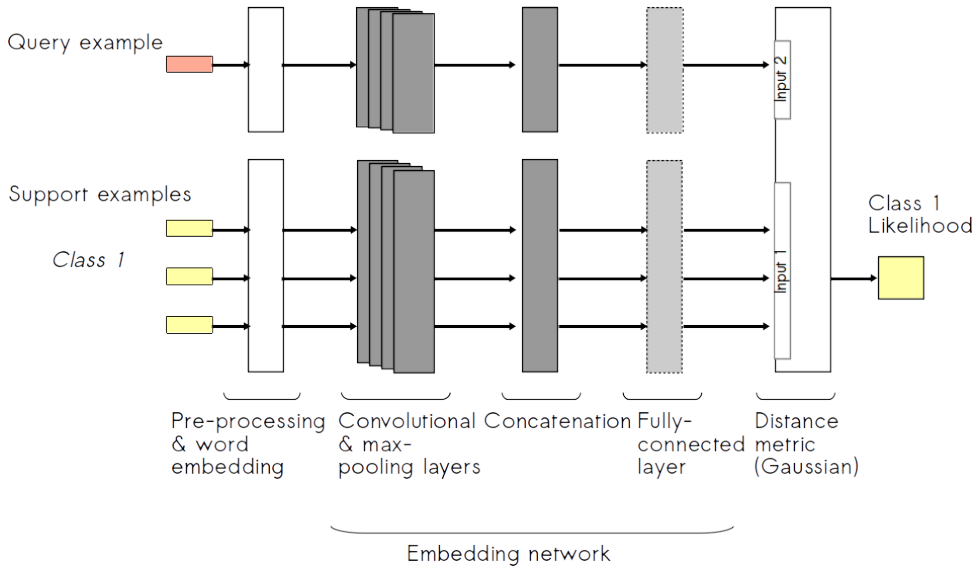

Figure 4. One-way prototypical network architecture used in our experiments.

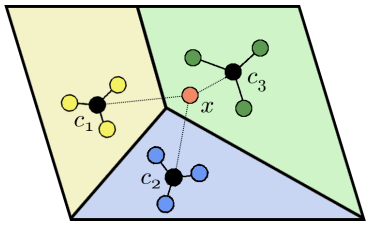

Figure 5. Calculation of class prototypes c_k by averaging support embeddings as proposed by Snell et al. (Snell et al. 2017).

EXPERIMENTAL RESULTS

In this section, we present the experimental set-ups and results for each of the three proposed approaches.

Dedicated event models

As described in the previous section, we start by training dedicated models for each event in the *CrisisLexT26* data set. Training is performed on tweets containing the matching hashtag from table 1 and unrelated examples from other events. The models are then tested on tweets from the considered event without the hasthtag.

The results are shown in figure 6. As expected, training individual models on the data specific to an event works very well due to the focus on a small set of topics or keywords. F_1 measures range between .8 and 1, with an average of .94. Events of types that occur multiple times in the data set produce somewhat lower values (e.g. floods, earthquakes), suggesting at least a partial focus of the model on the event type rather than the specific event. This is to be expected and not necessarily a problem for practical purposes, unless two events of the same type occur at the same time. Other influences may include the use of other languages than English in the event data, and the range of topics of interest during an event, which is also related to the duration of the event.

At first glance, these results appear higher than the state of the art; however, we are aiming for a different goal here. Due to a training strategy that is specific to certain events, models are able to develop a very narrow focus. We also

do not classify tweets with regard to their relevance or general event-relatedness, but rather by their relatedness to a specific event (with negative examples being tweets from other events). As such, the results are not directly comparable to the state of the art. Despite the high F_1 measures achieved with dedicated models, this approach will often be infeasible during an actual event. A significant amount of data for the event needs to be collected first, and then model training has to be performed and optimized. This strategy could be implemented for events that unfold over a longer timespan; however, this introduces the problem of shifting topics during the course of the event, for which the model may not be well-adapted anymore.

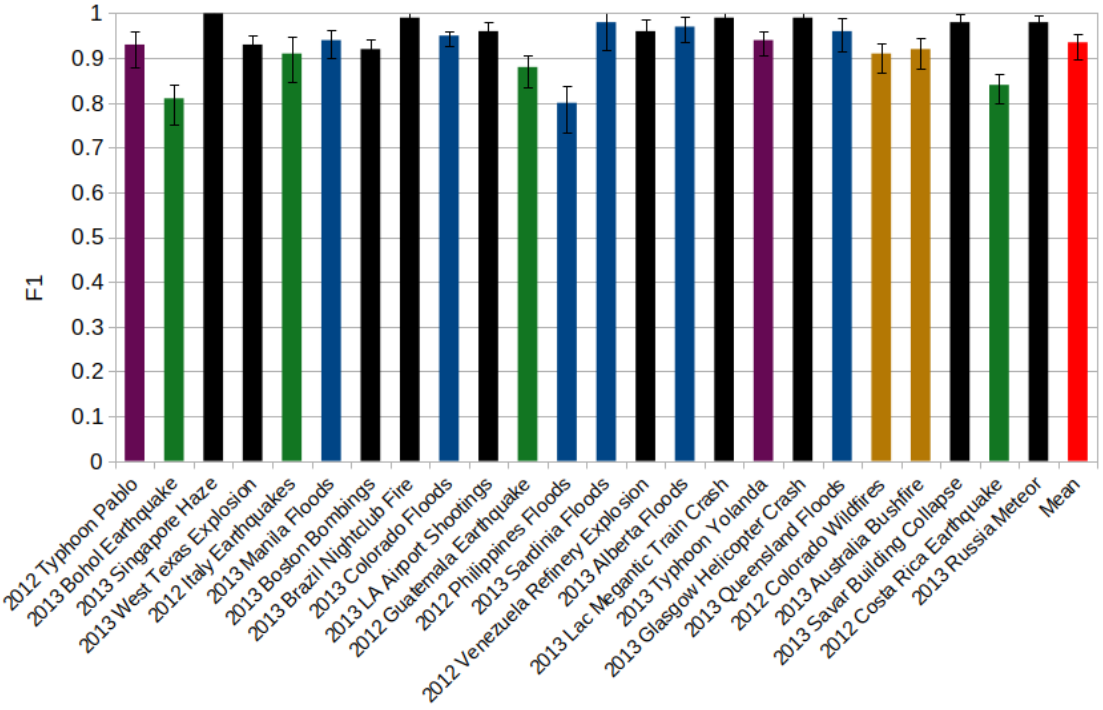

Figure 6. Results of the dedicated event model experiments. F_1 is shown for each individual event; the last bar is the mean. Colors correspond to types of events (black bars do not belong to a repeated type).

Matching networks

In our second set of experiments, we train matching networks. Training episodes are generated from random tweets from *CrisisLexT26* containing the matching hashtag from table 1 as the positive supporting examples, and random tweets from other events as the negative ones; queries are generated from event-related tweets without the hashtag, and once again random tweets from other events. This model is then evaluated on the *CrisisNLP* data set, where test episodes are generated in the same way. Positive and negative queries are selected with the same likelihood, resulting in a 50%/50% distribution for the two classes.

The results are shown in figure 7. In total, 40 configurations are tested: Training is performed with 1,280 to 12,800 episodes (colored bars), and the number of support examples per class is varied between 10 and 100. Testing is performed on 12,800 episodes in each configuration. As a general tendency, F_1 improves with more support examples and with more training episodes. However, as few as 20 support examples already produce an F_1 of .74 when trained on a sufficient number of episodes. The results become slightly higher up to 80 or 90 support examples. Providing more support examples improves the likelihood that a query tweet will be similar to one of the support examples. In our use case, the main difficulty for this lies in the negative queries, as those will be very diverse, just as the negative support examples. Considering the amount of training episodes, F_1 does not improve much beyond 6400. At this point, many of the possible permutations may already be covered in the randomly generated episodes. Further episodes then do not provide more information and just serve to effectively increase the number of training epochs. Of course, this is dependent on the size of the data set.

Over-all, the results do not vary highly across parameter configurations, and their tendencies are somewhat noisy. We believe that this has to do with the random creation of the episodes, especially with regards to negative examples. However, at a top F_1 of .76 on completely unseen events, this approach is feasible for use in a real-world system for

the detection of event-related tweets. With no necessary re-training, the model can be used out-of-the-box for new events. The result is somewhat lower than that of the state of the art for detecting related tweets (F_1 of .86 with the model from (Burel and Alani 2018)); however, our approach is specific to a certain event versus other events instead of a classification of general event-relatedness.

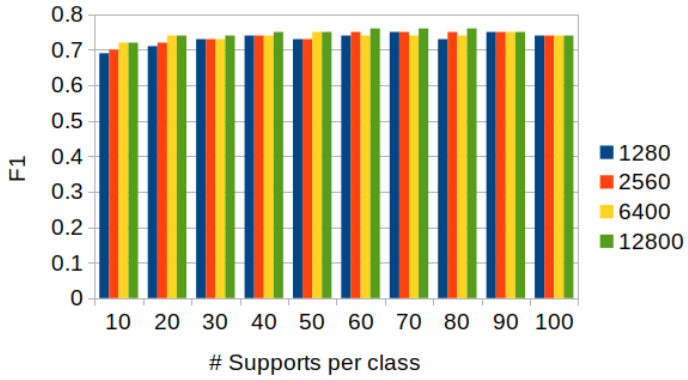

Figure 7. Results of the matching network experiments in terms of F_1 vs. number of support examples per class; colored bars represent the number of training episodes.

One-way prototypical networks

Finally, we perform experiments with one-way prototypical networks on the same data. As described above, these networks only require positive examples for the considered event, removing the issue of choosing a representative set of counterexamples. Once again, models are trained on 1,280 to 12,800 automatically generated episodes with 10 to 100 support examples for the one class, and tested on 12,800 episodes. Figure 8 shows the results.

The best achieved F_1 is 75%, demonstrating that this new type of network works just as well for our purposes as the previously existing matching networks. The trends are the same as in the previous experiment: More training episodes generally improve F_1, although further experiments show that this effect diminishes beyond 12,800. More support examples also help, but this does not change much between 40 and 100. Since this type of model calculates a Gaussian distribution on the support examples' internal embeddings, we assume that these distributions can be estimated well enough from 40 examples or even fewer. One effect that stands out is that these trends are much clearer here. This is probably the case because of the non-reliance on counterexamples. These introduce noise to the process, which might make the model work better or worse in some cases because of the selection of these examples and their distribution and relation to the positive examples.

Just like the previously analyzed matching network models, this method is well-suited for practical operation as no re-training is necessary for a new event. In contrast to the previous approach, only half as many support examples need to be collected, and no attention has to be paid to finding widely distributed counterexamples. In an additional experiment (not shown here), we also tried using tweets not related to any disaster as the negative queries, as opposed to training against negative queries from other disasters. This approach achieves an accuracy of around .8, which is around the state of the art for the relatedness task (Burel and Alani 2018). In many practical cases, this model will be sufficient, as users will often not need to distinguish events from each other if there is only one happening at that time. Despite some thematic overlap, this model will still be more focused on the event for which support examples are given rather than all events.

CONCLUSION & FUTURE WORK

In this paper, we demonstrate three approaches for detecting tweets related to a specific crisis. In the first one, we train dedicated models for this crisis. This results in a mean F_1 of .94. For the second experiment, we train matching networks for sets of 10 to 100 support examples and counterexamples for the considered event. We then develop this approach further by training one-way prototypical networks, which do not require counterexamples anymore. The second and third method produce F_1 measures of .76 and .75 respectively.

All three approaches are good enough to potentially be used as a filtering mechanism in crisis situations. However, training dedicated crisis models will often be infeasible as this takes up too much time and effort for a quick response. Both of the other approaches can be used out-of-the-box in a new scenario, only requiring some example tweets. As

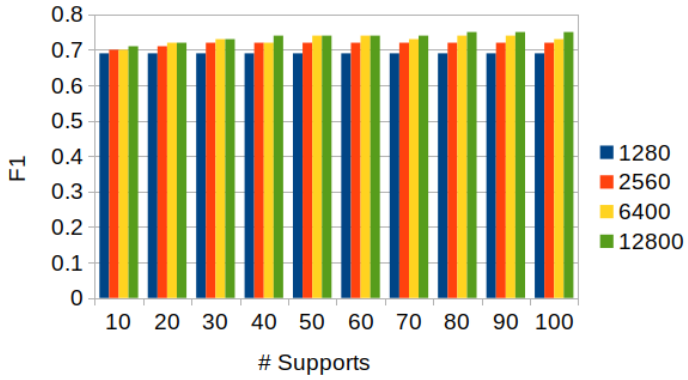

Figure 8. Results of the one-way prototypical network experiments in terms of F_1 vs. number of support examples per class; colored bars represent the number of training episodes.

the results produced by the matching network show, the selection of the counterexamples can have an effect on the over-all effectiveness of the model, depending on their variation and relatedness to the positive examples. The one-way prototypical network removes this issue and is therefore even easier to integrate into a live system.

Our experiments on the matching networks and one-way prototypical networks show that the number of support examples and the number of training episodes have a small effect on the test accuracy. In the case of the support examples, this effect disappears beyond 40, probably because this amount of support examples already covers the semantic space well in many cases. For the number of training episodes, we also observed diminishing returns after a certain number because many permutations will already have occurred at that point.

Some easy adaptations could be made to the processing stages of these models for a real-world system. Depending on whether better precision or better recall is required, the decision boundary can be adjusted accordingly. When topics during the event shift, new support examples can be picked on-the-fly. This is particularly interesting for live streaming operation. We also performed additional experiments (not shown here) on the same systems trained on support data for various event versus non-event data. This improved the accuracy to around .80, and may often be more suitable for a practical system.

In the future, these methods could be improved in a number of ways. Ideally, they could be trained on a much wider range of (disaster) events as this would help their generalization abilities towards unseen events. When possible, the counterexamples could be picked in a more directed fashion to stabilize the networks' decision boundaries, or the network could simply be enabled to process a much larger amount of counterexamples than positive examples without changing the class priors. Finally, the one-way prototypical network method itself could be expanded in multiple ways, e.g. by replacing the Gaussian probability layer with a Gaussian Mixture Model (Kersten 2014).

ABSTRACT

After a natural disaster or other crisis, humanitarian organizations need to know where affected people are located and what resources they need. While this information is difficult to capture quickly through conventional methods, aggregate usage patterns of social media apps like Facebook can help fill these information gaps.

In this paper, we describe the data and methodology that power Facebook Disaster Maps. These maps utilize information about Facebook usage in areas impacted by natural hazards, producing aggregate pictures of how the population is affected by and responding to the hazard. The maps include insights into evacuations, cell network connectivity, access to electricity, and long-term displacement.

In addition to descriptions and examples of each map type, we describe the source data used to generate the maps, and efforts taken to ensure the security and privacy of Facebook users. We also describe limitations of the current methodologies and opportunities for improvement.

Keywords

crisis mapping, crisis informatics, GIS, social media

INTRODUCTION

As social media and messaging apps continue to be important communication tools in people's everyday lives, they have also come to play an important role in how people prepare for, respond to, and recover from disasters (Palen and Anderson 2016; Castillo 2016). They are used by people affected by a crisis event, people responding to it, and people following and observing the event from afar (Olteanu et al. 2015). They can be used for individual and mass communication, information seeking, and gaining situational awareness. A significant body of research in crisis informatics has focused on studying these behaviors, and on developing techniques and tools for harnessing social media and other data sources for improved crisis response.

Many of these tools seek to extract information about what is happening in a crisis from the text of Twitter posts (Reuter et al. 2018), but a sparsity of location metadata can make it difficult to associate the extracted information with explicit locations. Alternatively, crisis maps collect relevant data on a map, frequently through the work of digital volunteers sifting through posts to both social and traditional media (Okolloh 2009), or by accessing geospatial data from official sources. The scale of social media suggests a potential for extracting unprecedented insights into how populations prepare for and react to hazard events, the impact those events have on these populations, and what needs these populations have that are not being met. Unfortunately, a dearth of precise location data can make much of this potential difficult or impossible to realize.

In the course of providing services to their users, many smartphones and smartphone apps regularly collect precise location information. In the case of Facebook, people have an option of whether or not to provide this information to Facebook (Facebook 2019). Location data is used to provide a myriad of services, including helping people find nearby friends, information about nearby Wi-Fi hotspots, and location-relevant ads. This data also enables targeting of AMBER alerts and prompts to check-in as "safe" after a hazard event. In addition to powering Facebook product features, this location data, when aggregated and anonymized, can provide insights about how populations are affected by hazard events as they happen.

While data from phones and apps has enormous potential, it also comes with notable risks for individuals. Location data is sensitive, and misuse could compromise the privacy and safety of individuals and communities. Any attempt to generate insights and share them with humanitarian responders must first address privacy and security to ensure that people are protected.

This paper presents Facebook Disaster Maps, a collection of methods for processing Facebook data into dynamic maps that highlight several key factors of how populations are preparing for, impacted by, and coping with natural hazards. The maps make use of anonymized and aggregated data, including current and historical location data, information about cell site connectivity, and data on phone battery charging. While the raw data for the maps remains available only to Facebook, the aggregated maps, with privacy and security protections like adding random noise and dropping small counts, are shared with humanitarian organizations on an ongoing basis in the days and weeks following a hazard event. The maps are meant to address specific needs that these organizations face in formulating and executing a response, therefore the research and development that goes into the maps has been (and continues to be) informed by discussions between Facebook researchers and individuals at the humanitarian organizations.

We first discuss existing research in the field of crisis informatics that has informed this work. Next, we survey five distinct categories of Facebook Disaster Maps, each of which aims to answer different questions that arise in formulating humanitarian response to hazard events. We discuss the methodology used in building each map and how privacy and security issues are addressed within that methodology. Next, we discuss current limitations on the utility of the maps and ongoing research that aims to overcome some of these limitations. Finally, we give examples of how each of these maps has been utilized by humanitarian organizations in the field.

RELATED WORK

In order to formulate an effective response to a crisis situation, first responders and relief organizations must combine many, diverse sources of information into "situational awareness," or a coherent, big-picture understanding of the situation. In a crisis, this situational awareness includes information about "the status of the hazard agent, damage done to buildings and infrastructure, the location of evacuation centers, and the number and location of injured people and/or animals" (Vieweg 2012), among other things. More generally, Sarter and Woods (1991) describe situational awareness as "all knowledge that is accessible and can be integrated into a coherent picture, when required, to assess and cope with a situation." While situational awareness is essential for some crisis response roles, the focus on a single "big picture" can be insufficient in some cases. It misses the fact that different crisis response roles (from a first responder to a digital volunteer to a humanitarian worker) have different information needs. Zade et al. (2018) argue for a focus on "actionability," which means understanding the different needs of people in different roles and focusing on getting them the information that they can act on.

Much existing crisis informatics research deals with enhancing situational awareness by identifying, extracting insights from, and generating predictions based on social media posts, mostly on Twitter (Vieweg et al. 2010; Cameron et al. 2012; Vieweg 2012; Imran et al. 2013). This is based on the idea of social media users acting as "citizen sensors" (Sheth 2009) who report on conditions as they experience them through their social media posts. Due to the high volume of social media posts during crisis situations, researchers have deployed myriad algorithmic and statistical methods for processing the streams, including natural language processing (NLP), semantic analysis, supervised machine-learned modeling, unsupervised clustering, and others (Castillo 2016).

A prominent approach to organizing and displaying crisis data for increased situational awareness is in the form of a crisis map. Crisis mapping involves the collection, analysis, and geospatial visualization of data. The data involved may come from a variety of sources, including social media and other citizen reports, traditional news reports, and official sources. For example, Google Crisis Maps[1] pulls together and displays public information, including storm paths, flood zones, evacuation routes, and more on top of Google Maps. Crowdsourcing and digital volunteers are used to collaboratively construct crisis maps and other datasets for improved situational awareness. Ushahidi (Okolloh 2009) is a popular and flexible crowd-sourced crisis mapping platform, which allows volunteers to, among other things, pin reports relevant to a crisis onto a shared map. In the immediate aftermath of the January 2010 earthquake in Haiti, volunteers used Ushahidi to collect reports about conditions on the ground from Twitter and other sources on a map (Starbird and Palen 2011; Meier 2012). Another notable achievement was volunteers using satellite photos to improve OpenStreetMap in the affected areas (Soden and Palen 2014). This later gave rise to the Humanitarian OpenStreetMap Team[2], which uses open mapping to support humanitarian action and community development more broadly. Castillo (2016) includes a detailed list of crisis mapping platforms and other tools for analyzing and visualizing insights from social media crisis data.

In their survey of research on social media in crisis management, Reuter et al. (2018) describe several types and aims of existing work related to the work described in this paper. In particular, they discuss the processing of social media data for monitoring ongoing events, and visualizing the results of analysis in order to make these results more salient and useful. These methods and insights frequently culminate in the design and building of tools and systems that address problems that arise in the course of crisis response. Some researchers employ participatory design, where professional crisis responders are involved in the design process of these systems (Hughes 2014; Hughes and Shah 2016). As Reuter et al. (2018) discuss, evaluation procedures for these systems vary widely and are often limited. Hughes and Shah (2016) evaluated the effectiveness of their Twitter-based crisis monitoring application by sitting with and observing public information officers using their tool while responding to wildfires. This allowed them to identify concrete contributions their tool made to the analysis, documentation, and reporting on social media produced by the participants.

Several of the data processing and mapping methods described in this paper highlight how population densities and movement patterns in crisis situations differ from pre-crisis situations. Human mobility has been shown to be highly predictable at city (Yan et al. 2014) and regional/national scale (Simini et al. 2012) in non-crisis times. Some research has found that even though mobility (e.g., travel distances and destinations) does change during crises, it can remain highly predictable (Lu et al. 2012). Wang and Taylor (2016) affirm this over a wide variety of hazard types and impacted regions, though they also found that some of the most severe crises can impact mobility patterns such that they are no longer predictable using pre-crisis states. This suggests that near-real-time insights into human mobility can be useful for gaining situational awareness and administering humanitarian assistance. To that end, Ciravegna et al. (2018), built a system for incorporating location tracking into mobile phone apps, processing the collected location data, and generating near-real-time insights into human movement patterns that may be useful for crisis response and recovery. For example, their visual analytics interface displays the frequency that different routes are taken, which, when compared across crisis and pre-crisis time periods, may highlight dynamic road access constraints. This paper, while using different data sources, builds on this line of work.

DISASTER MAPS DATASETS AND METHODOLOGY

In this section, we describe how each of the five Facebook Disaster Maps are produced. While we start with a brief overview of each type of map, we then describe concepts, privacy protection mechanisms, and computations that are shared by some or all of the map types. Once we have explained each of these, we discuss each type of map individually, including walking through examples based on real events.

Overview of the maps

As mentioned above, there are five distinct map types that make up Facebook Disaster Maps. Here we list each of them and state a fundamental question that each map type is intended to help answer. The first four listed maps rely on a shared calculation procedure where we compare counts of certain events during a crisis to baseline expectations from a pre-crisis period. In most cases, we produce these maps at regular intervals for two weeks after a crisis begins. Over these relatively short time scales, it is plausible that the main causal driver of population-level changes is the crisis event itself. The fifth map type, Displacement maps, relies on a different methodology.

[1] https://support.google.com/crisismaps/
[2] https://www.hotosm.org/

- **Facebook Population:** Where are there more or fewer Facebook users than we would expect based on pre-crisis levels? This can indicate areas that are affected by the crisis, or where evacuations are occurring.
- **Movement:** Which pairs of places are Facebook users moving between more or less often than we would expect based on pre-crisis levels? This can provide signal on large-scale population movements.
- **Power Availability:** Where are Facebook users charging their mobile phones more or less often than we would expect based on pre-crisis levels? In aggregate, this charging behavior can serve as a proxy for the state of the power grid.
- **Network Coverage:** Where does the usage of mobile phones indicate that there are more or fewer cell sites actively serving a location than we would expect based on pre-crisis levels?
- **Displacement:** In the weeks and months following a crisis event, where has the affected population resettled? Unlike the other map types, Displacement maps do not rely on a pre-crisis baseline computation, which can introduce additional complexities and caveats when interpreting the data. This will be discussed in detail in a later section.

Common concepts

There are several concepts relevant to understanding the maps. First of all, we construct maps using two different methods of identifying locations: tiles and administrative polygons. The **Bing Maps Tile System** defines a series of grids at different resolution levels over a rectangular projection of the world (Schwartz 2018). Each level is constructed by dividing the previous level into fourths. We typically use Bing tile levels 13 through 16, where level 13 results in tiles that are about 4.9 x 4.9 km at the Equator. The other method we use for identifying a location is **administrative polygons**, which define the political and geographic boundaries of countries, states, provinces, counties, cities, and more.

When generating a map for a crisis event, we specify a rectangular **bounding box** around the most directly affected area. The different map calculations, described in the following sections, are done relative to this region, and, for most of the maps, only data within this region is included.

Most of the map types are based on counting events that occur within a **time interval**, which is frequently 8 or 24 hours. The time interval determines what data is included in a calculation as well as the minimum frequency with which new maps are generated.

Privacy protection mechanisms

We employ a suite of privacy protection mechanisms in order to obscure the identity and actions of individuals and small groups while preserving the population-level insights that are useful for humanitarian response. Some of these are only applicable to a subset of the map types, which we will indicate in the sections below.

- **Random noise:** A small amount of random noise is added to count data to ensure that it is not possible to ascertain precise, true counts for sparsely populated locations.
- **Spatial smoothing:** We average counts for a location with those of surrounding locations using inverse-distance-weighted averaging. This gives more weight to closer locations and less weight to further locations.
- **Dropping small counts:** Locations with small counts are dropped from the final datasets. In cases where there are both baseline and crisis-time counts (as described in the next section), if either is less than a threshold value then both are dropped.

Common computations for maps with baselines

As mentioned above, four of the map types (Facebook Population, Movement, Power Availability, and Network Coverage) use a shared procedure for computing a pre-crisis baseline that can be compared to observations during and after a crisis. A baseline is computed for each location in a map (which can be a tile, an administrative polygon, or, as we will see for Movement maps, pairs of tiles or polygons). The duration of pre-crisis data available for computing a baseline differs for different source datasets, and is dependent on technical capacity and data retention policies. While these can change over time, all the map types described here use baselines derived from 5-to-13 weeks of pre-crisis data.

When computing a map for a given time interval after a crisis, we account for normally occurring daily and weekly patterns by computing a baseline using only data from the same time-of-day and day-of-the-week in the period preceding the crisis. Therefore, for a given location and time interval, the baseline dataset is composed of a set of counts from the same location over the same time interval on the same day-of-the-week for multiple weeks preceding the crisis.

Once we have collected the baseline dataset, we eliminate extreme values using winsorization. We do this by computing the mean and standard deviation of the pre-winsorization distribution, identifying the 2.5th and 97.5th percentiles of a Gaussian with that mean and standard deviation, and setting values outside those bounds to the lower and upper bound values if they are anomalously low or high, respectively.

With extreme values eliminated from the baseline dataset, we next compute the baseline mean (μ_{baseline}) and standard deviation (σ_{baseline}) from the remaining data. Finally, we compare what is observed in the current crisis time interval (c) to these baseline statistics. The first comparison is the percent difference between crisis and baseline:

$$\frac{c - \mu_{\text{baseline}}}{\mu_{\text{baseline}} + \epsilon} \tag{1}$$

where ϵ is a small value, usually 1. The second comparison is the z-score:

$$\frac{c - \mu_{\text{baseline}}}{\max\left[\sigma_{\text{baseline}}, \sigma_{\text{min}}\right]} \tag{2}$$

were $\sigma_{\text{min}} \approx 0.1$ is introduced to handle the case where there is no variance in the baseline distribution. The z-score highlights the areas on the map with the most significant differences between what is being observed during the crisis and what is typically seen during the baseline, so unless we note otherwise, this is the value presented in the example maps used in this paper. When sharing data with humanitarian organizations, we also include the percent difference, the baseline means, and the crisis counts. All of this data is modified for purposes of privacy preservation using the methods described in the section above, including dropping counts from locations where either the crisis or baseline value is less than a threshold.

Facebook Population maps

These maps show statistics about the aggregate number of people observed in a location (tiles or administrative polygons) in 8-hour intervals following a crisis compared to a pre-crisis baseline period. The counts include people with location services enabled on their mobile device. If the same person appeared at multiple locations in a time interval we only count their most frequent location, choosing the latest of their most frequent locations in the event of a tie. All of the described privacy protection methods are used on these maps to ensure that the locations of individuals or small groups cannot be identified.

Figure 1 shows an example of the Facebook Population maps[3] in the aftermath of Cyclone Gaja, which affected part of South India in November of 2018. The time interval is the 8 hours ending at 13:30 IST on November 17. The red and blue portions of the map show tile-level Facebook Population z-scores, which have been clipped to a range of -3 (dark red) to 3 (dark blue) for clearer interpretability. The eastern coastal region of the map, around the city of Nagapattinam, is where the cyclone made landfall and shows significant drops in the number of observed people compared to the baseline. These drops could be attributed to evacuations, loss of power, loss of network connectivity, or some combination of all three. Many parts of the west coast, on the other hand, demonstrate increases in the population when compared to the baseline.

Movement maps

These maps present statistics about aggregate movement between pairs of locations in subsequent time intervals. As with the Facebook Population maps, we use the baseline computation procedure to measure pre-crisis movement patterns, and compute statistics for comparing this with what is being observed in the post-crisis period.

Figure 2 shows selected movement vectors between administrative regions in the area impacted by Cyclone Gaja. Each line on the map represents a pair of locations for which there has been an observed change in the number of people moving during the baseline and the crisis time intervals. This map displays only the locations of movement

[3]Note that the methods described in this paper are under active development and considered a work in progress. Therefore, the figures reflect the state of our mapping algorithms at the time that they were generated, namely during the two weeks after the crisis event. As such, they do not always reflect the latest state of our algorithms at the time of publication.

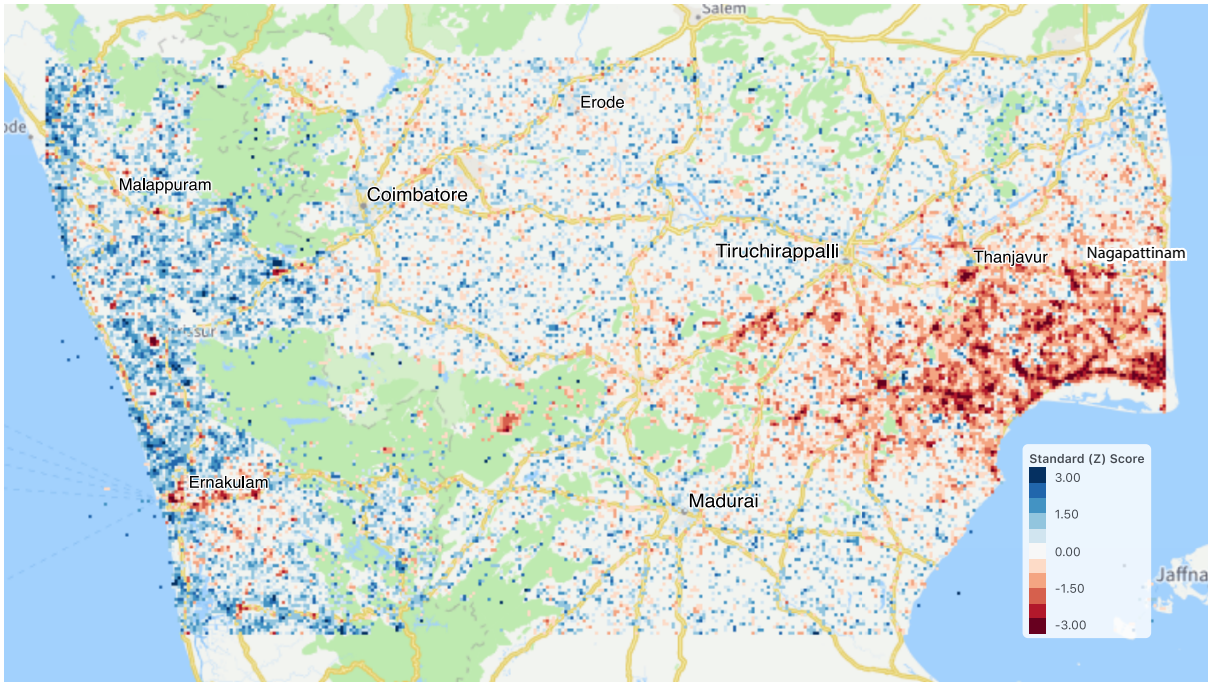

Figure 1. Tile-level Facebook Population map for part of South India on November 17, 2018, in the aftermath of Cyclone Gaja.

vectors. In an interactive visualization, a user of the maps could click on a vector or access the data in tabular form in order to see the actual values. Table 1 shows the percent differences from baseline to crisis for some of the major cities in the map. These differences are based on movement that occurred between eight-hour time intervals ending and beginning at 5:30 IST on November 19, 2018. Because of data sparsity, we only show vectors between larger population centers. While the data in this map does not show a complete picture of what is happening on the ground, it can be useful when combined with other data sources. For example, this map shows a potential increase in travel from Pattukkottai to Thanjavur, and, likewise, from Thanjavur to Tiruchirappalli.

Power Availability maps

For some people with Android devices, it is possible to observe when they connect to a power source. While that power could come from places like cars, generators, or external batteries, when taken in aggregate, it can provide a proxy for the state of the power grid in an area. For each location, these maps count power connection events for devices with location services enabled. We use the baseline computation procedure outlined above to process these counts and produce statistics that highlight where there appear to be significant changes after a crisis when compared to the baseline period. We also use all the privacy protection mechanisms described above in these maps.

Figure 3 shows two more maps related to Cyclone Gaja. The left side of the figure shows the baseline means for connections to power from the 5 weeks preceding the crisis (darker blue indicates more connections), while the right side shows the post-crisis z-scores for the 24-hour period ending November 18, 2018 at 5:30 IST (red indicates negative z-scores). By examining these maps side-by-side, we can see which regions typically show power connections and which of those seem to be experiencing significant drops during the crisis period. These include some of the larger, heavily-impacted cities, such as Nagapattinam, Thanjavur, and Pudukkottai. On the other hand, Tiruchirappalli and Kumbakonam do not appear to have experienced large-scale decreases in connections over this time period.

Network Coverage maps

Cell sites are points of connection in a cellular network made up of antennas with their basestations. A cell tower usually holds multiple such antennas, each of which has a unique identifier. For Android devices with location services enabled, we can use these cell site identifiers to infer network coverage. For each cell site, we draw an estimated coverage area describing the locations of the devices that are accessing that site to obtain cellular connectivity. These inferred coverage areas may overlap, and we count the number that overlap with any tile at any given point in time. These maps are only created for Bing tile locations, not administrative polygons. This

Figure 2. Movement map for Cyclone Gaja on November 19, 2018, highlighting where there were notable differences in movement between pairs of locations when compared to the baseline period.

Starting Location	*Ending Location*	*Percent Difference*
Kumbakonam	Thanjavur	19%
Pattukkottai	Thanjavur	69%
Pudukkottai	Tiruchirappalli	-19%
Thanjavur	Tiruchirappalli	21%
Thanjavur	Kumbakonam	-20%
Tiruchirappalli	Thanjavur	-4%
Tiruchirappalli	Pudukkottai	56%

Table 1. Selected movement data from Cyclone Gaja on November 19, 2018

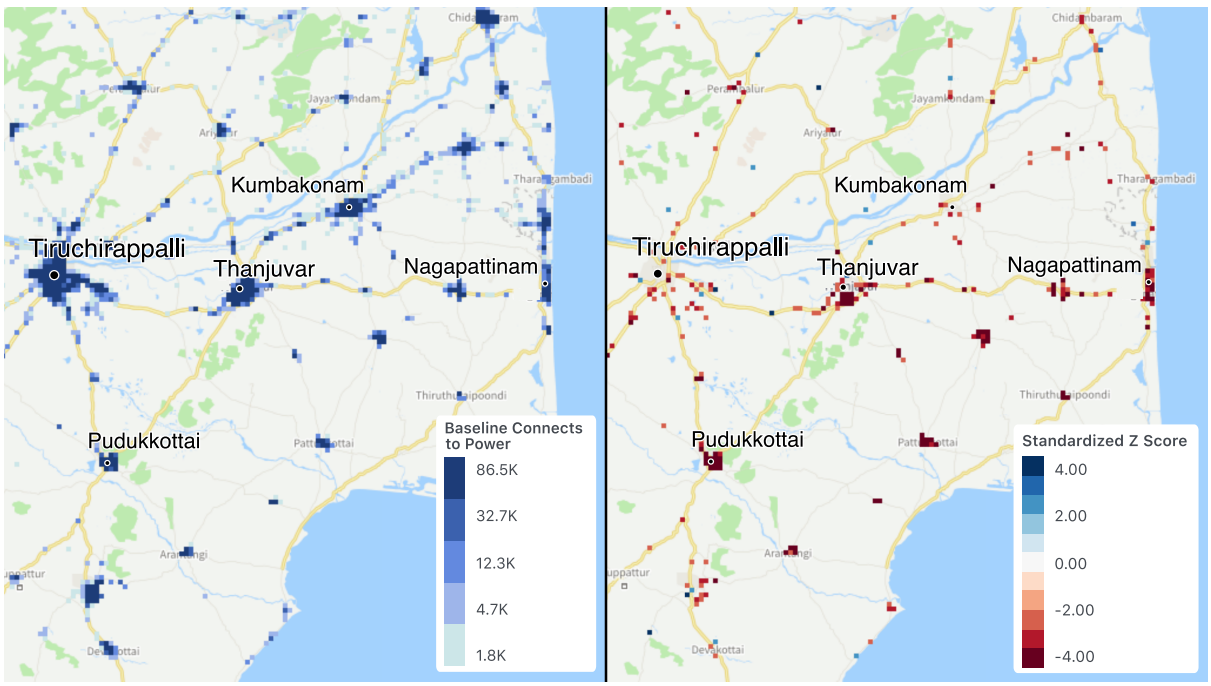

Figure 3. Tile-level Power Availability maps for Cyclone Gaja on November 17, 2018. The map on the left shows the mean power connections from the baseline time period, while the map on the right shows the crisis-time z-scores.

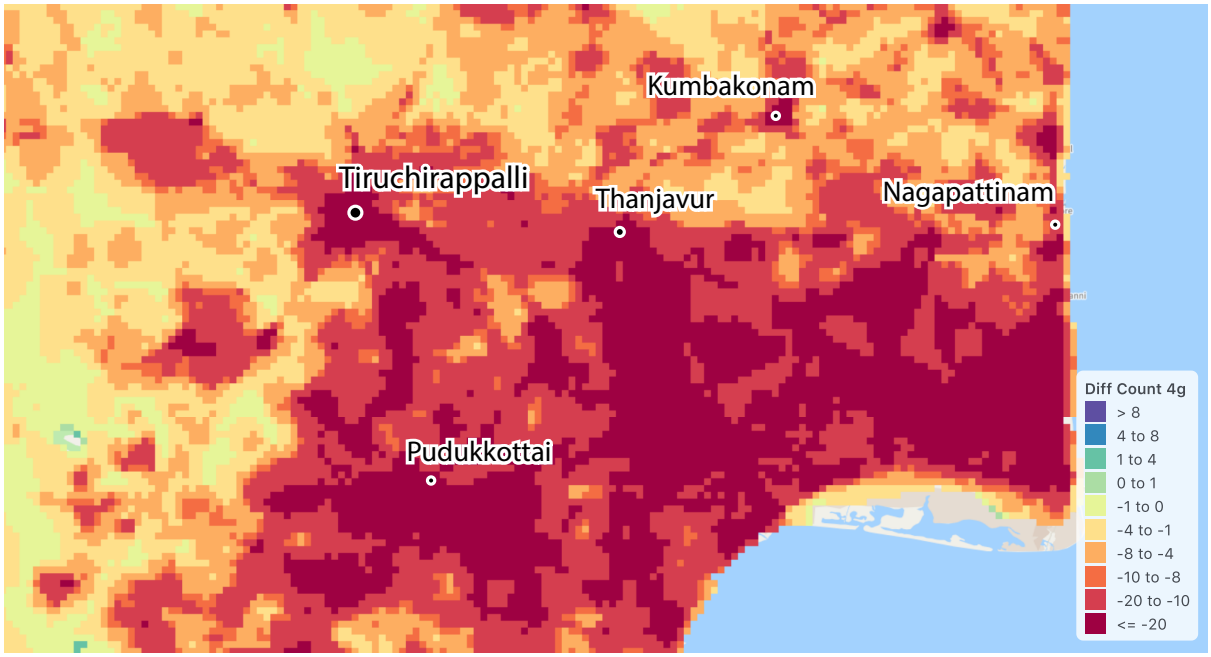

Figure 4. Tile-level Network Coverage map for Cyclone Gaja on November 17, 2018.

count is then compared before and during the crisis using the baseline computation procedure outlined above. We safeguard user privacy by aggregating this data across users and cell sites for each location. Additionally, we drop small counts in the same manner as for the other map types.

Figure 4 shows the a Network Coverage map for a detailed region impacted by Cyclone Gaja based on the 24 hour period ending November 18, 2018 at 5:30 IST. The colors on the map indicate decreases in the number of 4G network connections from a given tile in that time period, compared to the mean connections observed in a three-month baseline period. The patterns observed here echo those in Figure 1, where we saw many fewer people located in the coastal region around the city of Nagapattinam. This highlights an issue where these maps are unable to clearly differentiate between evacuations, loss of power, and loss of connectivity. When considered together, and in combination with other data sources, these maps will provide better, but not complete, clarity about the state of cellular network coverage during a crisis.

Displacement Maps

The final class of Facebook Disaster Maps are long-term displacement maps. The fundamental question that these maps address is the following: in the weeks and months following a hazard event, where has the affected population gone? These maps are based on locations, typically at the city-level, inferred from a person's internet connection.

The calculation procedure for the Displacement maps is as follows:

1. **Home city estimation**

   (a) For everyone who used Facebook from within the bounding box 1-to-5 weeks before the crisis, we identify the most common city from which they accessed Facebook. This city is treated as the person's "provisional" home city.

   (b) For each person identified in step a, we confirm that their most common city in the week immediately preceding the crisis was the same city as in step a. This is meant to filter out people that live in a city but were not present when the crises event occurred. The people that remain make up the effective population for a given home city H.

   (c) We filter to only include the population whose home city, H, is in the bounding box.

2. **Destination city estimation**: For each week following the crisis, calculate the most common city for the population identified in step 1. This destination city, D, does not need to be within the bounding box that defines the affected region.

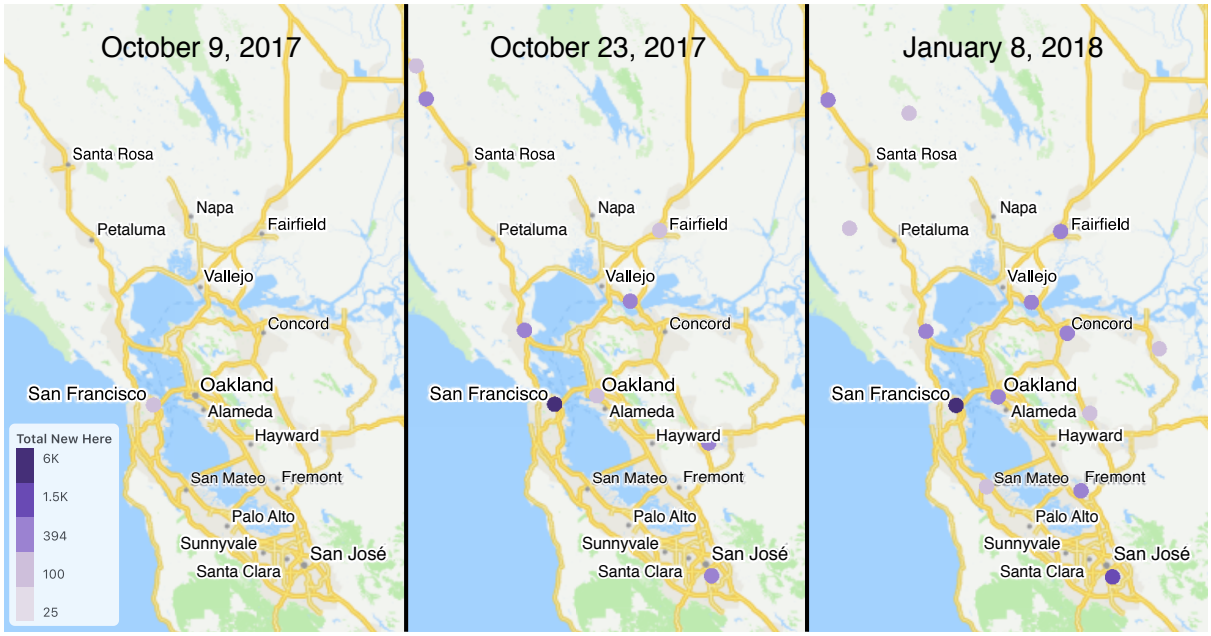

Figure 5. Displacement maps for the Tubbs Fire in the vicinity of Santa Rosa, California at three different points in time. The fire started on October 8, 2017. The maps place purple dots on cities outside of the immediately affected region that have been the destination for at least 100 people who lived within that region.

3. **Home-city-to-destination-city transition estimation**: Aggregate home city-destination city pairs and measure transition counts: of those people from home city H, how many are now in destination city D?

Figure 5 shows examples of the output of these calculations for the Tubbs Fire, which affected Sonoma County, California, in the vicinity of Santa Rosa, in October 2017. The maps place dots on cities outside of the immediately affected region where at least 100 people from the affected region migrated. Darker purple dots indicate the presence of more possibly-displaced people. The fire started on the evening of Sunday, October 8, and we see that on the following day, San Francisco is the only city with a dot. Two weeks later, we see that sufficiently large populations have moved to several cities around the Bay Area. The figure shows only Northern California, but by October 23, more than 100 people had gone to Los Angeles as well. By January 2018, additional Northern California cities appear on the map, and Los Angeles and San Diego would also appear if we zoomed out to include Southern California.

It is not surprising that some people who were in Sonoma County in September 2017 (the time period used to establish the home city estimates) would be in California's major cities by the end of the year. This points to a current limitation of this methodology: Although these maps would ideally measure the population that was forced to migrate because of the crisis, their current state is largely descriptive and does not address that causal question. This may not be a problem in the immediate aftermath of a crisis if we assume that the hazard event is the main driver of mobility in that period. However, as time progresses, the counts of transitions between cities become confounded by several other factors, such as seasonal effects, normal population flows, and fluctuations in rates of Facebook usage by the fixed population under consideration. Unlike our other maps, the displacement maps do not currently include any comparison of the observed counts to "baseline" values that encapsulate what we ought to have expected in the absence of a crisis event. Performing such a comparison could help isolate the causal effect of the crisis itself, and we describe ongoing work in this direction in the next section.

LIMITATIONS AND FUTURE WORK

The maps described above have the potential to provide a picture of crisis situations with a novel level of detail, timeliness, and global coverage. That being said, this picture is imperfect and has a number of notable limitations. In this section we discuss these limitations and directions for future research to address them.

First, our data sources are not representative of the population affected by crises, especially in regions where Facebook penetration is low. Moreover, for most of our maps, there is the additional restriction that we rely on Facebook users who have location services enabled. Drawing inferences based on their behavior may lead to a skewed picture of what is happening on the ground. We attempt to mitigate the risk this poses by ensuring that

partner organizations that utilize the maps understand these limitations and use them in combination with other sources of data in a process of triangulation.

In a similar vein, because our data sources depend on signals received by Facebook, different maps may conflate trends in people's movement, connectivity, and power availability. To give a concrete example, if the Facebook Population map shows a decrease in the number of people in a crisis region and the Network Coverage map shows a reduced number of active cell sites, we cannot be sure whether some people have evacuated, internet access has been disrupted, or both.

Recognizing these limitations, we are engaged in ongoing efforts to make the maps more useful and representative of the on-the-ground situations during crises. We are studying how Facebook users with location services enabled differ from the general population in different parts of the world. We seek to characterize this bias, understand how it affects insights drawn from the maps, and, ultimately, correct for it.

Apart from the representativeness issue, our maps may not always isolate the consequences of the hazard event from all other potentially confounding effects. This is particularly problematic for the Displacement maps, because they attempt to measure long-term effects. Many things can happen in the intervening time between the hazard event and map generation: there can be confounding effects from holidays, school schedules, other crises, etc. We are currently working on developing a baseline methodology for this map as well that could help isolate the causal effect of the hazard event.

REPORTS OF USAGE FROM THE FIELD

Since the launch of Disaster Maps in June of 2017 (Jackman 2017), our partners have grown to include more than 30 of the world's most significant nonprofits and UN agencies in disaster response, including the International Federation of the Red Cross, the World Food Programme, the United Nations Children's Fund (UNICEF), NetHope, Direct Relief, and others. Facebook has recruited partners for this effort through multiple channels, including a training partnership with the NetHope consortium, comprised of nearly 60 international NGOs with an interest in the use of technology for humanitarian response.

In the nearly two years since Disaster Maps launched, the maps have been used during major disasters in nearly every region of the world. When Hurricane Maria struck the island of Puerto Rico, NetHope and the American Red Cross used the maps to inform their deployment of nearly 100 Wi-Fi hotspots across the island to the areas that needed them most (Brinkhurst and Crowley 2018). During Hurricanes Florence and Michael, Humanity Road used the Facebook Population maps to monitor large-scale evacuations and determine where communities were still sheltering in place, sharing these insights with FEMA, the US Coast Guard, and state-response agencies (Waggoner 2018). During the Thomas, Carr, Mendocino Complex, and Camp Fires, Direct Relief used the maps to monitor how populations affected by wildfires were moving and then used this to guide distribution of hundreds of thousands of respiratory masks, as well as to coordinate with networks of health centers to alert hospitals that might see increased volumes (Snibbe 2018).

In August of 2018, Kerala, India experienced severe flooding that displaced over a million people. SEEDS India used the Facebook Population and Displacement maps to appropriately time their early recovery phase. After identifying when people appeared to begin to return home, SEEDS launched a nationwide collection drive for widely needed items (Gupta 2018).

When volcanic eruptions in Guatemala and a combined earthquake and tsunami struck the island of Sulawesi in Indonesia, UNICEF used the Network Coverage maps to determine how many people could be reached through U-Report, an outreach tool built on Facebook Messenger. In Guatemala, UNICEF reached 3,000 new people with information about what to do after the eruption and in Indonesia, U-report reached 3,500 people within 48 hours to understand how they were impacted (Brecha Cero 2018). As part of this deployment, UNICEF was better able to deliver on needs related to water, child protection, health and nutrition in collaboration with the Government of Indonesia and United Nations Office for the Coordination of Humanitarian Affairs.

CONCLUSION

We have described the data and methodology behind Facebook Disaster Maps, a collection of geospatial datasets meant to contribute to situational awareness during disasters. The maps are based on aggregated and anonymized data that is collected and employed in the course of Facebook usage, including current and historical location data, information about cell site connectivity, and data on phone battery charging. The privacy and safety of Facebook users is a primary concern, and a number of methods are employed to maintain privacy, including filtering and obscuring cases where data is sparse.

We describe five types of maps. The Facebook Population maps show regions where more or fewer Facebook users are present when compared to pre-crisis periods. This can highlight areas where people are evacuating from or to. The Movement maps show how movement between pairs of locations differs during and before a crisis. The Power Availability maps show where the crisis has been accompanied by a reduction in the number of people charging their phones, which can indicate disruptions in the power grid. The connectivity maps show regions with reduced connections from phones to particular cell sites, which can indicate connectivity loss for those sites. Finally, the Displacement maps show, in the weeks and months following a crisis, indications of the magnitude of the population that has been displaced from their home city and what cities that population has been displaced to.

In the section "Limitations and Future Work," we discussed a number of limitations of the maps that prevent them from being more useful to humanitarian responders. Our ongoing work aims to surmount several of these limitations, for example the problem of isolating the causal effects of the crisis on long-term displacement and the issue of representativeness across all five map types. One overarching goal of all of our research efforts is to better isolate the most actionable information in each map from the less relevant details. That goal will, however, never be perfectly attainable, given the uniqueness of each crisis event. Therefore, our partner organizations will always need to supplement our maps with other sources of data and with their own domain expertise to effectively formulate humanitarian responses.

A rigorous evaluation of the utility of Disaster Maps for humanitarian response is difficult, but should be attempted in future work. In lieu of such an evaluation, in the section "Reports of Usage from the Field," we have collected anecdotal reports of how the maps have been used in practice. While this does not substitute for more formal evaluation, it does provide evidence that the novelty of the data source, the spatial resolution, and the up-to-date nature of these datasets have provided concrete value for the organizations that have used them.

ACKNOWLEDGMENTS

We are indebted to the many people at Facebook who have developed and maintained the systems and infrastructure upon which Disaster Maps are built. We would also like to thank several specific colleagues on the Disaster Maps project, who have contributed to its creation and development and who have also provided helpful feedback on this paper. These collaborators include Molly Jackman, Chang Lang, Eugenia Giraudy, Sourav Chatterjee, Peter Tu, Lior Berry, Alex Pompe, and Sarah Vieweg. Finally, we'd like to thank each of the humanitarian organizations that have worked with us to make Disaster Maps a success.

ABSTRACT

Several research studies have shown the importance of social media data for humanitarian aid. Among others, the issue of missing and lost people during disasters and emergencies is crucial for disaster managers. This work analyzes Twitter data from a recent wildfire event to determine its usefulness for the mitigation of the missing and found people issue. Data analysis performed using various filtering techniques, and trend analysis revealed that Twitter contains important information potentially useful for emergency managers and volunteers to tackle this issue. Many tweets were found containing full names, partial names, location information, and other vital clues which could be useful for finding missing people.

Keywords

social media, Twitter, missing and found people, California wildfires, disaster response

INTRODUCTION

Natural and human-induced disasters bring challenges and uncertainties among victims and emergency managers. A recent destructive wildfire in California (a.k.a Campfire)[1] started on November 8, 2018, in Butte County, in Northern California later covered the densely populated foothill town of Paradise caused total damage worth $16.5 billion, destroyed more than 18,000 structures, and at least killed 86 people. In the early days of the fire, among several challenges that formal response organizations faced, the rapid increase in the number of people unaccounted for was a significant concern. The list of missing people once skyrocketed to more than 1,200. This work focuses on the issue of missing people during the California wildfire disaster and analyzes data related to this issue on social media.

People are increasingly using social media platforms such as Twitter during disasters and emergencies. Several research studies have revealed that information available on social media platforms could be useful for a variety of humanitarian purposes (Starbird et al. 2010; Heverin and Zach 2010). For instance, reports of urgent needs of affected people, information about injured or deceased people, reports of damages to the built structure can help formal response organizations enhance situational awareness (Imran, Castillo, Diaz, et al. 2015; Castillo 2016; Alam, Ofli, et al. 2018). Moreover, when official helpline numbers are down or overwhelmed, the general public turns to social media to get the latest updates about an ongoing disaster event to prepare their plans accordingly.

This work seeks to investigate the role of social media platforms, in particular Twitter, during the California wildfire event. Specifically, we focus on analyzing the content of tweets related to missing and found people. To the best of our knowledge, no previous study has analyzed Twitter data in-depth from the perspective of the missing and found people issue, especially during disaster situations, thus it is not known whether and in what form people share information related to this issue on Twitter. For this reason, we first aim to answer the following question. Does

*Work done while the author was an intern at QCRI.
[1] https://en.wikipedia.org/wiki/Campfire_(2018)

Twitter contain information about missing or found people? If the answer to this question is affirmative, we seek to understand what types of information are available on Twitter related to this issue? For example, do people share the names of their family members and friends who are missing? Do they also share location or other relevant information which can be useful in this context? Moreover, we determine whether such information, if present, can be helpful for emergency managers, volunteers, or the family members of missing people?

To answer the above questions, we first select tweets relevant to the missing people issue by applying various filtering techniques on the data collected during the California wildfire event. Next, by identifying trends and spikes which occurred due to high activities on Twitter during the timeline of the whole event, we select tweets from peaks and perform their content analysis. Our analysis reveals that the communications on Twitter during the California wildfire event indeed contain very useful information about missing and found people. We observe tweets with the names of missing and found people. Moreover, several tweets found to have a location and other helpful information such as how the missing person looks like, where he/she was seen last time etc. Such information can be very useful for emergency managers, officials and volunteers who are tasked to find missing people, if identified and processed timely using automatic techniques and systems such as (Nguyen, Joty, et al. 2016; Imran, Castillo, Lucas, et al. 2014).

LITERATURE REVIEW

Over the last few years, social media platforms have been used for several disaster response and management tasks such as situational awareness (Vieweg et al. 2010; Starbird et al. 2010). Research studies have revealed that social media contains a variety of information useful for disaster managers and first responders. This information includes reports of injured or dead people, infrastructure damage, urgent needs of affected people and so on (Imran, Castillo, Diaz, et al. 2015; Castillo 2016). Lindsay 2011 reports the results of a study commissioned by American Red Cross, that social media platforms are the fourth most popular sites which are used by people during a crisis, particularly for information gathering, information sharing, and for help and support purposes.

Although, several empirical analyses from different perspectives have been performed on social media data (Rosser et al. 2017; Wang et al. 2016; Acar and Muraki 2011), to the best of our knowledge no previous work has focused on studying the issue of missing and found people during natural or human-induced disasters. A recent study, which is not disaster-related, conducted by Tsoi et al. 2018, explored the effectiveness of Twitter to find missing persons suffering from dementia (a syndrome leading to progressive cognitive functional loss). The study showed convincing results, concluding that Twitter can also be helpful like traditional news reports in searching a person who got lost due to dementia (Kirkman 2006; Rowe et al. 2011). In an other study conducted by Hunt et al. 2010, the authors discusses the outcomes which can be witnessed if a driver suffering from dementia gets lost. The authors in this study accessed reports of lost drivers given by newspapers and media and concluded that patients who are lost while driving can face tragic incidents leading to death.

In this paper, we use Twitter to explore a potential issue of missing people during disasters and emergencies. We aim to analyze Twitter data shared during a wildfire event to determine whether the general public report about their missing family and friends or not. Moreover, we seek to understand what are the most prominent types of information available on Twitter related to the issue of missing and found people. We believe this study serves as a piece of foundational evidence to the research community to explore further and develop computational systems for the mitigation of this issue.

METHODOLOGY

To investigate whether Twitter data can be helpful for the missing and found people issue, we devise a methodology consisting of four steps. First, we collect Twitter data using a set of keywords during the California wildfires event. Next, we apply different filtering approaches to select the most relevant data to the issue of missing people. Third, we perform a trend analysis by plotting the frequency of tweets throughout the event and identify spikes. Lastly, we perform the content analysis of tweets taken from spikes and peaks. We describe these steps in detail in the following subsections.

Data filtering

Three types of filters are used to select relevant tweets. Specifically, in the first filter, we consider tweets mentioning the names of missing or found people; second, tweets containing particular hashtags related to the missing people issue; and the third filter selects tweets having keywords/terms related to this issue. To find tweets containing names, we first curate a list with names of missing and found people by manually searching different lists on the Internet at

the time of data analysis (i.e., January 2019). To find tweets containing hashtags relevant to the missing or found people issue, we first extract all the hashtags from our data and then manually search through them to find the relevant hashtags. To find tweets using keywords/terms relevant to the missing and found people, we first manually curate a list of terms and then search tweets containing one of those terms.

These three data filtering steps, which we describe in detail in the next section, are applied to the whole tweets set to extract tweets relevant to the issue of missing or found people. All of our further analysis uses the selected tweets.

Data analyses using emerging trends

Social media communications, in particular, Twitter, have reached unprecedented levels. Millions of users post tweets to report their thoughts, events around them, and breaking news. Each tweet is associated with a timestamp (i.e., the date and time when the tweet is posted), a user (i.e., the author of the tweet), and a short text, among many other meta-information. When a large number of Twitter users start posting about a similar topic (e.g., using a hashtag) at a given time/day, it becomes an emerging topic, which is also known as a trend on Twitter. Research studies have revealed that emerging topics often represent significant developments about an ongoing event and a real-time analysis of them can help understand the situation.

To identify significant moments during the California wildfire event, we plot day-wise distributions of both the original tweets and retweets retrieved after the data filtering steps (as described above). The emerged trends give us times and a subset of data where any significant activity happened during the wildfire event. We then closely analyze those trend and spikes to lay down our findings.

DATASET AND DESCRIPTION

Data collection

Twitter data: To collect data from Twitter during the California wildfire, we used the AIDR platform (Imran, Castillo, Lucas, et al. 2014), which is a free and open platform to collect and classify social media data for humanitarian purposes. In total, we collected approximately 4.8 million tweets from November 10, 2018, to December 7, 2018, using keywords *"California wildfire, California wildfires, California fire, California fires, Camp fire, California victims, California rescue"*.

Finding names of missing and found people (ground truth): One of the most important clues to determine whether a tweet is about any missing or found person, is to detect if the tweet contains the name of a person who is declared missing or found in an official list. With this hope that people mention the names of their loved ones who are missing in their tweets, we searched for records of missing or found people names on the Internet. The search result revealed a couple of lists shared by different sources including official, media, and volunteers. These lists contain names of missing and found people and were posted on various dates during the wildfire event. Many names were found redundant; thus we compiled a consolidated list having unique names. We include full names (i.e., when first and last names are available) and partial names (i.e., when either first or last name is present) in the final list of unique names. The consolidated list contains 4,167 unique full names and 3,363 unique partial names and referred as the Internet list in the rest of the paper.

The datasets used in this paper are available at: https://CrisisNLP.qcri.org/

Data filtering and selection

Since the focus of this work is to analyze tweets related to missing and found people, we apply various filters to select the data associated with this issue. Next, we provide details of these filters.

Name-based filtering

This filter aims to select tweets which contain one or more full or partial names of missing or found people. For this purpose, we use the Internet names list to find tweets which match any of the names. Due to some partial names like "Shell", "Donald", "Have" etc., a large number of tweets are retrieved. We further reduced this set by discarding exact duplicates. This filter yields 306,198 tweets in total from which 409 tweets were found to have at least one full name and 305,789 with at least one partial name.

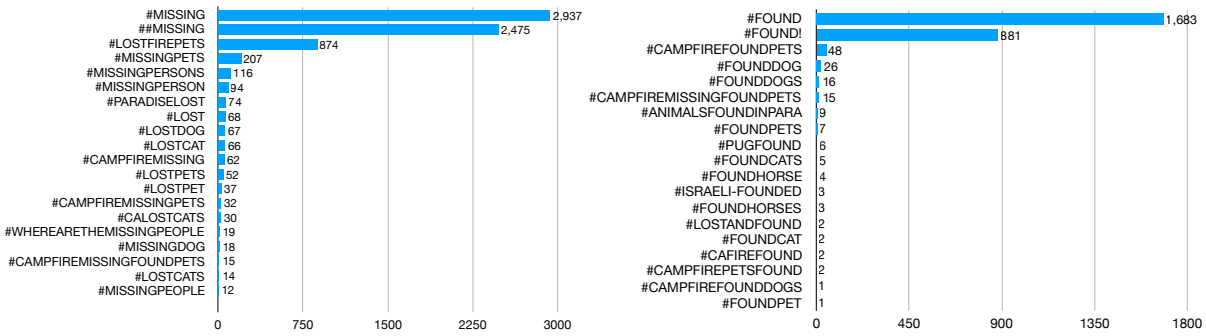

Figure 1. Top hashtags related to the missing (left) & found (right) people/pets issue

Hashtag-based filtering

Hashtags on Twitter allow users to tag a tweet with one or more topics. Famous hashtags start appearing on Twitter trends, which then allow users to search through related content easily. For example, #CampFire was one of the most used hashtags during the Campfire (California wildfires) event. To determine hashtags related to the missing and found people issue, we first extract all the hashtags used in the collected data. Hashtags related to the missing and found people issue are then manually selected from the list of extracted hashtags. In total, 63 hashtags were selected pertaining to missing-related and 19 to found-related tweets. Figure 1 shows the top 20 hashtags and their frequencies for both missing and found people and pets. Next, we find tweets containing at least one of the selected missing or found hashtags. This filter yields a total of 7,404 tweets having at least one of the missing hashtags and 2,720 tweets with at least one of the found hashtags. The complete list of hashtags are provided with the shared data.

Keywords-based filtering

After selecting tweets which fulfill the above two selection criteria, we may still miss tweets which are relevant but not mentioning any names or one of the selected hashtags. To overcome this potential issue, the third data selection strategy tries to find tweets based on keywords/terms related to the missing or found people issue. We use the following terms for this purpose. Missing-related terms: *"missing, search, searching, finding, find, looking, heard, contact"* and Found-related terms: *"found, safe, update, located"*. Next, tweets having one of these terms are selected, which were 144,113 for the missing case and 61,072 for the found case.

After removing the exact duplicates, the resultant set from all of the above filters consists of 340,452 tweets. We use these tweets for our further analysis.

TREND ANALYSIS

Trends related to the names of missing and found people

Figure 2 shows the day-wise distribution of the tweets and retweets containing at least one full name (left-side plot) and one partial name (right-side plot). Generally, on Twitter the proportion of retweets to tweets is always higher, we observe the same pattern in the case of missing and found people tweets in the both full names and partial names cases. Trends and spikes help find significant developments. In this case, the two obvious spikes of the retweets containing the full names are on November 11 and on November 25. We closely investigate these two dates and found the following important reports.

On November 11, a total of 72 tweets and 644 retweets were posted which were having at least one full name from our list. The following tweet about a missing person named "Barbara Carlson" was posted on November 11 at 00:08:15 2018[2], which received 322 retweets on the same day.

"HELP: my grandma (Barbara Carlson) and her dog (strawberry) are missing in the Camp Fire in paradise! My dad and I have been searching refugee camps with no luck. Her address is 5577 heavenly place, paradise California. We believe SHE IS STILL IN THE HOUSE."

The tweet clearly mentions the name of the missing person, and in this case the name of the missing pet too. Moreover, the tweet author specifies the address of the missing person. Several hours later on the same day at 05:01:05 2018, the following tweet about the same person was posted by another Twitter user.

[2]The time zone of all the times mentioned in this paper is UTC.

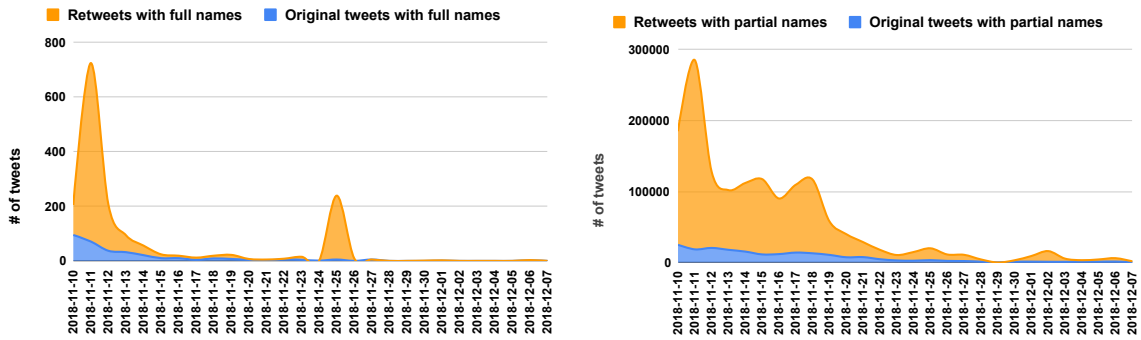

Figure 2. Distribution of tweets with at least one full name (left) and at least one partial name (right)

"The family of Barbara Carlson, who lived on Heavenly Place in Paradise with her sister Shirley and dog Strawberry, are still looking for her. She's 4'11 with gray peppery hair, freckles on her face and glasses. CampFire".

This tweet contains more information about the missing person i.e., the missing person lives with her sister and is 4'11 with gray peppery hair, freckles on her face and glasses. These are all important pieces of information useful for emergency officials and volunteers who are tasked to find missing people.

An update in the form of the following tweet came on November 12 confirming the sad demise of Barbara Carlson and her sister.

"Thank you for all the amazing support from everyone. We got confirmation the house where my grandma and her sister lived had two bodies found today. Barbara Carlson and Shirley Haley were two loved victims of the camp fire."

On the same day, we found several tweets (see below a few cases) reporting missing people and asking help.

T1: "Camp Fire Paradise, CA Missing Marc Handschuh who knows him, and has seen in the last few days, or has contact with him and Christina - Please let us know, we miss him"

T2: "@975krock @hitsfm @VOCMOpenline former coworkers please pray for my Uncle Randy Dodge who is still missing in the Paradise California fires! If you have any connections in the area please let me know. His house has burned down and we have called everywhere!"

T3: "We are looking for Tracey Philipson. If you have any information please contact"

T4: "A son looking for his mother, Barbara Allen who is well-known in Paradise, asked for help at the Camp Fire community meeting held at Chico State Saturday evening."

Moreover, we observe tweets about found people on the same day. For example, "Martin Sheen", who went missing in the early days, is reported found on November 11 in this tweet:

"Martin Sheen has been found after his son Charlie Sheen feared he had gone missing in the devastating wildfires in Southern California."

Another tweet about a found person came like this: "FOUND- Dan Sloane Camp Fire has been located and is safe with his two dogs."

A relatively small spike on November 25 also reveals important updates. One tweet that received more than 100 retweets out of all 208 tweets posted on that day was the following reporting several still missing.

"Soon Warner would discover that no one knew where his uncle Greg Rader, his aunt Michelle Sherman, his grandma Anne Thomas Sherman or his grandpa Fay Hubert Sherman were. His 96 yr old Grandpa was a WW2 Vet and was still living with his wife in Paradise."

Similarly, the following tweet posted on November 25 reports about a person (Sheila Santos) who was still missing several weeks after.

"STILL MISSING: Sheila Santos of Paradise. campfire campfiremissing campfirejameswoods"

We try to look back into our data and found that the first report about "Sheila Santos" came on November 13 in the form of the following tweet.

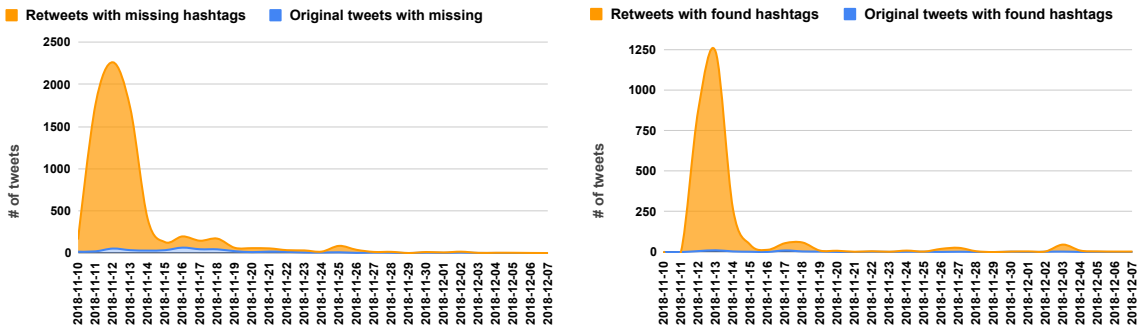

Figure 3. Distribution of original and retweets with missing hashtags (left) and with found hashtags (right)

"The last time anyone spoke to Sheila Santos, she was still groggy from sleeping pills. By that point the CampFire had already swept through town, and the roads leading to her Paradise trailer were closed."

The final update (see the following tweet) about "Sheila Santos" came on December 1 when sadly she found dead.

"Sad to report that, Tammie Konicki just learned that her mother's remains were found. Sheila Santos, 64, was another person killed in the state's deadliest and most destructive wildfire. CampFire @vicenews"

Overall, the spike on November 11 mainly represent several tweets and retweets of missing people. As time passes, the activity on Twitter reduced. However, on November 25, tweets with full names of missing and found people suddenly picked up. This was due to the sharing of missing and found people list by Sheriff around those days.

Several spikes appear on the right-side plot of the figure 2, which shows the distribution of tweets and retweets containing partial names. These spikes also reveal many important but similar updates[3] as in the case of the tweets with full names. However, we observe that partial names filter bring more noise than the full name filter. Hence, we recommend officials and automated system developers to first focus on analyzing tweets containing full names, as during a disaster situation both time and resources are usually scarce.

Trends related to the hashtags

Another convenient way to find updates about a specific topic on Twitter is through hashtags. Figure 3 shows the day-wise distributions of the tweets containing one of the missing hashtags (left-side plot) and found hashtags (right-side plot) from our selected hashtags.

In the case of missing hashtags, a big spike appears on November 12 followed by three, comparatively, small spikes on November 16, 18, and 25. On November 12, the following tweet from a daughter about her missing mother received several retweets.

"#Paradise #ParadiseFire #ParadiseLost #ParadiseEvacuees My mother lives in Magalia and I have not heard from her since the Camp Fire in Paradise started. We are searching all the shelters from Sac to Chico. Please share this post and pray that we can find her"

The tweet contains several hashtags, which is one of the reasons it reached to a broader audience. However, we found it using the `#ParadiseLost` hashtag. The tweet text does not contain the name of the missing person, however the name and a contact number are given in a photo attached to the tweet. Such cases signify the importance of analyzing other content types such as images, however this work only focuses on textual content analysis.

We observe several tweets about missing and found pets on the days with high tweets activity. People used different hashtags such as `#CALostCats, #LostPet, #MissingPet`, etc. to report about missing or found pets. Moreover, a large number of tweets found to give suggestions to the families of missing people to particular hashtags or follow particular Twitter users as doing so may help find their loved ones quickly. For instance, look at this tweet which suggests to follow the Twitter account of James Woods[4], a Hollywood star. "Please follow @RealJamesWoods as he helps find the missing lost in the CalifornaiaWildfires use hashtags..."

During the wildfires, James Woods, through his Twitter account, invited people to use the hashtags `#CampFireJamesWoods` and `#SoCalFiresJamesWoods` to post the names of missing family members and friends. He then shares the

[3]Notice that we omit several details due to the space limitations
[4]https://en.wikipedia.org/wiki/James$_{W}oods$

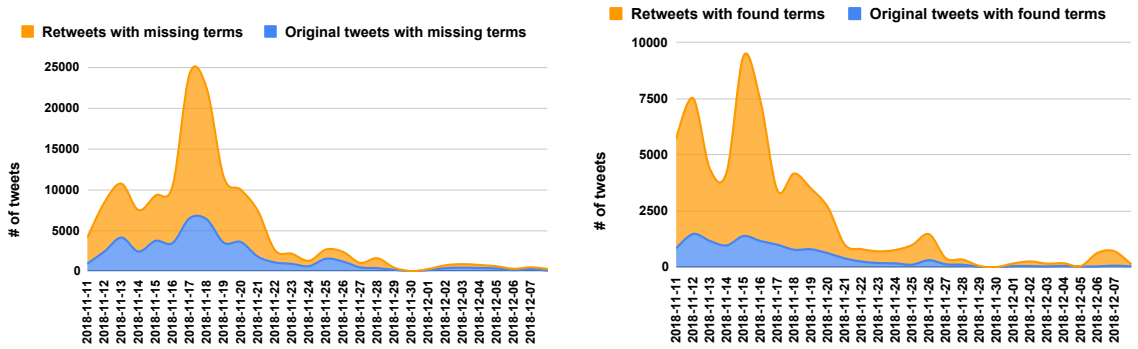

Figure 4. Distribution of original tweets and retweets with missing related keywords/terms (left) and with found related keywords/terms (right)

message to his more than 2 million followers. The following tweet was posted by James about lost horses, which were later found.

`She needs help with five horses. It was previously reported that her horses had been evacuated, but she says that did not happen. Please contact her at @Alyssa_Milano to get her location or use my hashtag #SoCalFiresJamesWoods This is a serious request.`

Another observation is that the tweets selected using hashtags contain more noise than the tweets selected using people names (as described above). For instance, many tweets containing missing or found-related hashtags, appear to provide general updates about this issue, e.g., see this tweet: `“More than 200 still missing in California’s deadliest wildfire on record blaze..."`

Moreover, many irrelevant tweets were found in which one of the relevant hashtags is used, but the tweet content is not related to the missing or found context.

Trends related to the terms

Figure 4 shows the day-wise distributions of the tweets and retweets obtained from the keyword-based filter.

One obvious observation, which is also consistent with names and hashtags trend analysis, is that the frequency of retweets increases with an increase in the frequency of original tweet. Several spikes emerged in both of the plots. In the case of missing-terms (left-side plot), spikes on November 13, 17, 18, 25, and 28 are visible. The largest activity was recorded between November 17 and 18 when 25k tweets were posted.

The tweets selected using keywords/terms contain more noise than the tweets selected using the names and hashtags. Terms such as “heard, safe, and contact" retrieved more off-topic results. Moreover, the term “Update" observed to retrieve tweets with general updates about casualties, damages, and missing people. However, rest of the terms yield many relevant results.

On November 13, we observe many general updates about various issues such as reports of deaths, ongoing humanitarian and search activities, reports of missing people and pets. Below are a few tweets from this day.

T1: `“RT @blkahn: BREAKING: The Camp Fire is officially the most deadly fire in California history. 42 dead, hundreds still missing"`
T2: `“BSG Teams search for bodies in California after wildfire claims 42 lives"`
T3: `“As of yesterday the death toll of CampFire has risen to 42, with more than 200 people still missing"`

During November 17 and 18, which is the period with largest Twitter activity, many tweets report about the increase in the winds. The Santa Ana winds gained much higher speed, resulting in spread of fire, and increase in casualties. We show a few related tweets below.

T1: `“California fires: death toll rises to 76 as winds threaten efforts to control blaze .wow. From 700 missing yesterday to 1300 now.“`
T2: `“At least 44 people are dead and more than 200 remain missing as two massive wildfires, fueled by easterly winds and a historic drought, continue to rage in California."`
T3: `“As the death toll and number of missing people rises, firefighters in Northern California are`

bracing for strong winds that could erode the progress they made on the deadliest fire in the country in at least a century."
T4: "RT @CTVNews: California fire latest: 76 dead, 1,300 missing and strong winds causing concern"

Furthermore, two relatively small spikes appear on November 25 and 28. Tweets posted on November 25 mainly contain general updates about the event, victims, and a few referring to people who are still not accounted for. However, many observed as less relevant to the context of missing and found people.

T1: "although the fires are contained the search for missing individuals continues hope this will be the last of these.."
T2: "authorities are still struggling to find human remains in magalia california after the horrible wildfire"

Figure 4 (right-side plot) shows the distribution of tweets containing any found-related terms. We observe spikes on November 12, 15, 16, 18, 26, and between December 6 and 7. On these days, again we observed many tweets reporting general updates about death toll, number of missing people, and showing their concerns. On November 12, a tweet giving general updates: "RT @stacos: BREAKING UPDATE: Death Tolls rise to 31, and hundreds still missing in California Wild Fire". On November 15 a tweet with updates: "California's deadliest fire: 13 more victims remains found ..".

Mostly tweets on November 16 and 18 talk about deceased and people who are still missing. Below are few examples.
T1: "At least 63 are now dead from the Camp Fire in Paradise, Calif. Officials say they have a missing persons list"
T2: "According to the Butte County Sheriff, an additional five human remains were found on Saturday, four in Paradise"
T3: "RT @DailyMail: At least 74 people have died in California wildfires as more than one thousand people are feared missing"

Many irrelevant tweets were found on November 26, December 6 and 7. Some generally discuss the event, victims, and response efforts from officials.

DISCUSSION & FUTURE WORK

This work analyzed the Twitter data posted during the 2018 California wildfires to investigate the types of information shared related to the issue of missing and found people. The analysis revealed that the tweets posted during the event contain important information in the forms of full names, partial names, locations, etc. about the missing and found people.

Around 400 tweets were found containing full names and about 300k tweets with partial names of potentially missing and found people. However, tweets with full names were found on-topic and considered more relevant to this issue compared to the tweets with partial names. Many partial names search retrieved tweets containing famous people names such as Donald Trump and other celebrities. The analysis revealed that people share names with different spellings, perhaps due to reasons such as interpreting and writing using phonetic knowledge, misspellings, typos, and sometimes using the auto-correct feature in mobiles. Officials and emergency managers can use tweets with names to help find missing people.

Furthermore, tweets selected using the related hashtags contain less noise than the tweets selected using the keywords/terms. Tweets of missing or found people with popular hashtags likely to receive more retweets. Moreover, tweets mentioning a famous Twitter user, as seen in the case of James Woods in this study, help spread the message quickly. The hashtags trend analysis revealed that many tweets report a missing person without explicitly mentioning a name. However, sometimes the names are found in an attached photo. Both hashtags and terms tweets contain general updates such as death toll, missing people count.

Although, our analysis revealed that Twitter contains useful information about the issue of missing and found people, performing manual analysis to identify relevant tweets is not a feasible option due to the sheer volume of data on Twitter. Therefore, we suggest developing or extending existing systems (e.g., AIDR (Imran, Castillo, Lucas, et al. 2014)) which can process and classify data in real-time to predict whether a tweet is about missing or found people issue or not. Moreover, automated solutions and systems to automatically detect tweets with names and locations, e.g., using named-entity recognition techniques need to be developed. Furthermore, we remark that incorporating images shared on social media related to the issue of missing and found people can substantially help concerned authorities to find missing people. Automatic image processing for this purpose would need extending existing techniques in this domain e.g., (Nguyen, Alam, et al. 2017; Alam, Imran, et al. 2017). We aim to work on these directions and develop needed solutions in the future.

CONCLUSIONS

This work analyzed Twitter data shared during the 2018 California wildfire event to investigate whether family and friends share information about their missing loved ones and whether that information can assist officials finding those missing people. Various filtering techniques were employed to select potentially relevant data. Moreover, a trend analysis of around 300k tweets was performed to investigate large activities during the timeline of the event manually. The analysis revealed that indeed Twitter contains various types of useful information about missing and found people. The study found that tweets containing the names of missing and found people, their last known locations, how they look like, etc. can provide vital clues to official responders to mitigate the issue of missing people. However, to achieve this goal, automatic systems need to be developed, which we consider as a future work.

Comparison of Social Media in English and Russian During Emergencies and Mass Convergence Events

ABSTRACT

Twitter is used for spreading information during crisis events. In this paper, we first retrieve event-related information posted in English and Russian during six disasters and sports events that received wide media coverage in both languages, using an adaptive information filtering method for automating the collection of about 100 000 messages. We then compare the contents of these messages in terms of 17 informational and linguistic features using a difference in differences approach. Our results suggest that posts in each language are focused on different types of information. For instance, almost 50% of the popular people mentioned in these messages appear exclusively in either the English messages or the Russian messages, but not both. Our results also suggest differences in the adoption of platform mechanics during crises between Russian-speaking and English-speaking users. This has important implications for data collection during crises, which is almost always focused on a single language.

Keywords

Social Media, Crisis Informatics, Twitter, Information Extraction.

INTRODUCTION

Over the last decade there has been increased interest in the use of social media for disaster communication. A wide range of studies suggests that information sharing networks, such as Twitter, can be very useful in times of crisis due to quick and effective dissemination of relevant news (Yin et al. 2015). Previous works have used quantitative data collection methods and focused on strategic keyword detection (Corvey et al. 2010), a perception of false RTs (Mendoza et al. 2010), and categorization of the tweets sent during disasters (Olteanu, Vieweg, et al. 2015; Öztürk and Ayvaz 2018), among many other topics (Castillo 2016). Most previous works considered tweets in English (Reuter, Hughes, et al. 2018; Reuter, Backfried, et al. 2018), with some exceptions (Zielinski et al. 2012; Doan et al. 2011). In general, messages are collected for emergency response or research purposes in a single language.

This study aims to characterize the differences between messages posted in English and Russian in social media during the same events. Specifically, we seek to address differences in the information conveyed (e.g., mentions of persons, organizations, and locations) and in the linguistic characteristics of messages shared (e.g., parts of speech being used). We ground these differences in "background" collections done in both languages during periods without events, which allows us to use a difference-in-differences approach to quantify changes.

Intuitively, one could assume that collecting data about a crisis in multiple languages should yield more information that using a single language. In this paper, we try to quantify how much is lost by doing a single-language data collection. Our aims in this research are:

- to create a method for finding, collecting and filtering relevant data in Twitter about crises in several languages;
- to create event-driven parallel datasets of events across languages;
- to identify the most significant features for the comparison of tweets across languages;
- to compare the information and linguistic characteristics of these datasets.

LITERATURE REVIEW

Social media has become one of the main sources of communication and information during crisis situations, including disasters and mass convergence events. Using computational methods from many disciplines (Castillo 2016) helps to build systems that can help emergency managers during real crises.

Disasters in Social Media

Modern disaster management processes can use social media technologies to capture event parameters, to help effective decision making, and to share knowledge (Yates and Paquette 2010).

The information in social media during a disaster depends on different factors. For instance, during Japan's tsunami in 2011, people in directly affected areas tended to post about their unsafe and uncertain situation, while people in remote areas posted messages to let their followers know that they were safe (Acar and Muraki 2011). Systematic examinations of a diverse set of crises has uncovered substantial variability across crises, as well as patterns and consistencies across dimensions such as informativeness, information type, and source (Olteanu, Vieweg, et al. 2015).

Languages in Twitter

In most research using Twitter data, the natural tendency has been to assume that the behaviors of English users generalize to other language users (Olteanu, Castillo, et al. 2016). However, given the widespread adoption of Twitter internationally, some researchers have investigated the differences among users of different languages. Examining users of the top 10 languages and general messages (not topic-specific), cross-language differences in adoption of features such as URLs, hashtags, mentions, replies, and retweets have been described (Hong et al. 2011). Regarding news media, the linguistic properties of tweets of selected English and German daily newspapers have been analyzed to identify the structural, discursive and rhetorical goals of newspaper tweets (Tereszkiewicz 2013).

This type of cross-lingual comparison has many challenges, including detecting different nationalities (Laboreiro 2018). However, it can also be very useful to help build models and tools for detecting differences in societal priorities, people's behavioral factors, social, economic, and environmental performances (Resce and Maynard 2018).

Multilingual users are very prevalent in Twitter (Hale 2014), indeed, there is a large interest within the research community on multilingual texts in Twitter and the interaction of multilingual users in the network (Papalexakis and Doğruöz 2015).

In addition to language, a further axes for comparative social media analysis are location and platform. Distance and related variables (language, country, and the number of flights) all have an effect on Twitter ties despite the substantial ease with which long-range ties can be formed (Takhteyev et al. 2012) There are also significant differences across platforms, e.g., in the microblogging behavior on Sina Weibo and Twitter. These provide valuable insights for multilingual and culture-aware user modeling based on user's behavior, microblogging syntactic, semantic and sentiment data (Gao et al. 2012).

In contrast to the previous works, our contribution is that we focus on changes during crisis events, which can be very varied but almost invariably leave a large footprint in social media communities. We compare multiple events in two languages: English and Russian, and our proposed research methodology includes not only an analysis of the linguistics characteristics of messages, but also of the informativeness of messages and their sources, and virality.

DATA COLLECTION AND FILTERING

In this section, we discuss our approach for collecting data: an Adaptive Information Filtering approach based on locations, which helps in the detecting new keywords and collect relevant data. After that, we briefly describe the classification model that helps us automate dataset creation for further analysis.

Overview

For data collection, we build a processing pipeline (Figure 1) that starts with a seed set of location-based keywords (place names) for real-time filtering of tweets and captures messages about an event that happens in the specified location(s). Public tweets were collected and stored independently by language using Twitter's public API. Next, we use an algorithm based on TF-IDF (Ramos et al. 2003) for gathering new keywords for searching and continuing

collecting messages. All tweets with keywords mentions were filtered by an automated classifier (Aggarwal and Zhai 2012) based on hand-labeled samples of data to obtain the final lists of tweets for analysis.

We used standard text data preprocessing and extracted informational and linguistic features. The final stage of the analysis was the difference in differences comparison (Abadie 2005) that shows similarities and differences of short-text messages between "normal" and crisis situations in Russian and English.

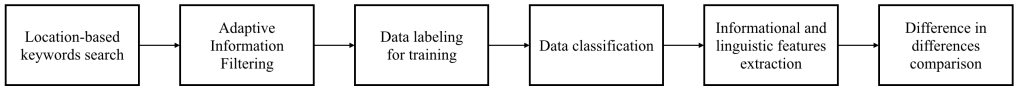

Figure 1. Pipeline of research system

The main challenge for collecting data that we faced is availability large events receiving wide media coverage in both languages, which already hints that information in Twitter in both languages might be quite different. Many large events were discussed quite prominently through tweets in English but were much less talked about in Russian tweets, and vice-versa.

Adaptive Information Filtering

The primary task of Adaptive Information Filtering is to reduce a user's information load with respect to his or her interest described by a request. The filter is supposed to correctly filter an incoming stream, such that relevant keywords are added to adapt the request described by the user. Thus, adaptive information filtering can be described as a type of unsupervised classification problem which must detect new topics in the incoming stream. The objective of our task is similar to the task of topic detection and tracking (TDT) (Allan et al. 1998). TDT is defined as an unsupervised learning problem. There are no relevance classes with respect to a particular user interest. The primary interest is to detect the occurrence of changes as early as possible. Once new topics have been detected, the tracking of new topics must be corrected.

In our implementation, the initial user's query contains only location keywords (district, city, country) which are related to the event. Through the Twitter API we perform a request for collecting public tweets in the stream which contain these keywords. When the number of messages collected surpasses a threshold, all collected documents processed by the Adaptive Information Filtering (AIF) model.

The first stage of our AIF implementation is a pre-processing stage, which starts with language detection. We use the standard Twitter API language parameter for this. After this stage, we had two datasets in different languages — Russian and English. All documents in every message are preprocessed — texts tokenization, deleting special symbols which are used in Twitter for mentions, hashtags, etc., and lemmatization because of in Russian language stemming shows lower efficiency for pre-processing texts (Jivani et al. 2011). Then, every document becomes a bag of words represented using the Vector Space model (Salton and McGill 1986). The vectors are built during the initial phase from the corpus created based on the request from the user.

After lemmatization, every text document is transformed into a list of words without functional words (also known as a stoplist). The words are weighed by the standard $TF - IDF$ product, with TF is the term frequency in the document, and $IDF = log(n/DF(i))$ with n the number of documents in the collection and $DF(i)$ the number of documents in the collection who contain the word i (Marinilli et al. 1999). Then we chose the L most popular terms in the collection, where L is set heuristically to 4 terms based on initial experiments. The new query contains terms which were chosen in the previous step. After the number of messages in the new query becomes the same as the threshold parameter, all new documents are again processed by our AIF-model. All documents in all queries are collected into one dataset which contains filtered tweets connected with the specified event.

The AIF-model approach allows capturing the data variability and collecting more informative data by adding new keywords and new threads which connected with the event.

Classification model

The messages we capture using the procedure described above include many messages that are not related to any specific event of our interest. Hence, the next step for creating the datasets is building a classification model for filtering tweets that are contain information about an event, excluding other information that is not related to an

event but is nevertheless captured by the data collection process. This task can be described as an supervised, binary classification problem.

We compared several learning schemes (Support vector machine, Stochastic gradient descent, Extremely randomized trees), based on word embeddings (similarly to (Wijeratne et al. 2016)). We first create words embeddings for every social media message with the help of the doc2vec embeddings model (Le and Mikolov 2014), which is well suited for short length text and outperforms the word2vec model and probabilistic latent semantic analysis model approach, as discussed in (Gupta, Abhinav, et al. 2013; Nguyen et al. 2016; Khosla et al. 2017). Now, each of the word embedding combines another feature vector which was formed using the frequency of each term available in a tweet. After preprocessing, we have one entire embedding vector of length 300 which will be the final representative of the respective class.

Social media tweets in our collections are transformed into vectors (each of length 300) in which the absence of most similar tweets are ensured. These embeddings will be the input for training models.

Training data includes two labeled collections of sport events containing 6 000 tweets and 3 000 tweets respectively, with 20% of tweets for testing and 80% for training. We use a batch-based online learning method with batch size equals 300.

During the training of the Random Forest model, entire training embedding vectors were cross-validated with K-folds (k=10), and showed maximum precision and recall in comparison with Support vector machine, Stochastic gradient descent, Extremely randomized trees, including F-Score (Table 1).

Table 1. Results of learning schemes comparison

	Precision	*Recall*	*F1*
RandomForest	**0.9022**	0.7339	**0.8079**
LinearSVM	0.8747	**0.7407**	0.8019
SGD	0.8819	0.6679	0.7550
ExtraTrees	0.8393	0.6372	0.7243

For our research we considered six events from September to December 2018 that were widely covered in both English and Russian in Twitter. Four of these events are disasters, while the remaining two are worldwide sports events with a significant footprint in social media in both languages. The amount of data collected, before filtering and after filtering using the AIF approach above and for each event is listed on Table 2.

Table 2. Collected data

		Number of tweets before filtering		Number of tweets after filtering	
Events	*Dates*	*English*	*Russian*	*English*	*Russian*
Anchorage Earthquake	01.12.18 — 03.12.18	36,865	1,263	26,691	1,082
Ebeko Volcano Activities	02.11.18 — 06.11.18	67,000	1,500	2,595	258
Kerch Poly Massacre	18.10.18 — 20.10.18	1,850	3,350	1,267	1,358
Paris Fuel Riot	24.11.18 — 26.11.18	163,345	2,344	64,385	676
F1 Race in Sochi	30.09.18 — 04.10.18	333	1,650	102	189
UFC229 Khabib vs Connor	05.10.18 — 07.10.18	650	600	267	190

EXTRACTION OF CONTENT FEATURES

Primarily, the motivation for this paper is to compare the informativeness of crisis tweets across languages. To quantify the extent to which information in each language is unique, we focus on Named Entities, which include:

- persons — these features consider mentions of people by users in their messages. Empirically they are typically politicians, celebrities or people directly affected by an event;
- locations — this feature considers mentions of places in their messages e.i. city, district, state etc.;

- organizations — this feature considers mentions of government or non-governmental organizations, for-profit companies, or other organizations or associations;
- time references — this feature considers time and time interval mentions.

In addition to named entities, we considered other features which are stylistic or refer to platform mechanics:

- type of account — it shows relation between regular users and verified i.e. accounts of politics, celebrities, media or another organizations;
- usage of links in texts — shows if the message is full or is it just a teaser of another material or petition;
- usage of numbers — this feature shows how much facts the message contains because digits/numbers are the main feature of fact in text;
- usage of quotes — this feature shows how much times users cite another person, direct participant of event or expert in disaster;
- dialogues (or @mentions) — it shows how much times Twitter users entered into a dialogue with another user;
- number of retweets — this shows how many times the message was re-posted in Twitter and is related to the relevance of the message for Twitter's community;
- usage of hashtags — exposure desire of an author come into trend connected with event.

The last group of features which were analyzed during this paper are part-of-speech elements, including:

- verbs — typically indicates actions described by users in their tweets;
- nouns — typically describes a variety of elements and objects that participate in those actions.

While extracting these features we were faced several complexities connected with language differences. For each of the two languages we created a separate analytics pipeline included linguistic resources (dictionary of stopwords, special symbols), morphological parser for POS-detection (Russian — pymorphy2[1] Python library, English — Python NLTK[2] pos-parser), Named Entities parsers (Russian — natasha[3] Python library, English — SpaCy[4] Python library).

RESULTS

Based on datasets we evaluated tweets for the purpose of detecting differences. The filtered datasets were used for comparison against the control group (regular Russian and English tweets collected while no large event was happening; 10 000 in both cases) and get the difference in differences (DD) index.

For calculating average DD for feature (example — persons in English tweets) at first we calculate feature values for every event. Then we calculate DD index for every event by the difference between the values during the event and during the general stream: $DD_{event} = value_{event} - value_{general}$. After that we calculate average value of DD for feature: $DD_{avarage} = (DD_{event}1 + DD_{event}2 + \ldots + DD_{event}n)/n$.

For calculating median DD for feature we also use DD indexes for every event: DD_{median} equals mean of the two middle values in the ordered row of DD_{event}. DD_{median} helps us to get "typical" value if some of DD_{event} values are extremely large or small.

In the tables we mark with an "*" in the English column cases where the $DD_{average}$ in English is larger than the $DD_{average}$ in Russian by more than one standard deviation among the different events as captured in Russian. Conversely, we mark with an "*" in the Russian column cases where $DD_{average}$ in Russian is larger than $DD_{average}$ in English by more that one standard deviation among the different events as captured in English.

Entities

During analysis of named entities we get interesting results that illustrate differences in Russian and English tweets published during disasters (Table 3). Both languages mention a similar number of person entities in the background collection, but during events these numbers similarly increase/decrease, depending on the types of event. During sport events and human-made crises we see more person entities, but during natural disasters this number decreases.

Table 3. Named entities analysis results. The "*" marks statistics for the Russian messages that differ by more than one standard deviation from the English messages.

	DD Average	*DD Median*
Av. persons in English tweet	0.0941	-0.0473
Av. persons in Russian tweet	**0.1133**	**0.0599**
Av. locations in English tweet	0.6708	0.6859
Av. locations in Russian tweet	**0.9021**	**0.8418**
Av. organizations in English tweet	**0.2549***	**0.1649***
Av. organizations in Russian tweet	0.0204	0.0148
Av. unique persons in English tweet	-0.0559	-0.0999
Av. unique persons in Russian tweet	**-0.0394**	**-0.0714**
Av. unique locations in English tweet	-0.0148	**-0.0122**
Av. unique locations in Russian tweet	**-0.0131**	-0.0332
Av. unique organizations in English tweet	-0.0868	-0.0659
Av. unique organizations in Russian tweet	**-0.0118**	**-0.0286**

During the analysis of the most mentioned persons (Table 4) we find that more than half (52,5%) of top-5 named entities in both languages are the same (Figure 2).

Table 4. Exclusive entities in top-5 distribution

	Exclusive English	*English and Russian*	*Exclusive Russian*
Persons	55%	42%	62%
Locations	43%	50%	50%
Organizations	86%	9%	76%

Texts in Russian language contain more location entities and this variable also increases during all types of events. We obtain opposite results for the number of organizations entities — their number in Russian tweets is lower in the background collection and remains lower during all types of events. These observations can be connected with Russian-speaking users who prefer to know more about where something happens but not interested in who made it happen.

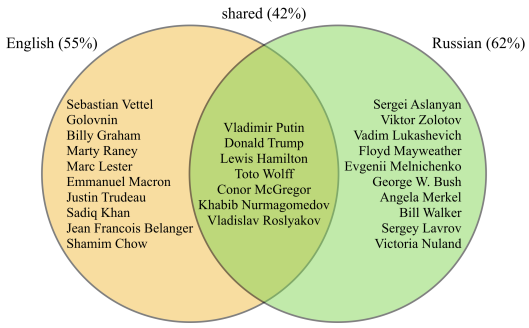

Figure 2. Persons entities distribution

Links and citations

In regular periods (background collection) tweets in Russian contain more links compared with tweets in English. But analysis of events shows this is reversed — Russian-speaking users prefer to share their own impressions, not to spread links (which come mostly from news and similar sites), while the number of links in English tweets usually increases. Tweets in both languages contain a lower number of citations during events than in regular time (Table 5).

Table 5. Links and citations analysis results

	DD Average	*DD Median*
Usage of links (number) in English	**0.4569**	**0.4747**
Usage of links (number) in Russian	0.2194	0.2649
Usage of citations in English	-0.0174	-0.0312
Usage of citations in Russian	**-0.0053**	**-0.0053**

Part of speech

For analysis we choose just nouns and verbs as informative parts of speech for our purposes (Langacker 1987). Part of speech analysis revealed that Russian-speaking users more often use verbs in regular tweets, but during disasters the number of verbs decreases. Actions in crises for Russian-speaking community are less often included in messages. On the other hand, the number of nouns in Russian tweets during events increases (Table 6).

Table 6. Part of speech analysis results. The "*" means a different of more than one standard deviation.

	DD Average	*DD Median*
POS-parsing (verbs) in English	-0.2891	-0.3262
POS-parsing (verbs) in Russian	**-0.0790***	**-0.2899**
POS-parsing (nouns) in English	-0.2247	0.0433
POS-parsing (nouns) in Russian	**0.8731***	**0.8810**

Platform mechanisms

Analysis of platform mechanics including as mentions, retweets, hashtags, and account verification shows that English-speaking users are more familiar with them than Russian-speaking users (Table 7). During events, verified accounts become more active. This is due to the activation of media — more news, analysis, and expert opinions about what happened. This is clear during the Kerch Poly massacre, where the amount of English-speaking verified accounts is much bigger than Russian-speaking while the amount of mentions in English decreases (see Appendix Table 9). This confirms decreasing numbers of mentions and retweets in both languages because users prefer to share their own impressions.

Table 7. Platform mechanics analysis results. The "*" means a different of more than one standard deviation.

	DD Average	*DD Median*
Type of account (name, verification) in English	**0.0328**	0,0157
Type of account (name, verification) in Russian	0.0175	**0.0164**
Dialogue (usage of mentions) in English	-0.4657	**-0.4011**
Dialogue (usage of mentions) in Russian	**-0.3458**	-0.4484
Spreading information (usage of RT) in English	-0.3701	-0.5167
Spreading information (usage of RT) in Russian	**-0.1377**	**-0.4068**
Want to trend (usage of hashtags) in English	**0.2430***	**0.1821**
Want to trend (usage of hashtags) in Russian	-0.0017	-0.0146

Times, numbers

Tweets in Russian contains less temporal references and during events this number further decreases. It shows that Russian-speaking users use Twitter as a real-time platform, to speak about what is happening now. The number of numerical facts (tweets including numbers) is similar in both languages in background collection and during events is similarly increased or decreased, depending on the type of event (Table 8).

Table 8. Times and numbers analysis results. The "*" means a different of more than one standard deviation.

	DD Average	*DD Median*
Av. time reference in English tweet	**0.0160***	-0.0417
Av. time reference in Russian tweet	-0.0100	**-0.0048**
Av. unique time reference in English tweet	-0.0178	-0.0400
Av. unique time reference in Russian tweet	**-0.0053**	**-0.0065**
Usage of numbers (check of using numbers) in English	**0.3284**	**0.0855**
Usage of numbers (check of using numbers) in Russian	0.0660	0.0372

CONCLUSION, LIMITATIONS, AND FUTURE WORK

We have made the first step for comparison of informativeness in social media in English and Russian languages. We found that analyzing tweets about an event in two languages simultaneous can yield substantially more information than in only one language.

Our analysis of named entities allows to capture a larger number of locations (in Russian) and organizations (in English), as well as learning about more people associated with an event (almost 50% of popular people are exclusive to each language). The analysis of messages in Russian indicates an increase in the information content through a decrease in the use of links and quotations, a simultaneous decrease in the number of verbs and an increase in the number of nouns. In future work, we plan to analyze the impact of these parameters on subjectivity in tweets. An analysis of messages in English language revealed the activation of verified accounts, as well as the use of numbers and time references.

Hence, the analysis of only English (or only Russian) tweets would miss a substantial amount of valuable data that can describe the effects of a crisis — detailed names of locations or new names of relevant persons. We will consider the size of the impact of this data in future work.

The main implication from this work is that collecting data in one language during a crisis means losing significant and relevant information. This can only be avoided by collecting information in several languages. While we have not analyzed the location of the users, we assume that users who write messages in the local language have more relevant information about a crisis, from relatives or local media, than users who write messages in other languages.

In the next steps of our research we will add more languages and concentrate in specific classes of disaster. We also plan to use more sophisticated classification models including convolutional neural networks (including LSTM) for filtering tweets that are relevant for an event.

ABSTRACT

During large-scale disasters it is not uncommon for Public Safety Answering Points (e.g., 9-1-1) to encounter service disruptions or become overloaded due to call volume. As observed in the two past United States hurricane seasons, citizens are increasingly turning to social media whether as a consequence of their inability to reach 9-1-1, or as a preferential means of communications. Relying on past research that has examined social media use in disasters, combined with the practical knowledge of the first-hand disaster response experiences, this paper develops a knowledge-driven framework containing parameters useful in identifying patterns of shared information on social media when citizens need help. This effort explores the feasibility of determining differences, similarities, common themes, and time-specific discoveries of social media calls for help associated with hurricane evacuations. At a future date, validation of this framework will be demonstrated using datasets from multiple disasters. The results will lead to recommendations on how the framework can be modified to make it applicable as a generic disaster-type characterization tool.

Keywords

Disasters, social media, hurricanes, data, framework, emergency response

INTRODUCTION

During the 2017 hurricane season, the United States experienced three major hurricanes of Category 4 or greater in less than two months. In August 2018, the Federal Communications Commission published a report on the 2017 Atlantic hurricane season and its impact on communications (Federal Communications Commission 2018). The report documented a disruption of service at 41 Public Safety Answering Points (PSAP) in six states and territories as a result of the three hurricanes. Examples of PSAP infrastructure disruptions included: completely out of service; unable to receive incoming calls; no location identifiers available on received calls; unable to re-route calls; and forced to re-route calls to administrative lines or another PSAP. When a primary means of reaching emergency response organizations fails, citizens resort to using social media as an alternative way to try to reach those organizations (Hughes et al. 2014), as well as publicly posting a message requesting help (Rhodan 2017). However, there are several problems in efficiently collecting these requests by emergency response organizations. For instance, in flooding situations—like those resulting from recent hurricanes in the U.S.—the challenge is that as citizens turn to social media to request evacuation help, official emergency response organizations have limited knowledge or experience of information processing in this new media environment (Hiltz et al. 2014; Hughes and Palen 2012; Stephens, Robertson, et al. 2018), especially for filtering this big crisis data to extract relevant, serviceable calls for help (Castillo 2016; Purohit et al. 2018). Furthermore, the public believes official agencies are monitoring social media (American Red Cross 2011), but that is often not the case as most agencies lack the available resources to dedicate to performing this emerging function while simultaneously fulfilling their other responsibilities (Peterson 2015).

In this paper, we use past research on social media use in disasters combined with first-hand emergency response experiences, to develop a framework useful in identifying patterns for the social media posts when citizens issue calls for help. We identify the importance and need for incorporating practitioner experience, knowledge, and feedback into computational methods for information filtering. We also discuss how future research can validate our framework, initially using existing data from past hurricanes, and then extending into other forms of disasters where evacuations are needed. Our goal is to systematize this chaotic process to help emergency response officials make sense of near-real-time data and supplement boots-on-the-ground evacuation efforts.

The rest of the paper is organized as follows. We first describe prior work on social media use in disasters, especially regarding calls for help, and review existing frameworks for processing social media. We then propose our framework for identifying and studying evacuation-related calls for help.

SOCIAL MEDIA USE IN DISASTERS

In the past two decades, research on social media use in disasters has significantly grown (Palen and Hughes 2018; Reuter et al. 2018). With social media technologies (e.g., Twitter, Facebook, Reddit, Snapchat, and Nextdoor), and the prominent use of mobile devices, people have many options for receiving information and even participating in disaster-related conversations (Hughes et al. 2008; Murthy and Longwell 2013; Palen and Liu 2007). Citizens are no longer reliant on official emergency information sources to disseminate urgent information because individuals can function as citizen journalists (Sutton et al. 2008). Meanwhile, emergency response organizations are seeking ways to effectively use social media in their response efforts, which includes searching social media channels for information that could be helpful in the formal response as well as monitoring for misinformation and false rumors that need correction (Denef et al. 2013; Hughes and Palen 2012; Latonero and Shklovski 2011). This type of monitoring can be challenging though, because emergency response organizations often lack the resources (staff and tools), expertise, and managerial support to do the task well (Hughes and Palen 2012; Plotnick and Hiltz 2016). The research presented here hopes to at least partially address some of these challenges by making it easier for emergency responders to find calls for help in the deluge of social media following a disaster event.

Social Media Calls for Help

While we know a considerable amount of literature concerning general uses of social media during disasters (Palen and Anderson 2016), the 2017 Hurricane season experienced a rise in the number of times that average citizens posted messages on social media requesting evacuation and other types of help—a phenomenon we refer to as a *call for help*. This is not necessarily a new practice (Hughes et al. 2014), but the idea of a public call for help is receiving attention from federal agencies like the Department of Defense and FEMA, as well as being seen in the recent research funding from the agencies such as U.S. National Science Foundation. In this paper, we further advance the notion of a *consequential call for help*, defined as a social media post by citizens in a disaster zone resulting from official public safety communication channels such as 9-1-1 in the U.S. becoming overloaded or disrupted as a result of the disaster impact.

By examining social media content, we propose to better understand how citizens interact with the evacuation practices communicated by emergency response organizations. While researchers have shown that private social media can be helpful in understanding what hurricane and flooding-related consequential calls for help look like in terms of images and text (Smith et al. 2018; Stephens et al. 2018), it is important to better understand what can be accomplished using public data from social media platforms like Twitter. Determining meaningful patterns and drilling down to specific disaster-related content, can be challenging using public data (Imran et al. 2014a; Li et al. 2015; O'Neal et al. 2018; Purohit et al. 2014). But once researchers and organizations optimize existing analytical tools for mining such public social data, it will be essential to have a robust methodological framework to systematically improve decision making for response to calls for help.

Getting access to private social media data is difficult, and by using public data, emergency response officials can call upon non-emergency management personnel and citizens to digitally converge and help make sense of social media data. Even though these digital volunteers may have no formal role in the evacuation process or direct contact with emergency response officials, they represent a powerful force that can be ready to serve in times of crisis (Hughes and Tapia 2015; Purohit et al. 2016; Starbird and Palen 2011).

Existing Frameworks and Tools for Near-Real-Time Social Media Analysis

There has been extensive research on social media analytics in the past decade and consequently, several frameworks and tools exist in the literature (Imran et al. 2015; Li et al. 2017; Poblet et al. 2018).

A systematic framework is required to computationally process big social data streams during disasters. Therefore, recent advancements in the design of real-time social stream analytics systems for disaster informatics applications have shown much promise (e.g., CitizenHelper (Karuna et al. 2017), AIDR (Imran et al. 2014b), Twitris (Sheth et al. 2014), CrisisTracker (Rogstadius et al. 2013), Twitcident (Abel et al. 2012)). The primary foundation of these frameworks is the use of machine learning and data mining, which may sometimes be erroneous in descriptive, predictive, and prescriptive modeling due to the lack of generalization of methods across the types of disaster events, languages, and regions. A gap in the design of such frameworks—one that we seek to fill—is that they do not effectively leverage human knowledge. Such knowledge can provide the context for information processing and can be extremely advantageous for improving the efficiency of near-real-time social media analytics during evacuations. We propose the need for utilizing human-in-the-loop methods for machine learning and data mining approaches such as active learning with concept drifts and the hybrid systems of human-knowledge driven rule-based learners and the conventional data-driven learners. Such human knowledge-driven methods would improve the capturing and processing of rapidly changing nature of the concept of relevant information in the data stream as the disaster evolves.

DESIGNING A PRACTITIONER KNOWLEDGE-DRIVEN EVACUATION ANALYTICS FRAMEWORK

We begin this framework development by identifying distinguishing features of social media content from both citizens and emergency response organizations. This framework was designed with the assumption emergency response organizations are aware their region could be impacted by the pending hurricane and have the ability to collect and monitor hurricane-related social media data. We propose using the Twitter Search API to access information about evacuation-related tweets. We focus on one social media platform, Twitter, to keep our demonstration of the framework manageable. We hope to expand our framework to include other social media platforms in the future. Although images can be helpful in analytics, and research literature has begun to determine how these classifiers will work (Stephens, Li, et al. 2018), we focus solely on social media text to avoid scope-creep in our proposal. With a goal of using this framework in near-real-time situations, we outline a model consisting of six major stages: 1) ***planning***, 2) ***collecting*** data, 3) ***filtering***, 4) detecting ***location***, 5) ***re-filtering*** based on changing disaster dynamics, and 6) sorting data into degrees of ***relevance*** to assist with emergency response. We begin by describing activities that happen before the disaster strikes.

Planning

Planning is an integral part of any disaster preparation. There are two key considerations in our framework that must be accomplished during the planning stage: 1) determining meaningful times for data collection and analysis and 2) identifying keywords for filtering.

However, before activity can begin, if research is overseen by an institutional review board (IRB) as part of a data collection and analysis process, getting that oversight process in place before the disaster strikes is important. Several scholars from the National Institute of Environmental Health Sciences Working Group have created helpful documents to assist researcher/practitioner collaborations in working with their IRBs (Packenham et al. 2017). Having conversations concerning how every member of the team will benefit from the intense near-real-time effort is an important part of making these partnerships sustainable.

Determine Meaningful Times for Data Collection and Analysis

One helpful thing about a disaster that develops over time, as opposed to an immediate threat, is the time people have to make decisions and prepare (Tierney et al. 2001). However, with this time also comes changing conditions—disaster dynamics—and that means emergency responders need to both predetermine and contingency plan for a meaningful time period for near-real-time data collection. This preplanning is important for emergency response personnel who are monitoring social media data because the amount of data will continue, and possibly increase with changing conditions. There needs to be time-points where some members of the team stop monitoring social media and spend time analyzing what they are seeing. This represents a meaningful snapshot that can be fed into the monitoring process to create a dynamic system to identify calls for help.

Figure 1 provides an illustration of how some virtual teams are analyzing social media data and feeding findings back to emergency response personnel. The gray circle represents a time-point during the disaster when data collection ends and analysis begins. The black arrows represent subsets of data created from adjusting the relevancy level of the original dataset. The Emergency Operations Center and/or assigned liaison receive findings from the virtual team and decide whether the information is suitable for communicating to the physical team in the field. This reporting structure is the demarcation between virtual and physical teams and ensures normal operating procedures are not disrupted.

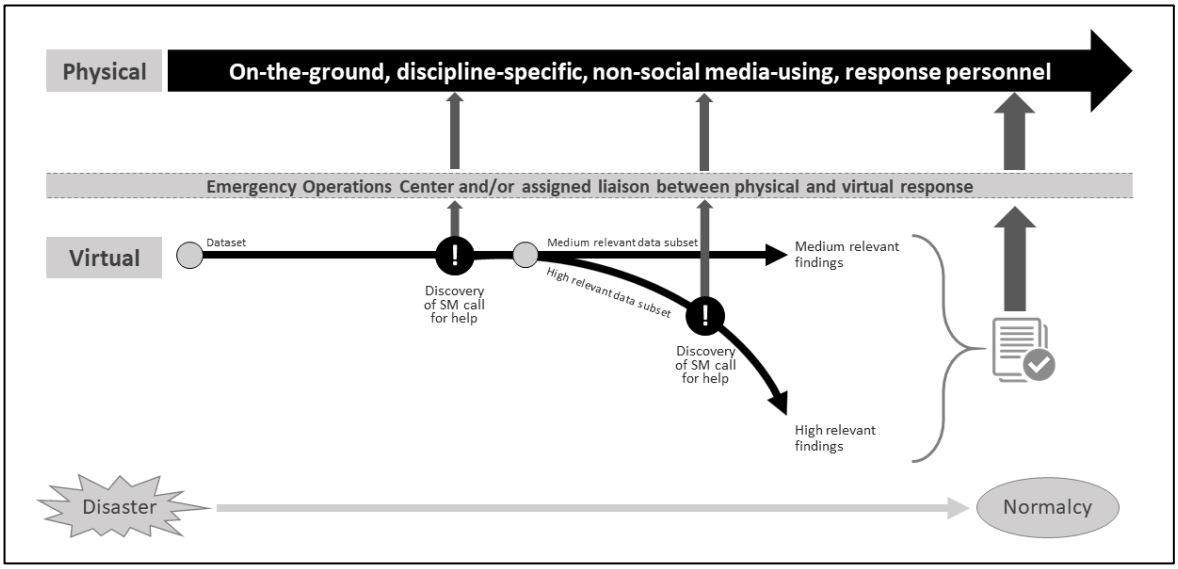

Figure 1: Example of How Social Media Findings Reach Emergency Responders through a Liaison

Identify Keywords

The second major task to accomplish before a disaster strikes is to determine keywords that have meaning for the respective emergency support function associated with the pending disaster. Table 1 illustrates examples extracted from a list of evacuation-related keyword/search terms our team generated by searching FEMA documentation, referencing past disasters that involved evacuations, and consulting emergency management officials. These keywords have been used to find relevant information in past events. Based on our research, these should form the starting point for a search for evacuation-related social media calls for help. Note that these keywords reflect a combination of transportation-related concepts, as well as descriptive terms helpful when searching public data for relevant indicators of calls for help.

Table 1. Keyword Sample Proposed for an Evacuation Analytics Framework

alternate	evacuate	junction	relocate
blocked	fuel	lane	route
closed	gas	mandatory	shelter
contraflow	highway	overflow	traffic
detour	interstate	parking lot	vehicle

We believe generating a large quantity of evacuation-related keywords, communicated either by emergency response organizations or by citizens or a combination of both, will hold a high possibility of discovering calls for help during hurricane evacuations. To strengthen results from this methodological framework, we recommend reviewing evacuation-related social media messages authored by emergency response organizations during past hurricanes to locate additional keywords.

Data Collection

After the planning stage, data collection begins. Sources for obtaining social media data during a disaster event include social media platform APIs (such as the Twitter Streaming API) or data aggregation tools. These sources are searched using high-level terms or hashtags (or location bounding boxes for the affected region) that capture a broad spectrum of data, which might be relevant to the event. For example, common terms for a hurricane include the name of the hurricane (e.g., Hurricane Harvey) and the locations affected by the event (e.g., Rockport, Fulton, Houston). As the event unfolds, these terms are often updated. The retrieved data contains a variety of metadata along with each social media message, including the message content, posting time, geolocation

coordinates if available, and the author profile information. The collected data is then stored in a database or a data file for later filtering and analysis.

Filtering

This step of the framework takes the data collected in the prior step and filters the data using the list of evacuation-related keywords that were determined in the planning stage. To filter the data, a computer program can be used to extract the social media messages containing the keywords. This step produces a subset of data that is more manageable and more likely to be related to an evacuation. A hurricane event usually produces far more information than can be examined manually. Therefore, the filtering step is important for narrowing down evacuation-related information, including calls for help, required to be examined more closely.

Location Detection

The next step in our framework is to associate a location with each message (when possible). Having a precise location for a call for help is essential provided the goal is to physically rescue the individual(s) or to provide evacuation-related information relevant to their location. But obtaining location information can be challenging when using public social media. A direct way to get location data is through geolocation metadata automatically embedded in the tweet data, however, geolocation data is not required and most messages do not contain it. Location can also be inferred from user profile data, social connections, or the content of the message (Stock 2018). Sometimes location data is manually entered by the social media end user. For example, during the 2017 hurricane season, some people posted their own address publicly, or a friend or family member did this for them (Stephens, Robertson, et al. 2018). For example, messages like this occurred:

> *My mother needs help. 3390 ISCRAM Lane. 2 older adults, 1 dog.*

There could be considerable privacy issues with this practice, but it appears that some people do not consider that a barrier when they feel their life is in jeopardy. Two challenges are associated with this process of manually sharing location data: redundancy and closing the loop (Smith et al. 2018). It is quite possible for multiple people to post the same location data either without or with full knowledge that these are redundant posts. Another challenge found in coordinating these types of rescues is that once someone was rescued, there is no easy way to close the loop (Smith et al. 2018). This challenge provides further evidence of the importance of emergency response organizations, or the dedicated resources assisting them, to centralize findings and communicate to responders in the field. Responders in the field are emergency response organizations' ground truth – confirming or delegitimizing social media calls for help. Therefore, in the process of including location data into the decision-making process, people monitoring social media should pay careful attention to redundancy, and look for alternative verifying information suggesting that people have been rescued.

Re-Filtering

In this step, we re-evaluate the way the data has been analyzed and filtered up to this point, incorporating insights based on changing disaster dynamics and the results of the location detection step. Figure 1 shows how it is not uncommon to have multiple teams analyzing social media, and this re-filtering step is a place in the framework where these teams can inform and shape the social media strategy for all teams. Re-filtering allows different views on the collected data for creating the task-specific filtered sets for different functions of the response stakeholder teams. This is also an opportunity to incorporate practitioner expertise into the filtering and analysis. Unlike most other analytics frameworks for social media in disaster, this framework seeks to leverage human knowledge (especially that of practitioners) and the re-filtering step is an important place where this can happen.

Message Relevancy

When combining the filtering process with location detection, the next step in our evacuation analytics framework invites people monitoring social media to assign relevancy criteria to each piece of data. Once again, the goal is to simplify the decision making during the chaos of a disaster, so we propose using a simple four-number Likert Scale rating system to help rate the quality of the calls for help data as done in the prior work (e.g., rating the serviceability characteristics of social media requests (Purohit et al., 2018)). The highest quality call for help is assigned a 3 and contains both evacuation-related key words and location information. Next, if the location information is missing, but the key words still indicate the tweet is evacuation related, it is assigned a 2. If there

is no location information and the key words are not clearly related to an evacuation need, it is assigned a 1. Finally, for all data that does not seem related to an evacuation, it is assigned a 0. Table 2 explains this rating system succinctly. The results of this step can then be aggregated and reported to the relevant emergency response organization.

Table 2: Criteria for Rating Filtered Twitter Data

Rating	Relevancy	Criteria
3	[HIGH] More accurate	Evacuation-related and location identified
2	[MEDIUM] Moderately accurate	Evacuation-related
1	[LOW] Less accurate	Evacuation-related uncertainty
0	No relevancy	No correlation to evacuation

The Framework

Our proposed framework (described above) identifies and isolates actionable intelligence associated with evacuations. This framework could become a pre-emptive strategy for implementation in future advance notice disasters, such as hurricanes, by practitioners. Figure 2 provides an overview of the steps in our evacuation analytics framework.

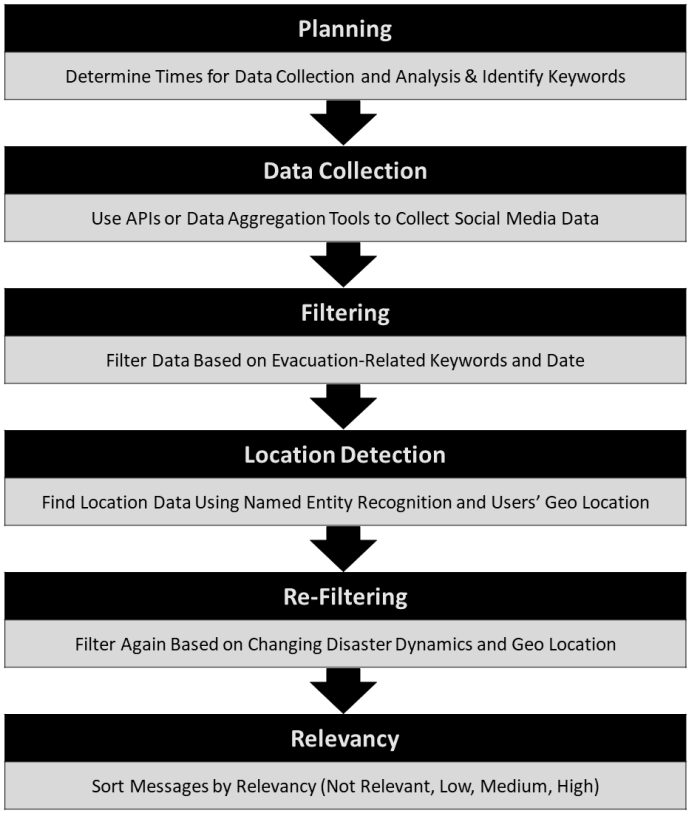

Figure 2: Framework for Extracting Evacuation-Related Social Media Content

VALIDATING THE PROPOSED FRAMEWORK

For validating the framework developed here, we propose using an approach similar to one used by Banujan, Banage, and Paik (2018). To ensure we have captured the most crucial, indispensable keywords that would be advantageous in extracting meaningful data from Twitter, we plan to compare three different social media disaster datasets related to hurricane evacuation. Also, we will perform a comparative analysis between the filtered results by consolidating all three dataset findings. This should surface data that identifies and describes common themes that will shed light on human behavior during hurricane crises. These findings may also aid emergency response organizations to take pre-emptive communication measures in future disasters, during the pre-crisis phase, to

disseminate time-sensitive emergency messaging.

However, the question remaining is whether citizen reports on social media during evacuation periods can be gathered, consolidated, analyzed, categorized, and verified for accuracy in time to be helpful during the same evacuation period. Conducting a comparative study as suggested in this paper should aid in answering this question. Specifically, applying the integrative methodology to the datasets should confirm whether or not this is plausible.

DISCUSSION

In this research, we propose a systematic framework that can be used to streamline a near-real-time public social media strategy to identify calls for help. Our review of the literature combined with the knowledge of emergency responders identified the importance of integrating social media planning—i.e., key word identification—into the disaster preplanning processes. Furthermore, by establishing multiple teams of social media monitors and analysts, these groups can more quickly identify calls for help, determine location data, rate the overall data, and share the prioritized data with responders in the field. This framework may seem overly simplistic. However, considering that social media has often been the afterthought of an emergency response, this practitioner knowledge-driven analytics framework can help systematize the inclusion of this important publicly communicated data within emergency response organizations' efforts in responding to a disaster.

Future Directions & Conclusion

The next step for this research, and one in which we are currently engaged, is to validate our framework using multiple hurricane data sets. Once this step is complete, we can see if with different keywords, the framework could be successfully applied to other disaster types. It will be important to ascertain if the framework can be applied to both advance-notice and no-notice disasters. It is also prudent that non-evacuation related social media calls for help are also captured, categorized, and studied to influence future mitigation efforts in the respective emergency support function areas.

We hope findings from studying multiple datasets—the keywords, differences, and similarities—will better position practitioners in future hurricane situations, as well as in other types of disasters. Testing and implementing this proposed framework for discovering actionable social media data pertaining to disasters could aid agency policy makers in adopting and promoting more integrative approaches to rescuing people. Results may also provide practitioners, especially those advocating to include social media, further evidence concerning how to retrieve, validate, and understand near-real-time social media data. This could assist in decision making as well as strengthen confidence in social media. It will take considerable research efforts, but these results may be the catalyst for addressing this need (Peterson et al. 2018). Finally, results may shed new light on this underexplored, critical area of the response phase of emergency management. These efforts have the potential to further enhance the value of preparing, responding, and recovering from emergencies by embedding social media within various constructs/organizational structures.

ABSTRACT

Limited research has studied how citizens' perspectives as end-users can contribute to improving the usability of disaster apps. This study addresses this gap by exploring end-user insights with the use of a conceptual disaster app in the New Zealand (NZ) context. NZ has multiple public alerting authorities that have various technological options in delivering information to the population's mobile devices; including social media platforms, apps, as well as the Emergency Mobile Alert system. However, during critical events, the multiplicity of information may become overwhelming. A disaster app, conceptualised in the NZ context, aims to aggregate, organise, and deliver information from official sources to the public. After the initial conceptual design, a usability inquiry was administered by interviewing members of the public. Partial results of the inquiry show that the public's perspective has value; in the process of understanding the new user's viewpoint, usability highlights and issues are identified.

Keywords

Usability inquiry, mobile application, disaster, alerts, public perspective

INTRODUCTION

Multiple apps exist to prepare and warn the public for disaster events. These include built-for-purpose disaster apps as well as social media platforms used by authorised agencies. Alerts and warnings can come from multiple sources through various platforms (Wright et al. 2014). However, during critical events, the multiplicity of information may become overwhelming for the user. Information overload can occur when human capacity can no longer process the torrent of data arriving (Stratmann and Boll 2016). To circumvent such difficulties, efforts have been made to create apps that curate emergency information needs. Disaster apps have been developed to have the capability to collate and disseminate information (Bachmann et al. 2015; Tan et al. 2017).

Disaster apps have the potential for improving the public's preparedness and response, but these technologies also pose risks if they are not appropriately designed in the context of its users (Tan et al. 2017). However, only a few studies on disaster apps have addressed the usability of the apps' interfaces (Romano et al. 2016; Tan et al. 2017).

The literature on the usability of technologies for disaster situations usually focus on responders as intended users and not the general public; for example, studies with police (e.g. Kuula et al. 2013) and firefighters (e.g. Prasanna et al. 2013). Only a few studies evaluate disaster technology applications from the perspective of civilians as the targeted users (Tan et al. 2017). Furthermore, most usability studies on mobile apps look into products used in casual environments and not in disaster contexts. For example, on social media apps (e.g. Hoehle et al. 2015), mobile banking apps (e.g. Mohan et al. 2015), and health apps (e.g. Schnall et al. 2016).

Considering these gaps, this research project seeks to explore how the insights of the citizens as users provide valuable perspectives in understanding and enhancing the usability of a disaster app. The research project employs usability inquiry, using interviews with eighteen participants, to investigate the users' perspective on a New Zealand (NZ) based conceptual disaster app.

The paper is structured as follows. The paper starts with a brief background on past studies of usability and disaster apps. Then we introduce the context and rationale behind our NZ based conceptual app. The methodology for the usability inquiry follows. Initial and partial results of the study are then presented. Finally, the paper concludes with the next steps for the research.

DISASTER APP USABILITY

It is important that users can effectively interact with apps; more so during crises, the apps should be usable even when users are under stress (Sarshar et al. 2015). Disaster apps must address the usability challenges of mobile interfaces and also consider the usability issues for safety-critical systems.

Mobile interfaces have their own set of usability challenges; specific issues, among others, include small screen size and the mobility of users (Gomez et al. 2014; Zhang and Adipat 2005). Using mobile apps may require more cognitive load from users; hence, mobile app usability models must consider new dimensions to account for the mobile app context (Harrison et al. 2013). Hoehle and Venkatesh (2015) conducted a prominent study on mobile app usability; they argued extensively for a differentiated mobile app usability model that diverges from software and website models. Analysing past literature on mobile app usability, as well as industry guidelines, Hoehle and Venkatesh (2015) proposed a mobile app usability model that comprised of six factors: app design, app utility, user interface (UI) graphics, UI output, UI input, and UI structure. However, literature that extended from this study has only been implemented on social media apps (e.g. Hoehle et al. 2015).

The lack of usability of crisis-related technological products can lead to compromised safety of its users (Nurse et al. 2012). Individuals can act differently when under pressure (Hiltz et al. 2010). In a review of safety-critical systems literature, supporting the human experience is essential to usability. Five recommendations are highlighted for disaster-related technologies: minimise user memory workload, use simple graphics and structure, avoid information overload, provide contextualised and updated information, and maintain a degree of automation but still keeps the user in the loop (Kwee-Meier et al. 2017). Understanding users and their decision making qualities in stressful conditions are essential when designing technologies for disaster management (Hiltz et al. 2010). User studies are valuable in guiding the design of safety-critical systems (Kwee-Meier et al. 2017).

Usability studies on disaster apps

As it applies to mobile apps and technologies for safety-critical systems, disaster apps should carefully consider usability. A recent study by Tan et al. (2018) tested and re-developed the Hoehle and Venkatesh (2015) model. Using survey responses from 270 actual disaster app users, Tan et al. (2018) proposed a usability-continuance model that fits the disaster app context; five factors were found to affect users' perception on whether to continue or abandon disaster apps: (1) app utility, (2) app dependability, (3) UI output, (4) UI input, and (5) UI graphics.

Before Tan et al.'s (2018) study, only a few papers had evaluated the usability of apps that are built specially for disaster purposes. Sarshar et al. (2015) investigated the usability of two disaster apps, GDACSmobile and SmartRescue; their study highlighted the importance of considering human-computer interaction (HCI) in the design of disaster apps. Furthermore, Sarshar et al. (2015) suggested that to have a deeper understanding of the usability of disaster apps, future research should investigate various usability testing methods.

Moreover, other studies on disaster apps focus on apps' functionalities and only briefly mentions engaging the users to assess usability (Tan et al. 2017). Often, user testing is employed either as a means to prove functional effectiveness or as a step to improve the app's functionality (e.g. Kaufhold et al. 2018; Kolathayar et al. 2018). However, Estuar et al. (2014) argued that engaging users should not just be for assessing functionality; understanding the user experience can help make an app's interface relevant to intended users. Reuter et al. (2017) encouraged the use of participatory methods with users to capture their perspective in the app design.

CONCEPTUALISATION OF A DISASTER APP IN NEW ZEALAND

This paper showcases how gathering user feedback through a usability inquiry can provide valuable insights in enhancing the usability of a disaster app. To begin, we introduce the app under study. This section discusses the rationale behind the conceptualisation of a disaster app in NZ. The disaster app concept is to aggregate the information available from authorised agencies about a crisis or a disaster and deliver it to the public through a simple platform.

In NZ, multiple agencies have the mandate to warn the public on actual or suspected threats, risks, hazards or emergencies (Ministry of Civil Defence and Emergency Management 2017). The Ministry of Civil Defence and Emergency Management (MCDEM) operates the National Warning System, which is the primary channel to communicate national level warnings to local Civil Defence and Emergency Management (CDEM) agencies. The members of sixteen regional CDEM Groups have the responsibility to provide official alerts, including calls to action, to their communities for hazards. Also, monitoring agencies such as GNS Science (geological survey) and the MetService (meteorological agency) also provide public alerting related to their respective hazards (Wright et al. 2014). Moreover, the NZ Police, Fire and Emergency NZ, NZ Transport Agency, Ministry of Health, and Ministry of Primary Industries also provide alerts related to their respective jurisdictions (Ministry of Civil Defence and Emergency Management 2017).

NZ CDEM collectively uses a multi-channel public-alerting approach, to ensure that many people can receive information, with redundancy. There are at least twenty public alerting platforms for these agencies to communicate to the public; these include billboards, radio announcement, cell broadcast, emails, loudspeakers, websites, etc. (Ministry of Civil Defence and Emergency Management, 2018). Multiple technological options exist to deliver alerts to the public through their mobile devices; these include apps, SMS-text message, phone calls, the use of social media platforms, and broadcast messaging (Wright et al., 2014).

Use of social media and apps in public alerting in New Zealand

Many of the NZ public alerting agencies use social media platforms to communicate (Wright et al. 2014). The public can access social media information through websites as well as through respective apps in their mobile devices. Through social media, the agencies communicate not only alerting messages but can also include everyday content such as preparedness advice (Wright et al. 2014).

However, in NZ the use of social media platforms have limitations. Users have to opt-in through individually following various accounts and have to check different streams and sources to receive updates (Wright et al. 2014). The presence of the agencies on popular social media platforms are not consistent. For example, not all NZ public alerting agencies have Facebook or Twitter accounts (Wright et al. 2014). A review of twenty-four alerting authorities on Facebook and Twitter shows that although most have official accounts on both social media platforms, some may have only one or the other, or none at all (Table 1 shows a cross tabulation). Another limitation of social media platforms is the reliance on third-party social media algorithms for providing information (Wright et al. 2014). Social media content does not necessarily come in chronological order (Biersdorfer 2016). Facebook prioritises posts from families and friends rather than organisations (Bromwich and Haag 2018).

Table 1. NZ public alerting agencies' social media presence as of 2018

		Facebook		Total
		Yes	No	
Twitter	Yes	18	2	20
	No	3	1	4
Total		21	3	24

When it comes to the use of mobile apps, three mobile apps are currently available in NZ that are affiliated with public alerting agencies. The GeoNet app is part of the geological hazard monitoring system in NZ; it is an app that allows the public to receive notifications for earthquakes and bulletins on volcanic activity (GeoNet n.d.). The MetService app provides information on weather conditions and forecasts as well as deliver severe weather warnings and watches (MetService n.d.). The Hazard app, developed and distributed by the NZ Red Cross, is a multi-hazard app endorsed and used by multiple CDEM groups (New Zealand Red Cross 2015).

Similar to the limitation of social media channels, mobile apps are opt-in platforms (Wright et al. 2014). Individuals have to consciously choose to download different apps to receive varying details of information on particular hazards that interests them.

With rapid changes in technology and the new media ecosystem, over-alerting can create issues in how the public responds to alerts (National Academies of Sciences Engineering and Medicine 2018a). During a crisis, users can encounter difficulties in making sense of too much data; information overload can occur when human capacity cannot keep up with the torrent of data arriving (Prasanna et al. 2013; Stratmann and Boll 2016). Aside from social media and other technological platforms, public alerting authorities can also push high-priority alerts via the Emergency Mobile Alert (EMA) system.

Emergency mobile alert in New Zealand

NZ had recently adopted the EMA system in 2017; which allows authorised agencies to release alerts via cell broadcast technology (Ministry of Civil Defence and Emergency Management 2017). Other countries have similar systems; for example, the Wireless Emergency Alert (WEA) in the United States of America (Bean et al. 2016), NL-Alert in the Netherlands (Gutteling et al. 2017), and Cell Broadcast Service (CBS) of Taiwan (Chang and Chen 2018).

The emergency alerts, different from text messages, do not cause network congestion as they are distributed through a geo-targeted wireless channel (Bean et al. 2016; Chang and Chen 2018). Moreover, the alert messages delivered to mobile phones are distinct from standard messages; they are uniquely displayed on devices accompanied by distinct tones and vibrations (Bean et al. 2016).

How an individual receives the message can affect how the individual responds to the threat (National Academies of Sciences Engineering and Medicine 2018b). During a crisis, users can encounter issues; anxiety, fatigue, and other stressors can hamper information processing (Stratmann and Boll 2016). The way information is processed, stored, and displayed can affect users (Prasanna et al. 2013). Technology for disasters must be efficiently designed to support the intake of information in stressful conditions.

Multiple studies have looked into the effectiveness of emergency alert messages; including studies on the technical capabilities (e.g. Chang and Chen 2018), on message content and style (e.g. Potter 2018), on citizens' response to messages (Gutteling et al. 2017). However, an understudied area is on how users interact with the alert message. The typical emergency alert message (see Figure 1) is delivered through a pop-up notification mechanism in the users' smartphone (Falcão et al. 2018). The simple message dialogue may be suitable to convey a single message during an unchanging situation, but multiple messages over a complex scenario may require a different manner of presentation to help the users' understand the situation (Iannucci et al. 2016).

Figure 1. Emergency alert example (Theunissen 2017)

Another interface issue, as encountered in the 2017 test broadcast in NZ, is the disappearance of the alert message when users tap on to the notification on their smartphones (Ministry of Civil Defence and Emergency Management n.d.). Although not identified in academic literature, smartphone users have anecdotally raised interface and retrieval issues for emergency alerts. Table 2 lists some of these anecdotes from users on online forums.

Table 2. Anecdotes on disappearing alert messages

Anecdotes	Forum
Last night I got an emergency alert. I didn't have my glasses on and as I reached for the phone, I lost the message. How can I find that message? Thanks. (2014)	Apple Discussions
I imagine most people push OK in a panic to stop the loud sound, and then are left wondering what it was exactly that was so important. (2014)	Android Stack Exchange
Where are emergency alerts (WEA) stored on the iPhone? One popped up and disappeared before I could read it. (2013)	Apple Discussions

Further research is needed to make the interface more intuitive. As technologies change, so do user behaviour and public response; continued research on human interaction with alert messages is critical (National Academies of Sciences Engineering and Medicine 2018a).

App conceptual design

The app used in this study, currently named 'NZ Alerts', aims to address the issues above. The app aggregates information from official sources and authorised alerting agencies into one platform; providing means to find critical information segregated from the noise of multiple media sources and other non-hazard related information. The app will collect, store, and display information that is made public by authorised agencies; these include preparedness information, social media messages, and EMA broadcasts.

The initial expectations for the app are (1) to lessen information overload by consolidating messages from various official social media sources and (2) to address the emergency alert interface issues by collating, storing, and displaying emergency alert messages for users. Also, the app provides preparedness information from reliable sources. The app's main features are partitioned into three screens (See Figure 2): home screen, prepare screen, and alert screen.

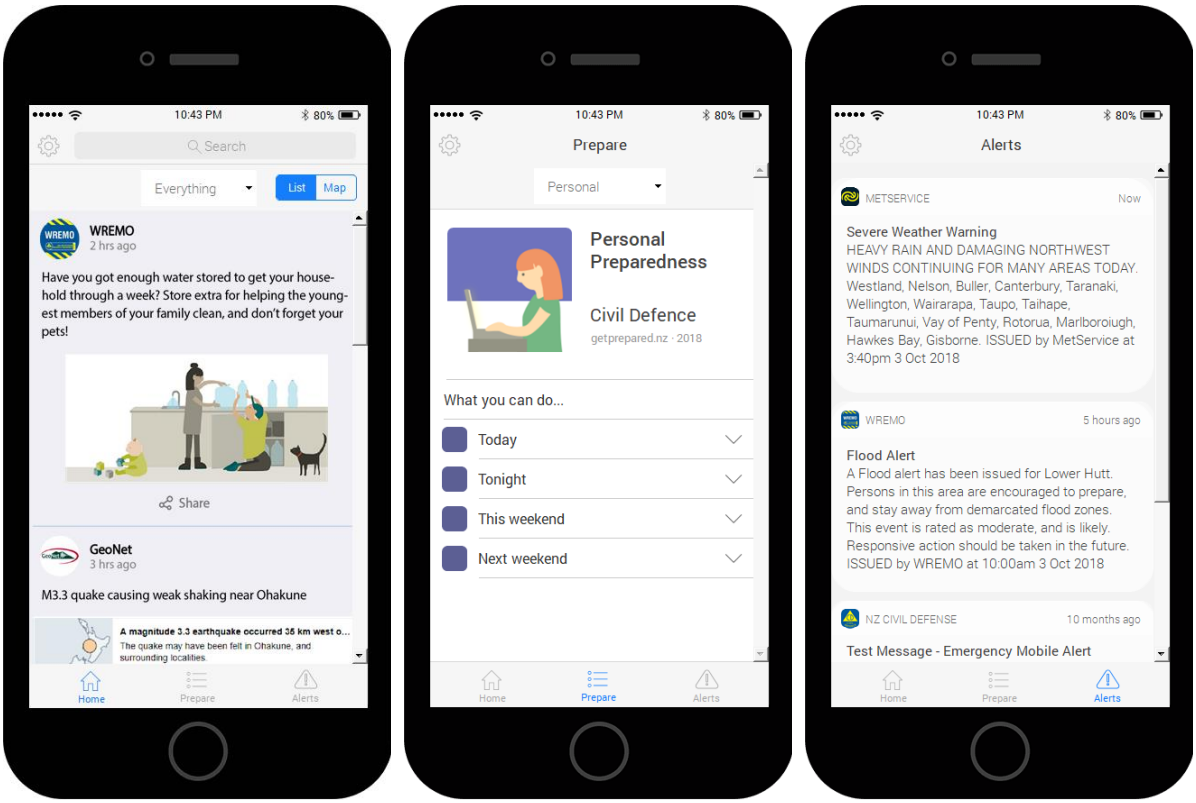

Figure 2. Screenshots of NZ Alerts app

Home screen

The home screen displays a real-time feed, harvesting content from participating authorities' social media channels. By collating information from official sources, it reduces the noise that may be encountered when using social media apps. In social media sites, posts on a users' feed can contain mundane topics that may become noise when seeking information about hazard events; separation of credible and reliable information from trivial ones is needed (Imran et al. 2015).

Prepare screen

Most of the apps in crisis informatics literature focus on the response and recovery stages (Tan et al. 2017). However, there is potential in utilising new media tools to encourage preparedness for a crisis (Veil et al. 2011). In addition to delivering up-to-date information from official agencies, the app will provide credible preparedness information. The prepare screen will be an offline repository of emergency preparedness information which users can access at any time.

Alert screen

The way information is processed, stored, and displayed can affect users' decision-making capabilities during critical scenarios (Prasanna et al. 2013). Users can make errors when under stress which may cause them to dismiss alerts before reading the information. The alert screen will collate, store, and display official emergency alert messages from authorities; allowing users to retrieve the information as needed.

With the combination of the above described three screens, the NZ Alerts app is expected to be a 'one-stop-shop' that aims to provide preparedness and response information on hazard events to the public living in NZ. It is essential that this initial app concept will be aligned with the expectation of the end-users when developed further to form a fully-fledged mobile app. Users can offer perspectives that can diverge or converge from the intended design; providing value in the design practices for disaster technologies (Petersen et al. 2015). The next section discusses the methods employed in this study to gain the users' perspective.

METHODS

The human-centred design is an important aspect in the field of disaster management (Fischer and Klompmaker 2012). As part of the user-centred approach taken in this study, inputs from potential users were gathered to obtain their perspective on the NZ Alerts app. A usability inquiry was conducted with the aim of recognising the new users' needs and understanding of the app. Inquiry methods directly involve talking to end-users; techniques include surveys, focus groups, or interviews (Folmer and Bosch 2004; Zapata et al. 2015). For this study, we conducted semi-structured interviews with eighteen participants. Before the recruitment and data collection, the usability inquiry went through an ethical approval process for human participation.

Participant recruitment

The target user for the app is an iPhone user living in NZ, aged eighteen or older; with or without previous experience in using a disaster app. The recruitment strategy was applied in two stages. First, we recruited participants from an earlier disaster app survey. The survey, of which had 562 participants, contained a follow-up question that asked whether the respondents would be willing to be interviewed for a usability study. We invited the willing respondents (n=89) to participate in the usability inquiry; of which nine people volunteered to be interviewed. We then recruited more participants by posting flyers in two university campuses. Another nine individuals participated until the interview data collection reached a saturation point.

Data collection

We first conducted two pilot interviews to refine the questions and the interview flow. All the interviews were conducted in-person only in Wellington, NZ; due to researchers' limitations. The interviews were semi-structured and had three parts (See Table 3). The interviews involved users interacting through each screen of the mock-up interface, and then the interviewer asked core questions and supplementary questions on each part. After interacting through the entire app, the participants were also asked core questions about the overall app in the particular context of a crisis scenario. Each interview took between 40 to 90 minutes.

Table 3. Interview guide core questions

Interview core questions
1. Demographic and participant information
2. Core questions for each screen (after user interacts freely with each screen)
a. Do you like the look? What comments or issues do you have?
b. Do you like the controls? What comments or issues do you have?
c. Is it intuitive to navigate around the screen? What comments or issues do you have?
d. Do you like how the information is presented? What comments or issues do you have?
e. Do you like the words and icons used? What comments or issues do you have?
3. Core questions for the app
a. In a crisis scenario, do you think the design of the app is appropriate?
b. In a crisis scenario, do you think the app will provide you with the needed information?
c. Given that the app may be used during a crisis, would you change how the app looks?
d. Given that the app may be used during a crisis, would you add/remove anything?
e. What would make you uninstall the app?

Data analysis

We used thematic analysis to examine the eighteen interviews. Thematic analysis is a 'method for identifying, analysing and reporting patterns (themes) within data', and a theme 'represents some level of patterned response or meaning within the data set' (Braun and Clarke 2006 p. 80). The study followed Braun and Clarke's (2006) 6-step process. The first step is familiarisation with the data starting with the transcription of the interviews. The second step is generating topics; for this study, we used a theoretical approach by using Tan et al.'s (2018) usability factors as the initial topics: app utility, app dependability, UI graphics, UI output, and UI input. The third step is searching for themes around the initial topics. The fourth step is reviewing themes; this involves refining the themes by collapsing and combining themes as necessary. The fifth step is defining and naming themes. The sixth step is to report the results. We discuss the initial results in the next section.

INITIAL RESULTS AND DISCUSSION

The study is still undergoing the data analysis process. Currently, the study is on step-3, searching for themes. A few themes have already formed (see Table 4). The themes are areas that the interviewees have expressed concern or interest in as they interacted with the app or as they answered the questions from the interview. The themes listed in the table is not yet exhaustive nor is it finalised as the analysis is still ongoing.

Table 4. Initially formed themes

Topics	**Initially formed themes**
App utility	Relevance of the content Clarity of the purpose of the app Frequency of use
App dependability	Accuracy Error-free operation Trust
UI graphics	Disengaged parts White, empty spaces Colour Simplicity/ complexity
UI output	Familiarity Salience of information Interesting/ boring Use of images and text Length of content
UI input	Auto-complete for search User power/control Settings/ customization Intuitiveness

For this working paper, a short discussion based on the findings so far will focus on some insights gathered around the app's interface output. The users' insights showcase the value of collecting user feedback for the design and development of disaster apps.

User insights on the interface output of the app

Interface output is about how well an app presents content effectively (Hoehle and Venkatesh 2015). Through the usability inquiry, we obtained an understanding of users' views and feelings on how the app presented its content.

The participants confirmed comfort and ease when they found familiarity with the interface. The participants found that similarity of the interface to other apps' helpful in using the NZ Alerts app.

> *I appreciate that it looks like an app that I am familiar with. […] It's what I'm used to. Which make me comfortable.* [Participant#05]

> *If people are not used to it, they will find it difficult to use.* [Participant#06]

On the other hand, the participants also raised concern, highlighting that too much similarity has its downside also. For example, a few participants questioned whether they needed to scroll far to get relevant news. Scrolling endlessly to retrieve information is an experience they relate to when using Twitter. Furthermore, participants expressed some concern about presenting information in a feed format, especially in the context of use during disasters.

> *But it can also be a bad thing, as you might need to spend too much time on your phone. Similar to Twitter; if [an organisation] posted something really important. You may have to scroll down really far.* [Participant#03]

> *During a crisis situation, we would be doing a lot of things. There are a lot of notifications – I might miss lots of information that is coming in.* [Participant#04]

Interface output helps with information overload, presentation affects how users perceive information to be compelling or salient (Prasanna et al. 2013; Stratmann and Boll 2016). Beyond raising concern on how critical information will be relayed, participants provided suggestions on how to make information more salient; such as using colours, providing time stamps, and pinning posts, among others.

> *The importance of each post may be different. There could be a generic colour for general things. For alerts, use range of colours, red, orange, yellow*. [Participant#01]

> *I might think the app is out of date. […] Maybe have your own time stamp that says 'this page has been updated 2 minutes ago'.* [Participant#02]

> *If there is a severe alert, there should be a way [for the post] to remain on the top. Even when you scroll, it remains on top.* [Participant#04]

Furthermore, the participants were also able to highlight which elements in the app already helped emphasise critical information.

> *I like how they have the logos [of the authorities] for each. Really helpful, especially when you are scrolling really quick to look for something.* [Participant#15]

NEXT STEPS AND FUTURE WORK

The importance of usability has been emphasised in safety-critical technology research (Kwee-Meier et al. 2017); however, limited comparable literature can be found on public-facing disaster apps. Furthermore, only a small number of academic work have employed user-centred methods in understanding the usability of disaster apps. This study addresses the gaps by highlighting and utilising citizen's feedback to gain insights on usability.

This paper has shown that the intended end-users' perspectives have value to the design and development of the NZ Alerts app. With the partial analysis for a single initial topic (UI output), the insights confirmed some design decisions, supplied particular concerns specific to the disaster context of use, and offered suggestions on improving salience. Through the full analysis of the usability inquiry, more themes will be reviewed and refined; potentially offering a holistic appraisal of the initial app configuration.

The next steps for this study are to complete the analysis of the usability inquiry and to present a comprehensive report of the results. Practical action forward for the NZ Alerts app is to use the results for the next iteration of design and development. Future theoretical work will build on the broader implications of the results; developing a case for a citizen-centric approach in enhancing the usability of disaster apps.

Predicting Hurricane Damage Using Social Media Posts Coupled with Physical and Socio-Economic Variables

ABSTRACT

During a natural disaster or emergency event, individual social media posts or hot spots may not necessarily correlate to the most devastated areas. To better understand the correlation between social media and physical damage, we compare Tweets, data about the physical environment, and socio-economic factors with insurance claim information (as a proxy for physical damage) from 2017 Hurricane Irma in the state of Florida. We use machine learning to identify relevant Tweets, sensitivity analyses to identify socio-economic factors, and statistical regression to determine the predictive capability of insurance claims as a proxy for damage. We find that Tweets alone result in a poorly fitted regression model of insurance claims, but the inclusion of physical features (e.g., power outages, wind level) and socio-economic factors (e.g., population density, education, Internet access) improves the model's fit. Such models contribute to the knowledge base that may allow social media to predict damage in real-time.

Keywords

Social media, disaster management, damage prediction

INTRODUCTION

The rise of social media over the past 15 years has marked a shift in the potential of how information is collected and disseminated during natural disasters (Reuter and Kaufhold 2018). The flow of information between authorities, like emergency managers and first-responders, and the broader community is becoming increasingly bi-directional. A person with an internet connection in the wake of a flood, wildfire, earthquake, or hurricane now has the ability to ask for help or report damage via Twitter, Facebook, Instagram, or another platform (Jurgens and Helsloot 2018).

The messages conveyed by social media may help people identify the most devastated areas before conventional post disaster damage assessments (Kryvasheyeu, H. Chen, Obradovich, et al. 2016; Resch et al. 2018). With knowledge of these areas, a decision maker may deploy personnel, aid, or other resources based on the singular post or "hot-spot" of posts (Gao et al. 2011). However, identifying areas most in need requires the filtering of social media content to identify the most relevant information (Leykin et al. 2018). Moreover, basing resource allocation decisions on social media posts may not necessarily serve communities posting the most (e.g., those whom have internet connection during a disaster) rather than those most at-need (Brynielsson et al. 2018).

Although researchers have correlated Twitter activity to economic damage (Kryvasheyeu, H. Chen, Obradovich, et al. 2016), an ongoing challenge in using social media for disaster management is addressing why a certain region may be more active on social media during a disaster. For example, social media posts may correspond with areas with younger populations that have higher social media adoption rates and not capture of elderly communities (Perrin 2015). Certain regions may have higher levels of internet connectivity resulting in more social media activity. Non-English speaking communities may be using other communication platforms aside from the ones monitored by authorities. Without understanding and accounting for biases is how posts are generated, using social media for disaster response may favor areas with higher adoption rates.

†corresponding author

Our goal is to determine the relationship between a sample of Twitter posts and insurance claims as a proxy for on-the-ground damage, while adjusting for demographic and physical factors that could impact a geographic area's ability to Tweet. To do so, we first test and apply machine learning based classification and filtering methods to Tweets from 2017 Hurricane Irma. Then, we apply a regression to estimate the relationship between filtered Tweets and insurance claims in Florida resulting from the hurricane. Further, we test how incorporating physical features (e.g., power outages, Internet access) and demographic/socioeconomic factors (e.g., population density, education, age, etc.) impact the model's fit.

BACKGROUND

Researchers have tested whether social media can be used for disaster management through outbreak detection (Earle et al. 2011, Kryvasheyeu, H. Chen, Moro, et al. 2015), information retrieval (Imran, Elbassuoni, et al. 2013), sentiment analysis (Stieglitz et al. 2018, Kryvasheyeu, H. Chen, Moro, et al. 2015), evacuation behavior (Stowe, Anderson, et al. 2018, Danaë Metaxa-Kakavouli et al. 2018), hazard assessment (Resch et al. 2018, Burks et al. 2014, Herfort et al. 2014), and damage assessment (Resch et al. 2018, Kryvasheyeu, H. Chen, Obradovich, et al. 2016, Guan and C. Chen 2014). By combining methods of prior work, our efforts to test Twitter's capability for damage assessment first requires determining what information is relevant and filtering that information. The second step requires providing context to how that information exists. In other words, what populations do the social media posts represent and can it be trusted and be representative? Finally, an actionable decision responding to the local damage assessment should be able to be made considering all factors mentioned above.

Filtering

Keyword-based filtering is a technique to select disaster-related Tweets, where the quality of the filtered Tweets depends on the keywords researchers or practitioners choose. Yet, keyword filtering may not be enough to eliminate noise from information (Leykin et al. 2018), which has led to the development of machine learning algorithms to better identifying disaster related Tweets (Li, D. Caragea, C. Caragea, and Herndon 2018; Mazloom et al. 2018; Li, D. Caragea, and C. Caragea 2017; Stowe, Paul, et al. 2016).

For example, Resch and colleagues (2018) developed a Latent Dirichlet Allocation (LDA) algorithm to determine the earthquake-related Tweets and damage-related Tweets in the 2014 Napa earthquake in California. However, their algorithm still requires extensive human involvement to identify the topics that the LDA generates. Imran and colleagues (2016) and Alam and colleagues (2018) tested Tweets classification tasks with deep learning, but their models, have not been utilized in any case study to perform damage assessment. We expand upon this prior work through testing new filtering techniques through combining keyword filtering, neural net Tweets classification, and sentiment cut-off.

Bias

Prior research focuses on correlating Tweet activity and disaster damage, such as the comparison of Tweets and earthquake-related physical variables to estimate earthquake ground shaking intensity (Burks et al. 2014), without study into who is generating the Tweets. Twitter user patterns may be skew to disproportionately represent certain segments of a population. Prior research has shown that older populations have less social media adoption compared to younger counterparts (Perrin 2015). Areas with limited internet connectivity are less represented in social media compared to urban population centers (Mislove et al. 2011). English is the main language involved in disaster social media texts classification machine learning training, such as from CrisisLex (Olteanu, Castillo, et al. 2014) and CrisisNLP (Imran, Mitra, et al. 2016) data sets. Minority ethnic groups typing different languages may be overlooked when researchers focus on English Twitter posts.

To build upon prior work, we include physical variables and societal factors to test whether they improve a social media based regression model's prediction of physical damage. Specifically, we build a Tweets-based regression model incorporating other correction factors to estimate county-level damage (in terms of number of claims). By doing so, we work towards the quantitative usage of Tweets in disaster damage assessment while adjusting for biases in how the Tweets are generated.

METHODS

The foundation of this paper is to determine the relationship between geo-tagged Tweets from Florida during 2017 Hurricane Irma and the geographic distribution of post-disaster insurance claims resulting from the event. We then

aim to understand if the predictive ability of Twitter data could be improved through incorporating socio-economic factors that may have better reflected those the communities generating the Tweets.

We first apply machine learning techniques to classify and filter the Tweets. Second, we conduct a sensitivity analysis to select socio-economic factors that may affect the ratio between disaster-informative Tweets density and post-disaster claims percentage. Third, we determine the relationship of the Tweets, socio-economic factors, and insurance claims by fitting the data into regression models.

For this study, we use 201,833 geo-tagged Tweets from Florida during Hurricane Irma are collected from August 21, 2017 to September 14, 2017. This timeframe encompasses when Hurricane Irma made landfall in Florida around September 10 and 11. County level insurance claim data is collected from Florida Office of Insurance Regulation (2018). Socio-economic data was accessed from an aggregate dataset based on information from the 2010 Census among others (Kirkegaard 2016).

Tweet Filtering by Keywords, LSTM, and Sentiment Analysis

To pre-process the data, the Tweets first are made lowercase and retweets such as "RT @:NAME", HTMLs, smiley faces and emojis are removed. Stop-word (some most common words in a language), are not removed because words such as "not" may affect sentiment analysis in the later filtering layer. We also do not perform lemmatization (return the base or dictionary form of a word), to facilitate the use of pretrained word embeddings. Hashtags (the words after "#") are not removed because they might indicate the topic of the Tweet. After the pre-processing, duplicates Tweets are removed from the data. The pre-processed Tweets are first filtered by the keywords including *hurricane*, *irma*, *flood*, *cyclone*, *storm*, *wind*, and *typhoon*.

Second, we use prior sets of labeled Tweets to train a neural network model to classify the level of relevance for each Tweet from our Hurricane Irma dataset. We apply Bidirectional Long-Short Term Memory (LSTM) recurrent neural network due to the potential to select Tweets more relevant to Hurricane Irma compared to simple keyword filtering (Leykin et al. 2018). We use prior English language crisis related Tweets that are previously labeled (Table 1) as training datasets.

Generally there are two types of supervised learning labels in disaster Tweets classification: relatedness and informativeness. Relatedness-based classification resembles a keyword-search whereas informativeness-based classification aims more at finding Tweets useful to humanitarian aid organizations or governments to take action. We apply the criteria for informativeness based of prior definitions as providing information that is useful to a person (Truong et al. 2014; Olteanu, Vieweg, et al. 2015). For example, a Tweet that states *This hurricane sandy twitter is so annoying* would not be considered informative (Truong et al. 2014). Informative Tweets fall in one of the following categories: affected individuals, infrastructure and utilities damage, sympathy and support, caution and advice, donation and volunteering other useful information. Further, the type of hazard in the training datasets greatly impacts the performance of the classifier (Li, D. Caragea, C. Caragea, and Herndon 2018). Therefore, we attempt to make the classifier hurricane-specific by choosing only hurricane and floods events from the available Tweet training datasets.

Table 1. Tweet Training Datasets

Database	Dataset	Reference
CrisisLex	T6 and T26	Olteanu, Castillo, et al. 2014
CrisisNLP	#1	Imran, Mitra, et al. 2016
CrisisNLP	#2,#3	Imran, Elbassuoni, et al. 2013
CrisisNLP	#6	Alam, Ofli, et al. 2018

Third, we classify whether the Tweets have a positive (>0, max 1) or negative (<0, min -1) sentiment using the `Python` library `textblob`. We chose to only keep Tweets with a sentiment of less than zero based on our quantitative analysis that negative Tweets generally exhibited higher levels of correlation to post-Irma insurance claims compared to Tweets of zero or positive sentiment. However, there are other interpretations of sentiment that is suitable for predicting disaster damage that we do not address here. For example, it is a separate issue to explain whether people with disaster damage are exhibiting more positive (hopeful) or negative (glum) sentiments post disaster.

The remaining Tweets are parsed at a county level to match the insurance claim data granularity. The Tweet count was then divided by county population to calculate Tweets per capital.

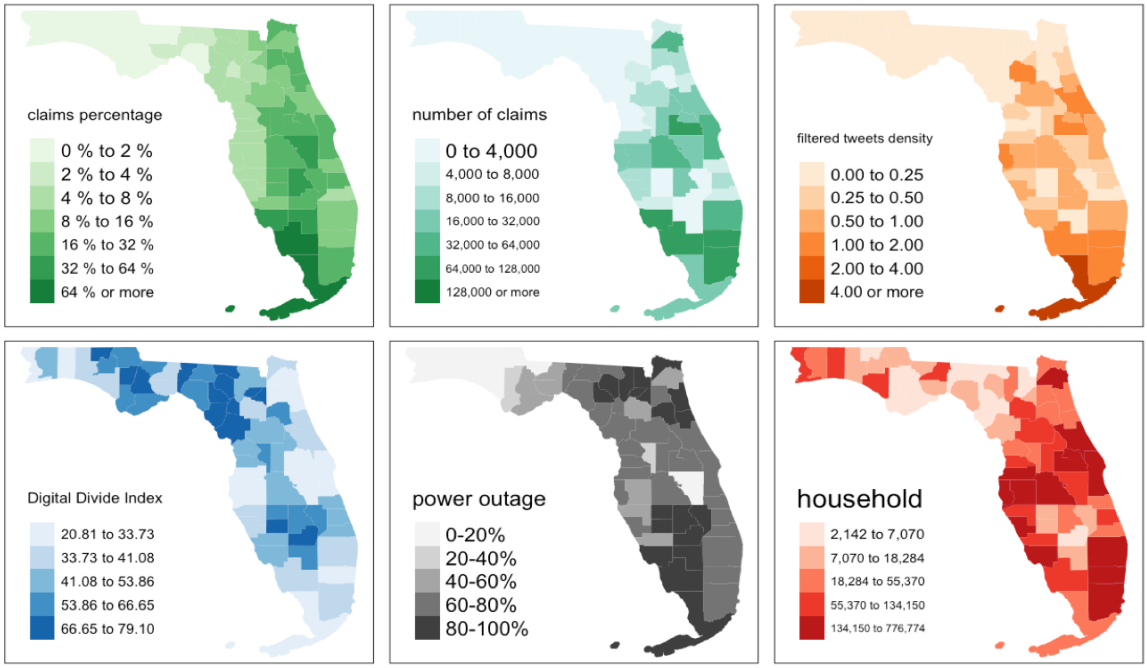

Figure 1. Example variables mapped at county level in Florida. Clockwise from the top left: Percentage of insurance claims per total number of households in the county, absolute value of insurance of claims, filtered Irma-informative tweets with negative sentiment per 10,000 population, Digital Divide Index as a proxy for internet connectivity, peak percent power outage on Sept 11, number of households.

Incorporating Socio-economic Factors and Insurance Claim Data

Social media may under-represent or over-represent different demographics due to varying levels of adoption (Mislove et al. 2011). To account for such variability, we identify demographic and socio-economic factors that may potentially explain the generation of Tweets and test whether their inclusion into the regression model improves the prediction of insurance claims.

To determine factors that are statistically relevant to insurance claims or affecting Twitter activity, a sensitivity analysis is applied to Irma insurance claims data, filtered Tweets per capita, power outage data at the county level, as well as approximately 70 demographic and socio-economic factors including ethnicity, age, income, education, household type, Internet access, and occupation. Claims data are extracted from the publication of Florida Office of Insurance Regulation (Florida Office of Insurance Regulation 2018). The demographic and socio-economic factors are obtained from the R-package "USA.county.data" (Kirkegaard 2016) and the US Census Bureau (2000). Internet connectivity data are attained from the Digital Divide Index (DDI) (Intelligent Community Institute 2017). Power outage data are attained from the US Energy Information Administration (US Energy Information Administration 2017). Wind speed, a binary categorical variable indicating whether the wind level is hurricane or tropical storm when Irma swept the county, is retrieved from a news report (Washington Post 2017). Example variables are illustrated in Figure 1.

We first exclude factors that are highly correlated (correlation 0.6 or above). For example, the two variables "percentage of people with at least a bachelor's degree" and "percentage of people with at least a master's degree" are highly correlated so only "percentage of people with at least bachelor's degree" is kept. We take such action as a measure to prevent multicollinearity.

We use random forest and distance-based sensitivity analysis (DGSA) to select predictor variables of the regression model. We use the metric "Increase in MSE" (IncMSE) to check the sensitivities in random forest. Two sensitivity analyses are conducted, each with a different response variable, namely claim percentage (number of claims normalized by number of households at county level) and ratio between filtered Tweets per capita and claim percentage. The former explores which factors may affect claims report in each county, while the latter tests which factors may explain the bias of using social media as a damage indicator.

Regression

A negative binomial regression with *number of claims* as dependent variable is created and evaluated based on *RMSE*. We model the "rate" of claims using *number of households* as the offset. The canonical *Moran I* Monte Carlo test (with 2000 simulations) checks spatial auto-correlation. Tweets, the demographic and socio-economic factors chosen from the sentiment analysis, power outages, and categorical wind speeds are included in the regression analysis. The zero-inflated negative binomial model estimates Tweets density in each county to look for the dominant factors affecting Twitter users' activity. In this regression analysis, Tweets count is the dependent variable (offset is population) while claims percentage belongs to one of the independent variables.

RESULTS

Tweet Filtering by Keywords, LSTM, and Sentiment Analysis

21,307 Tweets remain after the keyword filtering. In the next step, the pre-trained Tweet classifier selected related and informative Tweets from the set of 21,307 filtered by keywords. The relatedness-classifier attained 94.9% test accuracy with a training dataset of 16,000 Tweets, validation dataset of 5,000 Tweets, and test dataset of 5,000 Tweets. The informativeness-classifier had 32,000 Tweets of training data, 5,000 validation Tweets, and 5,000 test Tweets to attain 82.4% test accuracy. We choose to use the informativeness-based classifier to filter the Irma Tweets. 13,216 Tweets remain after applying the informativeness-classifier. 1,745 Tweets remain after applying the sentiment analysis.

Sensitivity Analysis and Regression

Factors such as *filtered tweets in 10 thousand people*, *power outage*, *Latino population*, *NBBND* ("percent of population without access to 25[Mbs download]/3(Mbs upload] fixed broadband," an indicator of local Internet access), and *UPS* (upload speed) play an important role in random forest regression with claims as the dependent variable. The random forest in Figure 2 shows that population over age 65, population density, school enrollment, races, internet access are significant to sway the ratio between Tweets and claims, while power outage is not significant.

Table 2. Negative Binomial Regression

Predictors	RMSE (claims %)	Moran I	Pseudo R-squared
Tweets only	14.71	0.0005	0.2588
power outage only	14.84	0.0005	0.2394
Tweets + power outage	12.35	0.0005	0.5536
Tweets + UPS + power outage	14.40	0.1224	0.6569
Tweets + UPS + power outage + wind	11.2	0.2529	0.7001
Tweets + UPS + Latino pop + power outage	9.84	0.0760	0.7000
Tweets + UPS + Latino pop + power outage + wind	10.11	0.1279	0.7122

The negative binomial regression is summarized in Table 2 and the coefficients of each term are given in Table 3. The zero-inflated negative binomial model is summarized in Table 4. Population density, school enrollment and claim percentage contribute positively to local Tweets density and NBBND (percent of 2010 population without access to 25/3 fixed broadband) explains the excessive zeros in the local Tweets density variable.

Table 3. Negative Binomial Regression Coefficients

Predictors	Coef.	p-value
log(filtered Tweets per 10,000 population)	0.10260	0.011673
power outage 40%-60%	0.38487	0.187015
power outage 60%-80%	0.92931	0.000152
power outage 80%-100%	1.96994	6.44e-15
log(UPS)	0.43172	0.000142
log(Latino population)	0.26240	0.084085
wind (Tropical storm)	-0.40955	0.107919

Table 4. Zero-Inflated Negative Binomial Model: the variables above are the count model coefficients; the variable below is the zero-inflation model coefficient

Predictors	Coef.	p-value
population density	4.454e-04	0.000304
school enrollment	1.063e-01	0.004693
claim percentage	3.175e-02	1.12e-07
log(NBBND15+1)	1.8394	0.00367

DISCUSSION

Our initial study demonstrates that incorporating demographic as physical factors could improve the prediction of a regression model, as demonstrated by the improved pseudo-R^2 fit in Table 2 to a value of around 0.7. More importantly, our study highlighted the challenges in fusing multiple streams of crisis informatics research, including classification, data integration, and prediction, to create a system of social media use for real time damage assessment.

Machine Learning Classifier

Although relatedness-based classification has a higher accuracy, it may be more meaningful to classify the Tweets using informativeness-based classification. The drawback of using the relevance classification is that some messages may be on-topic but it conveys nothing useful for disaster response. For example: *these hurricane sandy tweets are so hilarious tho* is an on-topic, but not informative Tweet extracted from CrisisLexT6 Hurricane Sandy dataset. However, the drawback of informativeness classification criterion is that its boundary of classification is blurry and subjective, which leads to low accuracy.

Sentiment Analysis

In sentiment analysis, the cut-off *<0* returned the highest correlation. A potential explanation is that negative sentiment could reflect hurricane damage better than neutral and positive Tweets. The drop in correlation with further decrease in sentiment cut-off might be due to too few Tweets included in analysis losing the power of representation.

There are also questions about the accuracy of `Textblob` since it is not specialized in disaster Tweets. At this stage, the sentiment analyzer is a "black box" which is plugged into the workflow. A more sentiment classifier specialized in disaster message could improve the sentiment analysis. Additionally, the sentiment analysis removed nearly 90 % of keyword and machine learning filtered Tweets and left a data-set of only 1,745 Tweets to analyze for the entire state of Florida. Future tests without the sentiment analysis can help determine whether there is any value in applying the sentiment analyzer.

Sensitivity Analysis and Regression

We did not do train-test split to the county-level data due to data limitations. The data available to us were the geo-tagged Tweets in Florida and claim data at county level, which was not enough to validate the model or to do extensive study on the impact of different classification techniques since the conclusions might over-fit the Hurricane Irma case. The regression models are explanatory instead of predictive.

We found that by including demographic and socio-economic factors could improve the performance of the model compared with only including Tweets variable itself. Tweets, Latino population, Internet access metrics (NBBND (percent of population with no access to fixed broadband), UPS (upload speed)), as well as power outage are the most significant indicators. Prior to the regression, we hypothesized that Tweets and power outage were the main predictors and that UPS and Latino population were the correction terms. More Tweets or higher power outage percentage would imply higher claim percentage. The coefficient of UPS was expected to be negative because UPS could serve as a correction to the bias of using social media: more Tweets would be naturally generated in counties with better Internet connectivity.

The coefficient of Latino population was expected to be positive because the Tweets we analyzed only English Tweets and Latino Population could compensate for the Spanish Tweets. The reason that Latino population was more sensitive than other population is that Spanish is the second most popular language used in Florida (Statistical Atlas 2018) while other languages are less prevalent.

The regression results support our expectation on all the variables except for UPS, the sign of coefficient of which is positive. We suspect it is because that UPS could represent the urbanization of counties. In an urbanized county, the homeowner insurance is more widely covered. Power outage is an important indicator for possibly two reasons: first, it indicates damage brought by Hurricane Irma, and second, it corrects the filtered Tweets variable since high power outage percentage would impede people from using their cell phone or other electronic devices. The sole power outage predictor could fit the claim data better than what the sole Tweets predictor could achieve (except the regression tree). A model using the two power and Tweets data simultaneously best fit the claim data.

The zero inflated negative binomial models shows that NBBND (percent of 2010 population without access to 25/3 fixed broadband) accounts for the excessive zeros in Tweets count, which means regions with poor internet access have less active Twitter users. Beside claim percentage, population density, which indicates populous urban environment, also plays a role in the model. The variable school enrollment is another indicator of development as well (Gennaioli et al. 2013). The absence of power outage in both random forest and zero negative binomial regression models implies that Twitter users may not be heavily affected by power outage and the power outage variable in the former regression models only implies physical damage but no compensation for the Tweets bias. However, since the Tweets count is aggregate throughout the whole period and is at county level, it is hard for us to capture the impact of power outage on Twitter activity.

More Tweets-based features will be explored once we can go beyond binary classification. Different information types may be related to local claims differently. We are also actively looking for claims data with higher granularity and an exhaustive collection of Tweets so that more data points could be leveraged in regression analysis so that we can come up with a better model and a better explanation of the connections between variables. We are also looking for data from another hurricane disaster to test how our model can be generalized. Besides, we will also explore the ability of Tweets to do a quick and reliable estimation of disaster damage by controlling the temporal duration of Tweets that are included in the analysis.

Limitations

Many variables are sensitive in sensitivity analysis but not significant in regression. The impact might be nonlinear and data might not be enough to obtain the true significance. Some variables are not sensitive perhaps because their range is not wide. For example, in Pew Research Center's report (Perrin 2015), females tend to use social media more frequently than males. However, gender was not significant in sensitivity analysis. The range of female percent is not wide (1st quantile - 3rd quantile: 49.9 - 51.5), which shows the female percent does not vary significantly among counties.

In this paper, we assume a monotonic relationship between Tweets density and claims percentage, which is open to discussion. Questions such as how the Tweets may trigger false alarm (local residents thought danger would come but the hurricane derailed later) are not considered. Considering 200,000 Tweets are a small sample of the total Tweets in this time period in Florida, we do not perform temporal analysis.

Because the sensitivity analysis and regression is done on the county level, we do not take the impacts of evacuation on Tweet generation into consideration for the scope of this paper. It is assumed that evacuation occurred within county. Monroe County is an exception, where the entire county was issued a mandatory evacuation order. However, we find considerable Tweets in Monroe throughout the time span, so we keep Monroe in our analysis.

Since this work was conducted using a sample dataset of geotagged Tweets, the initial classification result of filtered Tweets may be considered rather low in quantity (13,216) and accuracy (0.82). In the future, one possibility to increase coverage is to use the full Twitter "firehose" of Tweets, and georeference additional location information such as the mentioning of specific locations in the Tweet text. Further, the inclusions and parallel analysis of Tweets in other common languages, such as Spanish, may impact the social media based prediction. Accuracy may be improved by refining the annotation task for the training datasets. Although we take insurance claims as measure for damage, it is also important for future work to assess the distribution in insurance coverage and what inherent biases exist for claim request. Finally, demographic and socio-economic factors from 2010 US Census may not reflect the current demographics of Florida.

CONCLUSION

As an initial study, we built a bidirectional-LSTM network to filter disaster-informative Tweets. We studied Tweet feature selection and chose disaster-informative Tweets with negative sentiment to indicate damage level. Sensitivity analysis showed Tweets, Latino population, and upload speed (or some equivalent indicators to internet access) were significant predictors to insurance claims after Hurricane Irma in Florida. Internet access indicators and

urbanization indicators could explain the bias in social media users' representation of the whole population. A non-binomial regression model combining Twitter data, power outage data and social factors best fit insurance claim data.

ABSTRACT

In recent years, spontaneous volunteers often turned out to be a critical factor to overcome disaster situations and avoid further damages to life and assets. These Volunteers coordinate their activities using social media and mobile devices but are not integrated in usual command and control structures of disaster responders. The lack of professional disaster response knowledge leads to a waste of potential workforce or even dangerous situations for the volunteers. In this paper, a novel approach for a centralized coordination of spontaneous volunteers through disaster response professionals while using popular communication channels esp. messaging services (e.g. Facebook Messenger, WhatsApp) is presented. The architecture of a volunteer coordination system focusing on automated multi-channel communication is shown and the possibilities of a universal chatbot for individual assignment and scheduling of volunteers are discussed. The paper also provides first insights in a demonstrator system as a practical solution.

Keywords

Spontaneous volunteers, chatbot, social media, system architecture

INTRODUCTION

The growing number of disaster incidents in the recent past represents a new challenge for many societies and reveals new dangers for life and assets (e.g. Munich Re, 2018). Another problematic phenomenon for disaster response is the decreasing number of honorary volunteers in many security authorities and organisations (SAO) (e.g. McLennan et al. 2016). On the other hand, new technologies such as social media and mobile devices allow an even faster and more direct communication from SAOs to the people than ever before. This reveals new possibilities to use the potentials of unaffiliated citizens for provision of workforce and material in critical situations (Sauer, 2014). These spontaneous unaffiliated volunteers (SUV) do already play an important role and were crucial to overcome disasters, for example the Middle European Flood in 2013 (Thieken et al., 2016).

However, it is currently challenging for SAOs to access this new potential due to differences in the organizational structure and especially a missing direct, individual communication channel (Whittaker et al., 2015). Whereas SUVs use popular tools such as Facebook or Twitter to organise themselves, official responders have separate command and control systems and communication channels. The usual communication between these two groups is mostly conducted with mass media calls from officials or deployment of emergency call centres. Although sharing of information between civilians and SAOs in general makes great progress with tools such as Ushahidi or several warning apps, a direct communication for a goal oriented coordination and exploitation of the

spontaneous willingness to help in a disaster situation has not yet been established.

In recent disaster events, the self-organisation of SUVs often led to situations where official responders were overwhelmed by spontaneous converging volunteers. Coordination of these unexpected large crowds of people can be very challenging especially during critical response activities or under dangerous circumstances. Deficits in volunteer coordination can not only lead to a waste of workforce but also decrease motivation to offer help in future events or even cause improper and counterproductive actions of unguided, enthusiastic non-professionals, necessitating further response efforts or even cause new damages (Barsky et al., 2007).

To overcome this situation approaches such as Betke (2018) propose so called volunteer coordination systems (VCS) that provide a direct communication between official responders and SUVs for a goal-oriented management of volunteering offers and demands. A crucial feature of this kind of systems is the possibility to take the individual circumstances of each volunteer into account. This refers to the individual communication behaviour by supporting a variety of popular communication systems as well as to the individual volunteering offer in terms of e.g. time and capabilities. Since the necessary information would exceed the capabilities of official responders, we suggest a (semi-) automated solution.

In this paper, we take up the idea of the VCS and try to answer the question: how can chatbots be used to improve the coordination of spontaneous unaffiliated volunteers? Therefore, we discuss the idea and architecture of an automated multi-channel chatbot as communication interface for SUVs and VCS. This work is part of the research project KUBAS in which different aspects of a VCS are investigated to develop a suitable holistic system. The project follows the design science research process of Peffers et al. (2006) whereas papers such as Betke (2018) address the first phases, this paper addresses the design and development phase (phase 3). In the second chapter, we derive general requirements for a suitable coordination interface for SUVs in a volunteer coordination system. Then we take a short look at chatbots in general and their current application in disaster response in search of a possible existing solution. Chapter three comprises the discussion of new volunteer chatbot architecture with respect to the former derived requirements followed by an insight in an early demonstrator. The paper closes with a summary and outlook for the next project steps.

REQUIREMENTS FOR INDIVDUAL VOLUNTEER COORDINATION

To design a suitable communication interface for SUVs we first need to define the specific requirements. Betke (2018) presented user stories of volunteers and official responders to describe the functional demands of both user groups of a VCS. However, we excluded official responders' side since they did not address the volunteer communication. Instead, we take a closer look on the volunteer user stories to derive the specific requirements for a volunteer-coordination-interface (VCI) between SUVs and SAOs respectively the intermediate VCS. As a typical human-computer-interface, the VCI is a frontend module with the purpose to present, receive and transfer information.

Besides the functional requirements discussed below there are two universal demands on the VCI, whereby the first one is to include as many popular communication systems as possible to reach the maximum number of possible volunteers and the second is an automation of the communication as far as possible. The following table (Table 1) comprises the original user stories and a short explanation of the derivation of each functional requirement (R1-R13). The requirement have been discussed in a workshop with a complete crisis committee staff consisting of six staff members.

Table 1. Volunteer Communication Requirements

	User Story	VCI Requirement
R1	*As a volunteer, I want to be informed about relevant help requests so that I do not have to search for them.*	This user story implicates the need for an automated and individual notification about a relevant mission for the volunteer.
R2	*As a volunteer, I want to get detailed information about help request so that I can make a decision to help.*	The information about help requests must be presented in an appropriate way. The VCI needs access to all data important for the decision making of the volunteer. For instance, these may include mission site, period and type of mission.
R3	*As a volunteer, I want to see my volunteer mission details at any time so that I do not lose any information.*	Information received via the VCI needs to be persistent. It must be accessible and provided at any time so that there are no interruptions in the information flow.
R4	*As a volunteer, I want to provide sufficient information about my*	The VCI must record and retrieve completely and properly all the input data of the volunteer. A processing of different data

	volunteering offer so that I can get the best help requests.	types must be possible.
R5	*As a volunteer, I want to group with my friends so that we can work at the same sites.*	An opportunity to find and interact with friends must be given by the VCI. This can be realized by either using information from existing networks (such as Facebook or WhatsApp) or an underlying VCS. The feasibility and implementation of this requirement depends on the specific data protection laws of each country in which the system is used.
R6	*As a volunteer, I want to change my volunteer offers so that it matches my current circumstances.*	The VCI must provide a function to re-query specific data sets at any time and induce the overwriting process of obsolete data in underlying coordination system. This requirement aims at repeatability of R4. The processing and replacement of data however is a not a feature of the VCI but of the underlying VCS.
R7	*As a volunteer, I want to get information if my volunteering offer was recognized to be sure it will be taken into account.*	The VCI shall give a confirmation to the volunteer once his data was successfully send to the VCS.
R8	*As a volunteer, I want to be able to get offers from more than one request so that I can help at different sites.*	The VCI must be able to present information of a number of requests or accepted missions of a volunteer. This requirement refers to R2 and R3 and implies some kind of navigation through the available information. However, the background processing of data and matching of suitable requests /missions is not part of the VCI.
R9	*As a volunteer, I want to use mobile devices so that I am not bound to a single location.*	The VCI must be designed for deployment on mobile devices of as many different types as possible.
R10	*As a volunteer, I want to use different devices so that I can be sure that I get help request information.*	For the communication between volunteer and the coordination system a multitude of devices (e.g. smartphone, mobile phone, computer) and channels must be addressed. A great variety of devices and channels allows a great participation of potential volunteers. This also concerns universal design aspects as people can communicate and offer help according to their abilities.
R11	*As a volunteer, I want to get information about disaster incidents in my home area so that I can prepare myself.*	Besides features regarding the communication regarding volunteering, the VCI must also serve for information purposes, for instance to inform about critical incidents at the volunteer´s location.
R12	*As a volunteer, I want to share on-site information with disaster authorities so that I can report potentially dangerous incidents.*	The VCI must allow submission of disaster response relevant information. The transfer and presentation of information to disaster authorities is realised by VCS. In connection with a variety of supported communication channels, this requirement may also serve as a connection between physical and digital volunteers whereby the former send information from their mission site for analysis by the latter.
R13	*As a volunteer, I want to get information about the traveling options so that I arrive on site as fast as possible.*	The VCI must provide some kind of routing feature to the volunteer, e.g. via external applications and display this information appropriately.

The derived requirements may not be exhaustive but constitute a good basis with cornerstones for the development of a useful communication interface for SUVs. As stated in Betke (2018), most of the presented requirements, such as local independence or a persistent information flow, can be realised by a mobile app. However, the sole application of a mobile app restricts the communication with volunteers in many ways. On the one hand, the

potential user group is limited to owners of devices such as smartphones and tablets, excluding people with other devices such as simple cell phones or landline telephones. On the other hand, a stable broadband connection or wireless network must be accessible to guarantee the functioning of the app. Since this cannot be guaranteed in every disaster situation the usage of alternative communication channels should be taken into account. Apart from that, it is very important to include popular communication platforms especially social media, which recently became crucial for self-organisation of volunteers (Kaufhold and Reuter, 2016). To reach as many volunteers as possible and to utilise the full potential volunteer offers, we propose the implementation of a universal chatbot as VCI and discuss this in the following.

CHATBOTS IN DISASTER RESPONSE

Chatbots, also often referred to as conversational agents or virtual assistants, are software agents that enable an intelligent and individualised text-based communication between human and computer-based systems. As an extension to simple text-based dialogue systems, chatbots are able to understand, process and respond in natural language. Therefore, they are able to store the user input and respond to the request in the current context (Androutsopoulou et al., 2018; Ciechanowski et al., 2019). Present chatbot frameworks and platforms often offer a multi-channel integration (e.g. SMS, social messenger services), which allows the developer to design a single chatbot and let it interact on various channels. A further benefit of chatbots based on these frameworks is the lower effort for maintenance and adjustment. Another general advantage of chatbots is the high level of user-friendliness. Whereas app-users have to download and install the volunteer app to register for missions, chatbot-users can use a pre-installed messenger service, for example Facebook or WhatsApp, or simply communicate with the chatbot via SMS. Furthermore, the menu prompting of an app sometimes can be confusing. A chatbot however, leads the user through a dialogue requiring less technical comprehension and so also opens the system for further user groups, for example illiterate persons via text-to-speech technology. Chatbots can instantly respond if the user's entry was incorrect or unclear. Thus, users can always be aware that their input has been accepted. In contrast to an app, the communication between user and system can be designed personally and human-like. Due to the human-like behaviour, possible fears of using computers can be reduced (Zamora, 2017; Muir, 1987). The direct interaction allows monitoring of the users´ emotion, e.g. by analysing the choice of words to get insight into their satisfaction with the chatbot. Several studies have been conducted to analyse the user's perception of a chatbot. According to Zamora (2017), users consider the application of their own natural language and short interaction times as further advantages of chatbot communication. To what extent a chatbot is perceived by users as beneficial depends on its ability to lead human-like conversations and process and respond in natural language (Shawar and Atwell, 2007; Wuenderlich and Paluch, 2017).

Because of the previously mentioned benefits, chatbots take over the communication with customers in a rising number of business applications. In banking, finance and insurance sectors they take over tasks such as checking the balance or block the credit card in order to prevent a fraudulent use (Dole et al., 2015; Eling and Lehmann, 2018; Koetter et al., 2018). In the tourism sector chatbots inform about the cheapest flight available or book a table in a restaurant (Ivanov and Webster, 2017; Nica et al., 2018). They assist customers in finding the right product on e-commerce websites or answer product related questions (Johannsen et al., 2018; Cui et al., 2017; Thomas, 2016). In social networks social bots automatically communicate with users and are criticised for manipulating their opinion on political issues (Ferrara et al., 2016; Wagner et al., 2012).

In order to provide an overview on the current state of research devoted to the use of chatbots in disaster management, we conducted a literature analysis. For this purpose, the several scientific online databases, of ScienceDirect, ISCRAM and AIS as well as Google Scholar have been searched for the keywords "chatbot", "bot", "conversational agent" and "virtual assistant" in combination with "disaster", "crisis", "catastrophe" and "volunteer". The identified relevant literature gives evidence that chatbots have the potential to improve the communication between public authorities and the civilian population. They are especially qualified to provide clarification on complex issues and for information purposes in civil protection. (Androutsopoulou et al., 2018). Currently, chatbots are mainly used for decision support and information retrieval in the phases of disaster preparedness and response. Thus, Augello et al. (2016) propose a model where a chatbot is used to warn decision-makers and civilian population of impending environmental catastrophes and support them in decision-making. For this purpose, the chatbot collects information from various sources. Sensors at measuring stations provide data to predict the future development and describe the current status of a disaster. In addition, the chatbot uses input information about users, for example their current location. This information is combined to provide an individual situation aware risk assessment of the user situation and offers advisory function. Sermet and Demir (2018) follow a similar approach. They developed an intelligent system using an ontology based knowledge engine to improve societal preparedness for flooding with help of voice recognition, artificial intelligence and natural language processing. The chatbot uses information from an official flood information system

Besides these scientific approaches, chatbots are already used in practice. For instance, in the U.S. the Richter

chatbot assists users in preparation for an impending earthquake or tsunami (BotList, 2018). It provides educational videos about how to behave in a critical incident, provides the users with documents to create their personal emergency plan and informs about the nearest public shelter and emergency services. In Japan, Bebot, a multi-language chatbot, sends alerts and information about nearby evacuation areas to visitors (Japan Today, 2018).

The chatbots presented already meet some of the requirements from chapter 2. For example, the chatbot of Sermet and Demir is able to process natural language, which ensures that all user input is retrieved properly (R4). Almost any of the presented chatbots is able to inform the user on disaster incidents, which meets requirement R11. Nonetheless, the main intention of chatbots presently used in disaster management is merely information retrieval for improving personal safety. Therefore, existing approaches have a different target audience and none of them takes coordination of volunteers into account. Since the literature analysis did not reveal a suitable chatbot solution as communication interface for SUVs, we will discuss the design of an appropriate software artefact serving this purpose in the following chapter.

VOLUNTEER COORDINATION SYSTEM WITH MULTI-CHANNEL COMMUNICATION

As stated before, the purpose of the chatbot proposed in this paper is to serve as a communication interface between SUVs and a VCS, which processes data from volunteers as well as SAOs to support an optimal usage of the volunteering potential. We therefore designed the chatbot as one module of a holistic VCS. The respective VCS architecture extract depicted in Figure 1, consists of a communication subsystem comprising the chatbot, a management engine and interfaces for communication devices of the volunteers on the one hand and official on-site responders on the other. On site responders or crisis committees, send their requests to the coordination system, which are then handled by the management engine. SUVs send their offers through the channel of their choice, which are attached to the chatbot via web interface. The chatbot takes over the communication with the volunteer. Based on natural language processing (NLP), the chatbot detects the user intents and induces the management engine to process their request. Hereinafter the single modules of our proposed architecture are described.

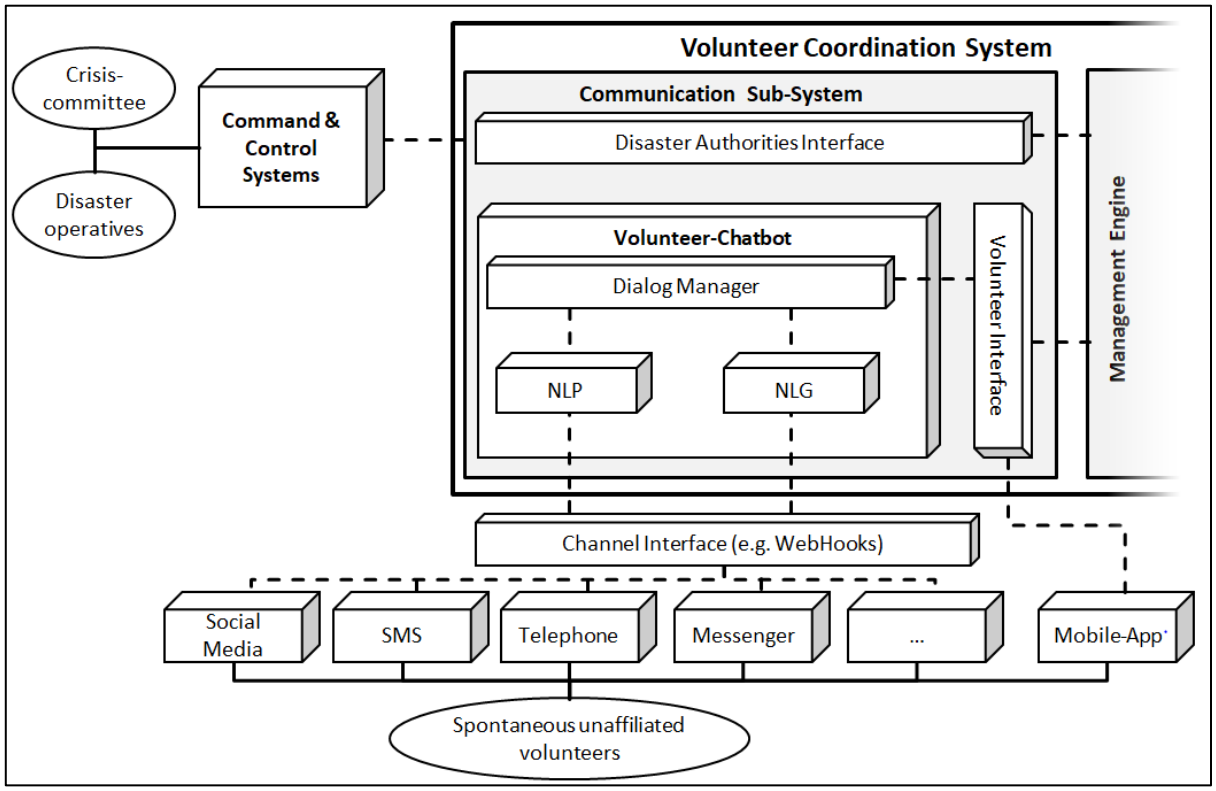

Figure 1. Volunteer Chatbot Architecture

The management engine in the proposed architecture consists of a workflow engine, which manages all in - and outgoing information as well as the interaction of all further system components. It comprises the database where all information about volunteer offers, help requests and volunteer user data is stored (R6). The engine monitors the individual status of each volunteer (e.g. offers, mission status, location, communication channel). Another major component connected to the management engine but not displayed in figure 1 is the decision support module

whose task is to constantly analyse the situation on volunteer offers and help requests to determine matches and provide information about which SUV should be alarmed for open help requests. For a detailed description of the concrete architecture of the coordination system and its modules see Betke (2018).

SUVs communicate their information, for instance registration information, volunteer offers etc. through the chatbot. The chatbot can be called via multiple channels, for instance SMS, Skype or messenger services such as Facebook messenger or WhatsApp (R9, R10). In our proposed architecture these channels are connected to the chatbot via webhooks. If the user's input is matched with a defined event, a callback function will be evoked and a HTTP – POST is sent to the web service, which returns the requested result (R3). To match a request or offer to the correspondent user, the assignment of a specific user id is required (R1). The user id can be extracted from the channel that is used by the user, e.g. account number of social networks, mobile number of messenger services or SMS or is generated and validated by the VCS.

To process user inputs and manage the dialogue between user and system, two solutions exist. The first is to use a simple, rule-based dialog system. To respond to the user input, these dialog systems refer back to pre-defined question-answer patterns. These patterns can be created by using AIML (Artificial Intelligence Markup Language), a derivative of XML. AIML patterns are grouped in intentional categories and contain templates with pre-defined answers. User input is matched against each pattern. Because of that, the chatbot is inflexible when it receives input, which has not been defined in a pattern. A chatbot using AIML is stateless and will not be able to store the conversation state and therefore is not aware of changing context. It can be assumed that volunteers would be unsatisfied, if the chatbot fails to handle their request properly. We therefore suggest the application of artificial intelligence instead of pattern oriented chatbots. Based on machine learning, these chatbots are self-learning and able to answer unexpected questions. In our proposed architecture, the dialog system consists of a natural language understanding (NLU) component, the dialog manager and a natural language generator (NLG). The NLU component is responsible for analysing the user input and triggering an action according to the user intent. For this purpose, intents have to be defined by the developer and the NLP component has to be trained on a variety of possible user input (R4) and chatbot output sentences. For example, to register for a mission a volunteer could ask "How can I register for a mission?" or simply "I want to help". Although the queries have a completely different syntax, both have the same intent (register for a mission). Based on machine learning the NLP component checks the query against every defined intent and matches it to the most suitable. To extract the specific parameters of an intent, for instance preferred date and time of a mission, entities need to be defined. Entities specify one or many actions of a single intent and represent a class of objects with values representing possible objects of this class. Another opportunity to train the chatbot for intent detection is the use of ontologies, which connect intents, phrases, nouns, adjectives and the relationships among them to a specific domain. For instance, if the user asks "How can I register for a mission?" the chatbot will parse the query and locate the register entity in the ontology. If the register entity is related to the time and date entity, the chatbot will ask the user to input their name to register for a mission.

After understanding the user intent, the chatbot needs to respond correctly and with the data that have been requested by the user. This is managed by the dialog manager. For this purpose, the dialog manager needs to maintain the context of the information and control the dialog or rather information flow. To execute the registration process, the chatbot needs to know all the relevant information, for instance user name, preferred mission site etc. If the input data of the user is unspecific and further information is needed, the chatbot needs to realize the missing data and request the user to fill in these slots. To avoid user input that cannot be processed by the chatbot or potentially leads to a misunderstanding and perhaps to cancellation of the registration process, we suggest designing a dialog, which is strongly guided by the chatbot itself. This can be done by providing the user with a set of predefined options. Thus, the user is led through the conversation by the chatbot and is always aware of what they say next. If there is nevertheless invalid user input, the chatbot will send a default message, implying that the input could not have been processed (R7). In order to fulfil the registration process, the dialog manager needs to pass the relevant data to the management engine. For this purpose, depending on the intents and entities extracted by the NLG component, a specific JSON code is generated and transferred to the management engine that can be called via REST API. To find an appropriate mission, the dialog manager sends the relevant data to the management engine and posts a request on available missions. The management engine will check the received data with the data sent by official responders and send these data back to the dialog manager (R8). Natural Language Generation is applied on constructing the answer containing the requested information on proposed missions. For this, the dialog manager uses templates and replaces the slots with the data retrieved from the management engine (R1, R2). If the user accepts the mission, this information needs to be stored in the database of the management engine and the dialog manager sends a confirmation to the user (R7). Besides registering and assigning for missions, users also required the opportunity to send on-site information to disaster authorities (R12). To realise this requirement, the chatbot needs to retrieve the needed information from the user by working through a series of questions determining the dimensions of the incident (e.g. What happened? Who was involved? When did it happen?). Again, the management engine manages the passing of this information to disaster authorities.

Furthermore, it was required for the communication system to have access to external applications. To provide general information on critical incidents at the SUV'S location, the communication system can be connected to a public warning system or retrieve information direct from official responders via the VCS (R11). The data is processed and preselected by the management engine, which triggers the chatbot to start a warning dialogue. To group with friends (R5), access to social networks is required, whereby the interface of social networks usually can be called via webhooks. Alternatively, the user can group with friends within the communication system by providing identifying information such as mobile number, sur- and last name. For on-site routing (R13), access to travel apps is needed, for instance map services or train connections. For this purpose, the chatbot needs a template, which can integrate and display the routing graphically or work as announcer for a navigation system.

SIMPLE CHATBOT DEMONSTRATOR

So far, we have implemented a first simple prototype chatbot on Facebook messenger via Chatfuel. Chatfuel is a bot platform for creating simple dialogs on Facebook messenger. We decided to use the Facebook messenger for a first exemplary implementation since it offers a mature API, large user base and is an important platform for volunteers. This chatbot is used as demonstrator to evaluate the technical feasibility and give a first impression on the user acceptance for this communication method.

The chatbot's ability to respond to user input depends on the amount of training examples connected to the specific intent. We generated training examples by searching a thesaurus for synonyms, for example "help", "register" and "volunteering". The training examples were supplemented in the course of time with the growing experience that we made with users testing the chatbot. To minimalize the risk of wrong user input, we designed the chatbot to suggest a set of options from which users can choose. In addition, it is possible to interact with the chatbot by putting own questions. Every dialog starts with the chatbot introducing itself and offering the user to either register for a mission, to get information on the VCS-system (called KUBAS in our example) or the possibilities of voluntary work in general. If the user wants to register for a mission, the chatbot then asks about their preferred work. If there is a suitable mission for the volunteer, the user is then asked to confirm their offer and will be sent a confirmation (Figure 2).

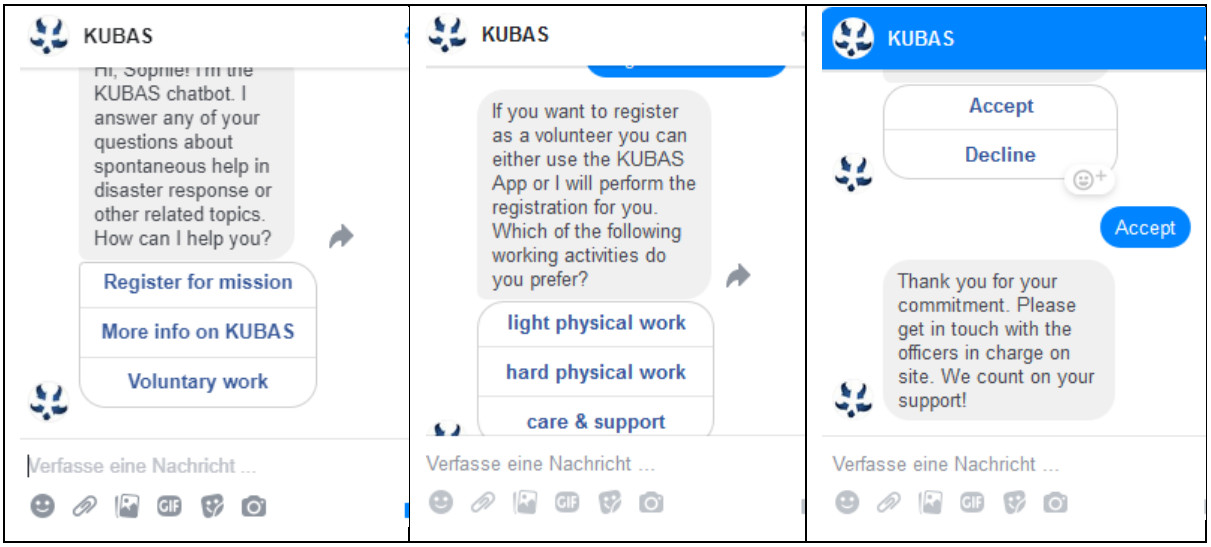

Figure 2. Chatbot Functions (Welcome message, Offering working activities, Confirmation of mission)

On an invalid input, the chatbot will send a default answer, informing that the user input has not been understood and referring to our KUBAS website for further information and assistance.

Our chatbot demonstrator has been presented to a specialist audience of disaster authorities and organisations at several workshops and got thoroughly positive feedback. Testers especially highlighted the integration in existing social networks, uncomplicated usage via natural language, direct feedback and reduced workload though automatisation. They mentioned a great potential for the application of chatbots in disaster response and volunteer coordination. However, at the present time the chatbot is not able to connect with the coordination platform, and therefore, volunteers are not able to register for a mission. In addition, we learned from user testing, that a more human-like conversation is desired. For this purpose, more training examples need to be provided. As the use of emoticons, such as the like-button on Facebook is very common, especially on messenger services, the processing of emoticons needs further exploration. Requirements such as grouping with friends or integrating information from external applications have also not been implemented yet. Our next steps will be to switch to another platform

that will allow multi-channel integration, such as Dialogflow, and to further develop the dialog and connect the chatbot to a VCS platform.

CONCLUSION

To reach a wide range of volunteers and to increase resilience by using a large variety of communication channels, we proposed an architecture that comprises a chatbot to handle the communication flow between VCS and SUVs. We used user stories, that have been developed in earlier work (see Betke 2018), to retrieve requirements for a communication system. We consider chatbots to be a suitable tool to meet these requirements, since just one chatbot is able to operate on many different channels, such as SMS and messenger services. Furthermore, chatbots are considered to be user-friendly and have the potential to simplify the registration process for the volunteer. So far, a simple chatbot has been implemented in our KUBAS Facebook messenger.

However, this chatbot does not meet all the requirements set out in this paper, as it is only able to conduct a basic conversation with the user, but not connected to a VCS. Future work focuses on further development of the demonstrator chatbot including the necessary VCS integration, multi-channel support and redefinition of the dialog modelling based on natural language processing. We plan to evaluate the usability of the chatbot in a large-scale exercise with a large number of SUVs and disaster authorities. Evaluation will include a comparison of SUV coordination with volunteer coordination app, chatbot and social media.

ABSTRACT

With the growth of social media and crowdsourcing in disaster response, further research is needed on the motivations and contributions of digital volunteers. This study applies a user-centered design approach to understanding how we might make better tools to support digital volunteers. This user-centered design approach involves stated preference elicitation methods through an online survey to understand what digital volunteers want in such tools. Through choice-based conjoint analysis, we contribute to mixed-methods research to gain additional insight into motivations and user preferences for a set of design features that might be incorporated into an online tool specifically for digital volunteers. Initial results show preferences for measures of success that were not monetary, which aligned with directly stated motivations for volunteering. Our findings corroborate with previous research in that feedback to volunteers is very important, as well as being able to measure the impact of their work.

Keywords

Disaster Response, Crowd-sourcing, Digital Volunteer, Social Media, User Design

INTRODUCTION

Emergency and disaster management has been transformed by mobile technologies and social media. Social media is particularly useful for emergency responders to communicate and gather information, meet and manage citizen expectations, increase situational awareness, and leverage citizens as force multipliers (Williams and Phillips, 2014). Previous uses of social media by the affected community and through global digital volunteers through Open Street Maps (OSM) and Twitter have largely been effective (Bjerge et al., 2016). Briony (2018) has made a number of observations about the value of social media for disaster response, particularly in the Caribbean. First, social media has shown potential as an additional channel for disaster response functions and services: Facebook offers preparedness information, WhatsApp has been relied upon for coordination and planning, and Twitter has been used for real-time weather updates to an extent. Second, social media is particularly useful as they are free to access with an internet connection, require little authentication to use, and are available in real-time. Third, the increasing use of social media, especially in small island developing states (SIDS), is important due to islands in the Caribbean featuring compressed spatial scales (local level is similar to national level). Further, the expanded use of social media has led to the growth of resilience and preparedness information online. Finally, as a tool to facilitate hurricane resilience, social media is a priority for SIDS to encourage and enable community engagement (Briony, 2018).

Despite the usefulness of social media, a main challenge is lack of relevancy and clarity of information provided due to the massive volume of available information after events and the fact that much of it can be considered noise (Cobb et al., 2014). There are often tradeoffs between gathering enough information to assess disasters and reducing

‡http://meche.mit.edu/ and http://ideation.mit.edu/

information and channels to be able to respond quickly (Leidner et al., 2009; Zhang et al., 2002). Many involved in disaster management are not always able to distinguish between channels, leading to uncertainty and loss of time (Bjerge et al., 2016). This may be partly due to lack of standardization as there is no customary approach across all actors to evaluate information (Commonwealth Telecommunications Organisation (CTO), 2006; Leidner et al., 2009; Williams and Phillips, 2014; Meissner et al., 2002). There has been growing interest and research on how to leverage the deluge of social media data for disaster management, including online platforms and tools that focus on crowdsourced data (Poblet et al., 2018).

Crowdsourced efforts can be critically important in disaster response, especially as they can be a way to handle big data and reduce the noise in information from social media. Crowd participation can better handle large tasks and data analysis needs through bringing digital volunteers together (Briony, 2018). Digital volunteers are those remotely located to a disaster that contribute either as individuals or within networks or organizations to the response effort (Poblet et al., 2018). They are unaffected individuals using social media and other online tools to assist in disaster response efforts by taking on tasks such as information processing through filtering and mapping crisis-related social media data (Cobb et al., 2014). Social media has become the main tool for digital volunteers, and the use of crowdsourcing platforms has improved volunteers' contributions to disaster management. A main task that digital volunteers conduct is media monitoring, including social media posts, to find new, relevant information and curating it into usable resources (Cobb et al., 2014). Given the value of social media's role in facilitating the efforts of digital volunteers, it is clear that there are substantial opportunities for the creation of online tools to better support their efforts. In this paper, we take a human-centered design approach to these tools that begins by understanding the needs and motivations of digital volunteers.

This study explores two main research questions on digital volunteers in disaster response: what features do they prefer in a digital volunteer platform and what are their main motivations to volunteer in disaster response? We conducted a multi-faceted survey with digital volunteers and potential digital volunteers to (1) assess their preferences for a digital volunteer platform, (2) assess their stated motivations for digitally volunteering in disaster response, and (3) gain insights into the design features of tools for crowdsourcing. Through this study, we hope to identify opportunities to improve the future design of digital volunteer and crowdsourcing tools for disaster response.

RELATED WORK AND RESEARCH GAP

Digital Volunteer Roles

Digital volunteers have become an established feature of crisis events. The main reasons for this include: (1) their motivation to make citizen-reported information usable and (2) access to online tools that allow them to access this information and coordinate their work (Cobb et al., 2014). Digital volunteer communities are one of four roles that crowds take on in crisis management based on distinct skills and expertise. Liu et al. (2014) identified these four roles as: 1) affected populations, 2) diasporas, 3) social networks, and 4) digital volunteer communities. In these roles, disaster-affected populations provide "local, timely, and direct experiential information", diasporas provide unique "socio-cultural tacit knowledge", social networks provide "varied background with unexpected and possible fortuitous experience', and digital volunteers offer their "capabilities in processing and managing crisis data" (Liu et al., 2014). Further, digital volunteers can take on different organizational forms in disaster response.

Empirical research on recent disaster events shows digital volunteer work can take place in four different organizational forms: established, extending, expanding, and emerging (Cobb et al., 2014). The emerging or 'emergent' category is identified by ordinary and local individual citizens that contribute to emergency response through new and informal groups (Sebastian and Bui, 2009). Emergent organizations of remote actors connected through social media are "now a feature of disaster response milieu," as evident through various examples of emerging organization assistance in the Haiti earthquake, Alabama and Joplin tornadoes in 2011, and Hurricane Sandy in New Jersey (Cobb et al., 2014). The expanding category is identified by having an established structure between events, but increased capacity for response during events by activating part time volunteers and bringing in new ones (Cobb et al., 2014). This category includes ongoing digital volunteer organizations that use online tools to provide remote assistance during disaster events, such as Crisis Commons, CrisisMappers, Standby Task Force, and Humanity Road (Cobb et al., 2014). In various organizational forms, digital volunteers have proven as key actors in a disaster response. We focus on the role of digital volunteers as emergent actors by assessing their motivations and incentives.

Digital Volunteer Motivations

Previous studies have surveyed digital volunteers that processed online and social media streams during crisis events and identified important motivations and incentives. A large number of studies have used Open Street Maps as a case study to determine the engagement and motivations of citizens as volunteers and have found participants

want to share their knowledge, experience community, learn new things and advance their career (Baruch et al., 2016). For other platforms, there can be very different motivations such as the desire to contribute to scientific discovery (Baruch et al., 2016). Santos Rocha et al. (2016) review literature on citizen engagement and identified motivations of digital volunteers including: connection to the area, ideology, personal satisfaction, community, humanitarian values, and desire to apply and improve technical knowledge (Santos Rocha et al., 2016). Other important incentives include: encouraging volunteers by giving feedback, recognition, appreciation and gratitude; cultivating sense of ownership and accountability; generating a feeling of inclusivity based on collaborations; and providing training and capacity-building opportunities for volunteers (Santos Rocha et al., 2016). In regards to the effort input of an individual, this is higher when the individual expects that the contribution will yield results (Santos Rocha et al., 2016). Among these incentives, they can influence volunteer's accuracy and task completion differently. Daniel et al. (2018) review crowdsourcing literature and identify that incentives affect the attractiveness of a task in crowdsourcing (Daniel et al., 2018). Incentives can target the extrinsic (reward-driven) or intrinsic (interest-driven) motivations of workers. Increasing extrinsic motivations leads to faster task completion while increasing intrinsic motivations leads to higher quality (Daniel et al., 2018).

Other studies have found motivations can vary based on previous experiences. Cobb et al. (2014) interviewed those who worked remotely to process social media streams as digital volunteers or as emergency response professionals and found a main reason to become a digital volunteer as believing that social media and non-local responders can have an impact during crises. Other reasons they identified included: gain skills for their career, "give back to society because they want to pay it forward and they were impacted," they have extra time on their hands, and they have a personal connection to the area. Among those who used social media in an official capacity, their motivations were to gauge community opinions and misunderstandings so outgoing messages could be tailored to specific needs and they then connected to people doing digital volunteer work (Cobb et al., 2014). This study also found different motivations for continuing as a digital volunteer, especially considering many interviewees described disaster fatigue can occur after responding to an event since continued participation has a significant cost (Cobb et al., 2014). Motivations for sustained membership included: altruism, making an impact, knowledge of definitive impact, formation of identity as a digital volunteer, connecting their work in the crisis space to their self-identity, the personal relationships that volunteers forge with each other, and gain new skills through digital volunteer work that may benefit them in other areas of their lives or in future disaster (and non-disaster) scenarios (Cobb et al., 2014).

Baruch et al. (2016) examine online crowdsourcing from the perspective of volunteers and the campaign coordinator of Tomnod, an online mapping project owned by Digital Globe that uses crowdsourcing to identify objects and places in satellite images (Baruch et al., 2016). Through online surveys, they found participant demographics influence their motivations including being retired or having a disability or long term health problem leading them to use Tomnod as a "better use" of time or "help in anyway possible" (Baruch et al., 2016). They also found a majority of general motivations aligned with an altruistic theme, including explicitly mentioning that they want to help people in urgent need of assistance (Baruch et al., 2016). Further, some saw contributing to Tomnod as an alternative to charity work and other motivating factors included involvement in a global community, looking for people they know, enjoying the task, and taking part in a fun pastime (Baruch et al., 2016). Altruistic motivations may not be enough, but successful campaigns benefit from volunteers having a sense of satisfaction and achievement on their contributions (Baruch et al., 2016).

For crowdsourcing campaigns in humanitarian applications, there is a need for further research into the motivations and preferences of users (Baruch et al., 2016). The current literature need mixed-methods research to provide an additional depth of insight into digital volunteers (Baruch et al., 2016). In particular, there is further research needed on understanding stakeholder needs and values for the development of a platform used by digital volunteers. This study seeks to contribute to this research in order to improve upon sources of information that help meet the needs of those affected by an emergency or disaster.

Design Features and Conjoint Analysis

Using similar methods to identify motivations for participating as a digital volunteer, previous studies have found specified features of a platform or tool that volunteers would prefer. As found in Baruch et al. (2016) through an online survey, the main features that are preferred in a digital volunteer platform include feedback on quality of contributions, follow-up on how data was used, education or training to improve skills, and engagement with formal organizations like Tomnod. Overall, there was a sentiment of a participant's wish to be more engaged, such as by getting a "certificate of participation or some kind of award" (Baruch et al., 2016). Moreover, a majority of participants referred to wanting some sort of feedback and desire for more information on the campaigns, including how data was used (Baruch et al., 2016). A key feature of various digital volunteer platforms is an 'agree' score that shows how many participants also tagged the same location, but this was viewed negatively by some as it reflected how a volunteer may be wasting their time and they would rather prefer to get feedback on their impact or results (Baruch et al., 2016). Other features that volunteers would like included: greater control over data

(i.e. a more transparent platform), links to Google maps, ability to see what other volunteers are doing, ability to discuss observations with others, and a voting system to choose the campaign that is activated (Baruch et al., 2016). Including this study by Baruch et al. (2016), directly stated questions in surveys and open-ended questions in interviews have largely been used to identify preferences for features of crowdsourcing and digital volunteer platforms for humanitarian and disaster response applications. In other work on individual motivations for digital volunteering and design preferences for crowdsourcing platforms, interviews for persona identification and user trials have been used (Yu et al., 2012b; Ludwig et al., 2017). We seek to apply an approach of user-centered design to understand the preferences and motivations of digital volunteers that has been seldom applied in the field of disaster response.

This study applies a user-centered design approach to understand stakeholder perceptions and motivations for being a digital volunteer in disaster response and to determine important features for a platform for digital volunteers. To obtain meaningful and accurate information from users, conjoint analysis is a widely used and cost-efficient tool to capture preferences for products. Conjoint analysis addresses the additive effect of a set of individual variables on consumer preference (Bao et al., 2014). The type of conjoint analysis used in this study is choice based conjoint, which presents participants with several products with different combinations of attributes and asks them to choose which they prefer (Bao et al., 2014). An example of choice based conjoint analysis is in c, where this method was used to identify preferences for product appearance of solar panels. In the humanitarian and disaster response field, there have been few uses of conjoint analysis including identifying preferences for aid delivery plans (Gralla et al., 2014). Although widely used in market research, conjoint analysis has largely not been used in the field of humanitarian and disaster response nor to capture preferences in crowdsourcing platforms. In this study, the preferences of potential and previous digital volunteers for features of a digital volunteer platform were examined using conjoint analysis.

METHODS

User-based Design and Conjoint Analysis

In this study, choice based conjoint analysis is used as the main preference elicitation method. Conjoint is used widely in marketing for understanding the preferences among attributes in a group of people. In a conjoint analysis, several attributes of a product are chosen, and each attribute can be varied at discrete levels. A controlled set of potential configurations is created by experimental design, and each configuration contains a combination of the attributes (Kuhfeld, 2003). After the set is prepared, users are asked to rate, rank, or choose among the product profiles. Choice based conjoint presents several configurations with different combinations of attributes to users and asks them to choose the one they like the most (Kuhfeld, 2010). With the user ratings, utility models can be built and predictions can be made about users' future preferences. Conjoint analysis is used to address the additive effect of a set of individual variables on consumer preference and is widely used in market research to determine user value of different features that make up a product or service (Green, 1974). As conjoint belongs to the category of stated preference eliciting methods, this was supplemented by directed stating preference methods in the online survey we conducted.

Data Collection

This study's first part includes presenting users with an online survey on a digital volunteer platform with varying features and related questions on experience and potential motivations for volunteering in a disaster response. The details of creation of the survey, administration, and participant demography follow.

Attribute Identification

A literature review was conducted to identify features (or attributes) of crowdsourcing platforms (Poblet et al., 2018; Hossain and Kauranen, 2015), including websites (Yu et al., 2012b), public displays (Ludwig et al., 2017), apps (Gu et al., 2017; Morschheuser et al., 2018; Li and Ulaganathan, 2017), among other systems (Ogie et al., 2019; Yu et al., 2012a), as well as to identify motivating factors for digital volunteers (Cobb et al., 2014; Daniel et al., 2018; Baruch et al., 2016; Spatharioti and Cooper, 2017; Santos Rocha et al., 2016). This was supplemented with an analysis of the attributes of major crowdsourcing platforms for digital volunteers, including Tomnod, CrowdSource Rescue, Ushahidi and Open Street Maps (OSM). In this study, analysis of the literature and currently available resources identified five key attributes that are related to the motivations of digital volunteers in a crowdsourcing platform:

1. Volunteer Profile
2. Volunteer Measure of Success Shown on Profile
3. Social Network of Volunteers
4. Feedback to Volunteer

5. Social Media Post of Volunteer Task

In the survey, each attribute was varied on 3-6 levels, which are shown in Table 1. We only considered design features of a crowdsourcing platform that are most directly related to motivating factors for digital volunteers. For the sake of simplicity, we also do not consider any other user interaction or design features than those listed, and hold all other attributes constant.

Attribute	Num. of Levels	Level 1	Level 2	Level 3	Level 4	Level 5	Level 6
Volunteer Profile	4	Display past experiences in volunteering	Display volunteer's location	Display volunteer's calendar	Display when volunteer is working on task		
Volunteer Measure of Success Shown on Profile	5	Rank among other volunteers	Points earned based on task completed	Money earned from tasks completed	Awards won based on tasks completed	Money earned from donations	
Social Network of Volunteers	4	View volunteers nearby	View volunteers with similar interests	View volunteers working on similar tasks	No Social Network		
Feedback to Volunteer	6	Get verification from formal organization	Earn points for accuracy in the results of tasks	Enter to win reward for highest accuracy in results among group of volunteers	Earn money per task completed	Earn money from donations depending on who sees your profile and tasks completed	Earn money based on accuracy in results of tasks
Social Media Post of Volunteer Task	4	Add to LinkedIn skills or experience	Post on Facebook	Post on Twitter	Post on Instagram		

Table 1. Levels of attributes influencing design features of crowdsourcing platform

Survey Design and Participants

A seven-part survey was designed, with a summary of its structure shown in Table 2. The sequence of different parts of the survey was designed so directly stated questions came after pairwise choice questions to reduce potential bias of preference. Specific questions were introduced as cross checks to see if respondents answered the same questions the same way again. Directly stated questions on motivation and social media use were elicited in Part VI in the survey. The survey was created and distributed using SurveyAnalytics. Informed consents from the participants were obtained at the beginning of the survey. A total of 695 participants took part in the survey. Two criteria were used to screen the data:

1. **Completeness**: Respondent data was assessed based on total completeness of survey. Incomplete questions were identified and rejected.
2. **Quality Control Questions**: Two quality control questions were included to ensure respondents did not thoughtlessly provide answers. The questions were dispersed throughout different parts of the survey and included a fixed question with a simple 'please select continue response' direction. In addition, a question from Part V was reintroduced in Part VII to cross check whether respondents answered in the same way. Respondents that did not pass all quality control questions were rejected.

This led to 389 valid responses for final data analysis. Among the valid data, demographic information of the participants is as following: 269 females, 117 males, age ranging from >18 to 60+, and 371 participants stated they reside in the United States.

Conjoint Data Analysis

A multi-nomial logit model was used to determine the conjoint part-worth values. In this model, $w(a, l)$ is the part-worth value for a particular attribute a and level l and x is an array which is equal to 1 if a specific attribute and level are present and 0 otherwise. Where U_x is the sum of the part-worths for the attributes and levels present in a configuration, this model assumes that for a choice between N configurations, the probability configuration 1 will be chosen is:

$$P_1 = \frac{exp(U_1)}{\sum_{i=1}^{N} exp(U_i)}$$

Following with this model, the choice probability of choosing the c^{th} configuration out of total C configurations in the t^{th} task for the n^{th} respondent is:

$$P_{ntc} = \frac{exp(X_{rtc}.w)}{\sum_{i=1}^{C} exp(X_{rti}.w)}$$

Part I	Introduction: general introduction of study and volunteering for disaster response
Part II	Disaster Experience Level: two questions on experience levels in an area impacted by a disaster or emergency, including if have known someone else with a first-hand experience
Part III	Preference as Volunteer for Platform: five-question pairwise choices questionnaire. Each question asks participants to choose preferred set of features of platform among five other sets of features.
Part IV	Preferece as Donor for Platform: five-question pairwise choices questionnaire. Each question asks participants to choose preferred set of features of platform among three other sets of features.
Part V	Volunteering Experience Level: two questions on experience levels in volunteering and digital volunteering for emergency or disaster situations
Part VI	Directly Stated Preferences: two questions asking motivating factors for volunteering and social media use. Question one asks participants to rank possible motivating factors if they were to volunteer in an emergency or disaster. Question two ask participants to specify level of use of various social media
Part VII	Demography: a questionnaire asking basic demographic information including age range, gender, income level, education, and residential location.

Table 2. Survey Structure

As per the algorithm by SurveyAnalytics (SurveyAnalytics, n.d.), a log-likelihood measure for all responses is used, forming a multi-dimensional non-linear continuous maximization problem. This is solved using a Nelder-Mead Simplex Algorithm to find the part-worth values. Finally, the part-worths are re-scaled so that for any attribute they have a mean of zero and then normalized for graphical representation on a percentage scale of 0 to 100 percent. The relative importance of each attribute was calculated by considering how much difference each attribute could make in the total utility of a product, where the difference is the range in each attribute's utility values. The importance measures are ratio-scaled and relative, study-specific measures. Utility value is calculated by the average of the part-worth values. Part-worths are scaled to an arbitrary additive constant within each attribute and are interval data. The equation used in this study for calculating a relative attribute importance was:

$$RelativeImportanceofAttribute = \frac{(HighestUtilityValue - LowestUtilityValueofattribute)}{\sum UtilityRangeofallattributes}$$

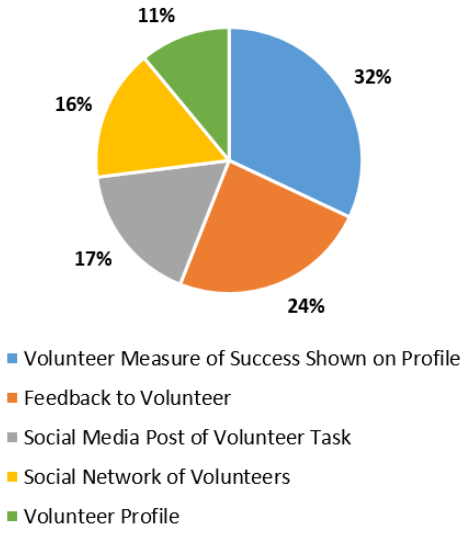

Figure 1. Relative Importance of Attributes

2.	View volunteers working on similar tasks
3.	Get verification from formal organization
4.	Post on Facebook
5.	Rank among other volunteers

Figure 2. Best Profile

RESULTS

The relative importance of each attribute was calculated by considering how much difference each attribute could make in the total utility of a product. The results shown in Figure 1 are the part-worth utilities of each attribute level, which indicate the preference level of that attribute. The higher the part-worth, the more important the attribute is to the respondent. The *Volunteer Measure of Success* attribute was found as the most important followed by *Feedback to Volunteer*. The results for all attributes are shown in Figures 3 and 4. Among all the possible combinations of attribute levels, the 'best profile' made up of the most important level for each attribute is shown in Figure 2. For the top attribute of the *Volunteer Measure of Success*, the level with the highest utility (or part-worth) was *Rank among other volunteers* at 91.4% and the level with the lowest utility was *Money earned from donations* at 0.7%. For the directly stated question on motivation factors for volunteering in a disaster or emergency, the results are shown in Figure 5. The average rating of motivation factors are shown, based on participants rank ordering each factor from 1-8 (1 being highest). The motivation factor with the highest average rating was *Personal connection to area*, followed by *Give back to society* and *Make an Impact*.

DISCUSSION AND CONCLUSION

Digital Volunteer Motivations and Design Preferences

Similar to previous studies on digital volunteer roles and motivations (Cobb et al., 2014; Baruch et al., 2016), important attributes for a crowdsourcing platform were found to be the measure of success of volunteers and the feedback provided to volunteers. Within these two attributes, the least preferred levels were those related to monetary compensation. This aligns with the directly stated results for rating of motivation factors in the survey, which found earning a reward (monetary, prizes, etc) as being rated the lowest. For the remaining three attributes of a crowdsourcing platform, the utility values for the levels within the attributes were less varied, indicating that users did not strongly prefer these certain features of a crowdsourcing platform over others. As the conjoint results

indicate, digital volunteers value understanding their success and would prefer to view this on a digital volunteer platform in the form of a rank among other volunteers or as awards won. Similarly, digital volunteers also value feedback and would prefer to view this on a digital volunteer platform in the form of verification from a formal organization or entering to win a reward. Conjoint analysis elicited such preferences of digital volunteers and revealed the importance of evaluation of a volunteer's performance. The main findings of this paper are that the future design of digital volunteer platforms should consider the importance of measuring volunteer's success and providing feedback to volunteers, particularly in a form that confirms to the volunteer that they have made a useful contribution.

Overall, this study has shown a user-centered approach can be applied to understanding digital volunteers and in the field of disaster response. Moreover, this study contributes to mixed-methods research to gain additional insight into motivations and user preferences for a set of design features that might be incorporated into an online tool specifically for digital volunteers. A limitation of this study includes that the survey used written description of features of a digital volunteer platform rather than visual depictions or examples, which may impact the understanding of respondents and preferences of features. Remaining work still needs to be done in building individual preference models, aggregated preference models, and comparing subgroups. Future work could also include different scenarios for volunteers to select motivating factors, as well as an experimental evaluation of accuracy in a digital volunteer task compared to motivating factors.

ABSTRACT

This paper describes the use of a previously established qualitative coding scheme developed through a design workshop with public safety professionals, and applied the schema to social media data collecting during crises. The intention of applying this scheme to existing crisis datasets was to acquire training data for machine learning. Applying the coding scheme to social media data revealed that additional subcategories of the coding scheme are necessary to satisfy information requirements necessary to dispatch first responders to an incident. The coding scheme was refined and adapted into a set of instructions for qualitative coders on Amazon Mechanical Turk. The contribution of this work is a coding scheme that is more directly related to the information needs of public safety professionals. Implications of early results using the refined coding scheme are discussed in terms of proposed automated methods to identify actionable information for dispatch of first responders during emergency incidents.

Keywords

Dispatch, Public Safety Answering Point (PSAP), Social Media, Qualitative Coding.

INTRODUCTION

Researchers have been working for almost a decade to refine methods to identify information relevant to crises posted by digital bystanders on social media (Hughes & Palen, 2009; Imran, Elbassuoni, Castillo, Diaz, & Meier, 2013). Recently, new fieldwork with 9-1-1 call-takers at Public Safety Answering Points (PSAPs) in the United States has extended this work by identifying information requirements necessary to dispatch first responders (Kropczynski et al., 2018). Understanding information requirements is a helpful as a first step to automating methods to identify actionable information on social media such as requests for assistance and enhancing situational awareness (Vieweg, 2012). In this paper, we describe early work to apply these information requirements to social media data collected during crises using qualitative coding. We begin by describing the 6W (Where, What, Weapons, When, Who, Why) information requirements that must be satisfied to dispatch first responders identified through a design workshop with public safety professionals at a PSAP in the United States (Kropczynski et al., 2018). We then use manual coding to identify information satisfying these requirements in social media posts. Results are used to refine this coding scheme. Finally, we used the refined manual coding scheme to code social media data and develop insights about next steps to automate the detection of actionable information using machine learning techniques.

Previous work in coding and classifying information posted to social media has identified information that is informative (Imran et al., 2013), enhances situational awareness (Vieweg, 2012), or general relatedness to a crisis (Olteanu, Castillo, Diaz, & Vieweg, 2014). These works have evolved over several years to allow the development of machine learning classifiers used to automate detection of social media data that may be useful for situational awareness (Caragea, Silvescu, & Tapia, 2016; Herndon & Caragea, 2016). Equally important to these efforts are works to filter irrelevant information from bots (Wang et al., 2014), or to sort posts by news sources and external observers (Olteanu, Vieweg, & Castillo, 2015; Starbird, Palen, Hughes, & Vieweg, 2010). Despite this evolution, PSAPs in the United States do not currently utilize protocols that detect and respond to requests for assistance that are posted to social media. Instead, dispatch of first responders is based on information gathered through phone calls. In this trajectory to refine automated detection of useful information, it is important to consider the information requirements to dispatch first responders to a crisis.

Today, PSAP call-takers use computer-aided software to gather information from individuals that call 9-1-1, such as ProQA (https://prioritydispatch.net/discover_proqa/). ProQA software provides 9-1-1 call-takers with scripts that distill caller information into emergency types and results in the dispatch of firefighters, law enforcement, medical responders, or other first responders to resolve the request for assistance. Logic used by ProQA is rather complex, however, prior to the use of computer-aided software, 9-1-1 call takers utilized a basic information gathering protocol called the 5W's/6W's, in which call takers ask 1) *where* is the incident taking place, 2) *what* is the nature of the incident, 3) are there *weapons* involved, 4) *when* did the incident occur/is the incident ongoing, and 5) *who* is involved or how many people are involved. Some protocols include a sixth W, which retains any information about *why* the incident occurred. Table 1 shows the results of previous fieldwork with PSAP call takers, dispatchers, and first responders worked create a qualitative coding scheme to identify social media posts that contain information that is necessary to determine emergency types and send first responders to emergency locations.

Table 1. Original 6W Qualitative Coding Scheme (Kropczynski et al., 2018)

Label	Coding	Representative Examples in Fieldwork
Where	Place where help is needed; where an incident occurred; location of victim/suspect/witness; Directional guides/points of reference	"Northland Mall parking garage"; "in the corridor at univ high"; "@ st philip & george"; "headed west on I-26 at Ashley Phosphate"
What	Type of incident; indications of severity	"car accident"; "boat on fire lots of flames"
Weapons	Indication of whether weapons are present and if so, the type of weapons present	"#shooting"; "assault rifle"; "gun"
When	Time the incident occurred; indication of whether incident is still occurring; time lapse	"just now"; "7:32am"
Who	Number of people injured, or number of people armed; Description of victim/perpetrator/vehicle ; nature of observer (firsthand vs. secondhand account)	"3 injured"; "2 armed men"; "tall skinny white guy in blue jeans and a white v-neck tee.. 20 yrs old-ish.. Brown hair"; "we"
Why	Chain of events that led to emergency; Rationale for occurrence that may be helpful to an investigation	No examples

The 6W coding scheme has been applied to fictional social media posts generated by professionals working within a PSAP that were asked in a design workshop to "…construct a 280-character Tweet (Twitter's current character limit) that they perceived was descriptive enough for someone in their professional position to take action on" (Kropczynski et al., 2018). For each of these information labels, previous work has been identified to mine social media data for location information (Bilhaut, Charnois, Enjalbert, & Mathet, 2003; Daly & Thom, 2016; Grace et al., 2017; Han, Cook, & Baldwin, 2014; Intagorn & Lerman, 2010; Quercini, Samet, Sankaranarayanan, & Lieberman, 2010), incident types (Herndon & Caragea, 2016; Li, Caragea, Caragea, & Herndon, 2018; Mouzannar & Awad, 2018), using bag of word techniques or convolutional neural networks (Caragea et al., 2016) may be used to detect presence of weapons, timestamps aid in the identification of when an incident occurred, but no tools currently combine these techniques into one tool. This paper describes early work to move the trajectory of identification of actionable information forward in order to create such a tool.

Research Question

Although the 6W coding scheme has been applied to fictional social media posts, it has not yet been applied to social media posts generated during a crisis. The overarching research question guiding this work is: When applied

to social media posts generated during a crisis, does the 6W coding scheme help to identify information that is actionable for dispatch of first responders according to previously established information requirements?

METHODS

The primary objective of this research is to verify the application of the 6W coding scheme to social media posts generated during a time a crisis using qualitative coding. As a large, pre-labeled dataset, the CrisisLex T6 dataset (Olteanu et al., 2014) was viewed as a viable dataset for the purposes of this analysis. The dataset contains data collected from Twitter during 6 different disasters between October 2012 and July 2103 in English-speaking countries. For each of these incidents, randomly selected tweets have been pre-filtered to label data as related/not related to a disaster, and either informative/not informative. Although this dataset has since been criticized when applied to establish, machine learning classifiers due to methods employed to collect data, for our purposes, our intention is only to qualitatively observe the presence of 6W information in social media generated during a crisis. The purpose of this activity is detection, but coding of relevant and informative data in order to establish whether the 6W coding scheme can be used to satisfy information needs of dispatch.

In the CrisisLex T6 dataset, 3926 tweets have been labeled as both related and informative to the crisis that they were collected during. Our method is to qualitatively code these pre-labeled tweets using the 6W coding schema. For each of these tweets, trained qualitative coders were asked to review contents, and if present, copy and paste the contents of tweets related to one the W's according to the coding schema into an associated column of a spreadsheet. The purpose of retaining content rather that indicating presence/absence of the W was to review the way that each of these W's are represented in actual tweets. In addition, there was some hope that text related to each W label might be used for training purposes for machine learning.

RESULTS

Results showed that the majority of tweets labeled in the CrisisLex T6 dataset as informative and relevant contained *where*, *what*, *who*, and *why* information. Less prevalent was information related to *weapons* and *when*, however this varied by incident as only 2 of six incidents would be expected to mention *weapon* information (Boston Bombing and LA Airport Shooting). The low incidents of *when* information was anticipated because the implication of many tweets is that the information being posted is currently happening.

Table 2. Percent of Tweets Labeled by 6Ws

W Label	Percent
Where	78%
What	88%
Weapons	3%
When	5%
Who	68%
Why	72%

Although, the application of the 6W qualitative coding scheme demonstrated that many of the W's are present in these tweets, examination of the content contained in these tweets showed that very few tweets contained information requirements to dispatch first responders. Beginning with *where* information, this is necessary to identify a location to dispatch first responders. As written in the original coding scheme, *where* information is quite broad in its' description. This resulted in the contents of this coding to frequently include the name of a state, region, or town. Although this type of information may be quite helpful for situational awareness, it is the case that few tweets contained information that would satisfy the requirement of identifying a location where a first responder may be sent.

What information was present in the majority of tweets, however, the information requirement that this information must satisfy is to identify statements that can be associated with a type of incident to help understand the type of first responder to be deployed (fire, law enforcement, medical). As written, qualitative coding resulted in many statements that simply reiterated the subject of the tweet rather than information that helped identify a specific incident. Of all 6Ws, *weapons* information was most accurately coded in line with information aims—identifying the presence or absence of a weapon. *Who* information typically took the form of an @mention of another Twitter user, although a small number of tweets contained the number of victims or perpetrators involved in an incident. Finally, *why* information frequently included statements that were duplicated in *what* information, for example, "mandatory evacuations" may be *what* is happening in one tweet and the reason *why* is "flash flooding," however, flooding may also be considered *what* information. Based on these results, it was determined that the use of the 6W coding scheme, as written was not useful to identifying actionable information for dispatch.

REFINEMENTS TO CODING SCHEME

These early results indicated to our research team that further refinements to the coding scheme in terms of subcategories for each of the 6Ws would be necessary to focus on stratifying PSAP dispatch information requirements. The subcategory coding schemes contain subcategories that are intended to only focus on actionable information, provide a specific coding criteria, and examples borrowed from actual tweets in the dataset. Further, we have reduced the 6W coding scheme to a 5W coding scheme by eliminating the *why* information category due to the lack of actionable information for dispatch that is typically present in this category. These subcategories have been tested for clarity with qualitative coders on Amazon Mechanical Turk, but future work will be conducted to better understand the presence of these tweets within a larger dataset. Only a small sample of 200 tweets from the CrisisLex T6 dataset were used for the purposes of understanding if subcategories would be a viable method to refine the coding scheme.

Qualitative coders were given the following instructions: For each tweet, the coder should copy and paste words from the tweet that match the particular subcategory, if the information is present. If not present, the form should be left blank. Please keep in mind that the goal of this work is to help identify information that will be relevant to first responders during an emergency event. If something in a tweet seems important for a first responder to know, but does not fit into a category, please make a note under the "other" category. Also, if you find some of the coding descriptions confusing or misleading, you can also list that information under the "other" category.

Subcategories are described in sections that follow:

Where Information Subcategory Coding Scheme

Our results showed that state, region, and town are often considered as *where* information and although useful to situational information, it is assumed that in a tool that is used by dispatch, social media posts will likely be aggregated from a particular city, town, or regional bounding box. Therefore, tweets relating to an entire state is simply too broad to be actionable in most cases. The coding scheme subcategories have been updated as follows:

Subcategory:	Street address
Coding:	(If present, please write) Number of building and name of street
Example:	123 Main St.; 456 East Ave.; 789 MLK Rd.
Subcategory:	Building name
Coding:	(If present, please write) Name of well-known building
Example:	Sears Tower; Kirkland Mall; the Courthouse
Subcategory:	Location within building
Coding:	(If present, please write) If building name is known, this information specifies a floor, room, or orientation within a building
Example:	Near the east entrance; the southwest corner of the building; Near Taco Bell in the Mall
Subcategory:	Intersection
Coding:	(If present, please write) Location of incident in the form of the intersection of two streets. Both streets must be named to be an intersection.
Example:	Main and Vine; Main St. and Vine St.
Subcategory:	Words that indicate a moving target (vehicle in motion)
Coding:	(If present, please write) direction of moving target (i.e. north, south, east, west) or area that moving target is heading in the direction of (i.e. toward Main St.; toward Taco Bell)
Example:	headed north on Main Street; took off in the direction of Taco Bell
Subcategory:	Situational awareness in neighborhood/city/region
Coding:	(If present, please write) Name of neighborhood, city, or region
Example:	Highland Neighborhood; Townville, Low Country

Information that is not actionable: reference to state

By employing the above subcategories, none of the coders indicated that coding information are unclear. Results showed that the sample of 200 tweets contained 19 street addresses, 12 building names, 3 locations within a building, 7 intersections, 3 moving targets, and 90 tweets that contained information that may be useful for situational information.

What Information Subcategory Coding Scheme

Results of original coding scheme found that *what* information was often interpreted as the subject of the sentence, based on this result, two subcategories were created to better satisfy information requirements for dispatch. These subcategories asked qualitative coders to specifically identify requests for assistance and words that indicate there is an emergency situation or a situation that can/should be addressed by a first responder.

Subcategory:	Request for assistance
Coding:	(If present, please write) Information that relates to the type of assistance being requested - or full request for help
Example:	in need of rescue; building collapse; stranded
Subcategory:	Words that indicate there is an emergency situation or a situation that can/should be addressed by a first responder
Coding:	(If present, please write) Information about a crisis event taking place
Example:	Fire, flood, crash

None of the coders indicated that the coding scheme for these subcategories are unclear. Of the 200 tweets coded, 10 contained requests for assistance and 143 contained information that coders believed would be useful information for first responders. This information often contained very general words such as "flood", "shooting", or "wildfire" which indicates that this category should be further explored. In many instances, it is simply the case that the tweet did not originate from an eyewitness or victim of an event, but instead originated from a news source or outside observer of the event on social media. Techniques currently being used to better filter tweets by eyewitnesses (Caragea, Squicciarini, Stehle, Neppalli, & Tapia, 2014; Li et al., 2018) will help to further refine work in this category.

Weapons Information Subcategory Coding Scheme

Although this category already produced useful information, we attempted to further refine to two subcategories in line with information requirements which includes information that indicates a weapon is present and words that indicate what kind of weapon is present.

Subcategory:	Words that indicate that weapon is present
Coding:	(If present, please write) This information may simply indicate that a weapon is present, but does not indicate what kind of weapon
Example:	shooter, shots, explosion, loud pops
Subcategory:	Words that indicate what kind of weapon is present
Coding:	(If present, please write) Indication of type of weapon present
Example:	gun, bomb, rifle, AK47, baseball bat, mace, tire iron

None of the coders indicated that the coding scheme for these subcategories are unclear. Of the 200 tweets, 66 related to incidents where a weapon may have been present (Boston Bombing and LA Airport Shooting). Of those, 61 contained information coded was words indicating that a weapon is present and 11 contained words that indicate what kind of weapon is present. In the case of the kind of weapons present, many wrote "bomb" or "rifle," based on this result, a bag of words technique where weapon types are pre-loaded may be more useful for detection of this subcategory. None of the tweets from incidents related to natural disasters (wildfires, flooding) contained information coded as *weapons* information.

When Information Subcategory Coding Scheme

This category was further refined into three subcategories, information that indicates that a situation is ongoing, happened in the past, or will happen in the future.

Subcategory:	Indication that situation ongoing
Coding:	(If present, please write) Any information that indicates that the situation still requires the help of a first responder
Example:	Just now, a minute ago, breaking, latest, exact time mentioned by user, but not the timestamp of tweet
Subcategory:	Indication that situation happened in the past
Coding:	(If present, please write) Any information that indicates that the situation happened in the past and may not still require the help of a first responder
Example:	earlier today, yesterday, ambulance just left, but not the timestamp of tweet

Subcategory: Indication that situation may occur in the future
Coding: (If present, please write) Any information that indicates that there is an impending threat of emergency that is about to occur and will require the help of a first responder
Example: threat, headed this way, worried about possible

None of the coders indicated that the coding scheme for these subcategories are unclear. Of the 200 tweets coded, 15 contained information that indicated that a situation is ongoing, 10 contained information that indicated a situation happened in the past, 11 contained information that indicated a situation may occur in the future.

Who Information Subcategory Coding Scheme

Results of our analysis showed that *who* information may be interpreted as an original poster of a tweet, news source or agency mentioned in a tweet, which is not often actionable information. Subcategories focused on actionable information now indicate who is in need of assistance and who is the perpetrator.

Subcategory: Who needs assistance
Coding: (If present, please write) Any description of a person in need that will help a first responder identify them, or information that will help a dispatcher identify number of resources to send to the scene
Example: Lady on ground, person in red car, three children, a busload of people

Subcategory: Who is the perpetrator
Coding: (If present, please write) Any description of a person that law enforcement or a first responder should be aware of
Example: Person in yellow jacket; black SUV

None of the coders indicated that the coding scheme for these subcategories are unclear. Of the 200 tweets, 21 contained information related to who is in need of assistance. None of the tweets contained information about a perpetrator.

Other Information Identified During Coding

As mentioned in the coding instructions, Amazon Mechanical Turkers were given the option to share any information that they thought may be important to a first responder but does not fit into any category. They were also encouraged to state any notes related to coding instructions that may have been confusing or misleading. None of the coders stated that coding instructions were confusing or misleading. Some coders included words that seemed useful to situational awareness for citizens such as “emergency declaration” or “campus closed” but no theme emerged that led to the inclusion of a new category.

CONCLUSION AND FUTURE WORK

Based on these results, we believe that the 5W coding scheme with categories included show promise for the development of tools to automate detection of actionable information. While this is the case, of the 200 tweets coded for refinement of this coding scheme, few contained actionable information. An original aim of this work was to utilize actionable information present in social media posts generated during a crisis, however, in attempting to identify these tweets for machine learning training using manual coding, we found that the dataset we have utilized contained few incidents of actionable information. For many of the subcategories, other techniques or dataset may be useful for the automated coding of actionable information that does not require large datasets of actionable information. These subcategories include: street address, building name, intersection, neighborhood/city/region, presence of a weapon, type of weapon, and past/present/future tense words. Categories that will need attention in the future include requests for assistance. Existing presorting techniques may be employed before attempting to find this type of data in future work.

ABSTRACT

When a major event such as a crisis situation occurs, people post messages on social media sites such as Twitter, in order to exchange information or to share emotions. These posts can provide useful information to raise situation awareness and support decision making, e.g., by aid organizations. In this paper, we propose a novel method for social media crawling, which exploits a Bayesian inference framework to keep track of keyword changes over time and uses a counter-stream to gauge the inclusion of noise and irrelevant information. In addition, we present a framework to evaluate real-time adaptive social search algorithms in a reproducible manner, which relies on a semi-automated approach for ground-truth construction. We show that our method outperforms previous methods for very large scale events.

Keywords

adaptive crawler, real-time adaptive search, event tracking, crsis communication

INTRODUCTION

Nowadays, social media platforms have become an essential communication tool since they provide an open medium on a diverse spectrum of topics. As an accessible and near real-time reflection of such events and their perception, Twitter has attracted the attention of many researchers across different domains. Twitter content analysis is useful for different applications including but not limited to detecting customers' reactions towards a product (Chen et al. 2013), analyzing public political polarities (Conover et al. 2011), predicting election results (Tumasjan et al. 2010), monitoring news (Magdy 2013), identifying and analyzing researchers (Hadgu and Jäschke 2014) and crisis management (Castillo 2016). As a foundation for those analyses, the task of adequately collecting relevant content for an event of interest, has also gained some interest in the research community recently.

Since manually checking and changing keywords as an event unfolds, requires a lot of effort and is inefficient, different automatic query keywords adaptation strategies have been proposed (Wang, Tokarchuk, Cuadrado, et al. 2013; Magdy and Elsayed 2014; Sadri et al. 2016) to monitor unfolding events on Twitter. All different adaptive search methods try to adapt the search keywords as the event evolves through out the search process. An intuitive method is to consider the most frequent hashtags that appear in a time interval and use them as the next query keywords. However, this technique has major limitations. In particular, many people exploit trending hashtags through hashtag hijacking (Hadgu, Garimella, et al. 2013) to diffuse opposing views and unrelated content, e.g., marketing companies take advantage of frequent hashtags to promote their ads. Another problem is that the same

hashtag could be used for different events that may happen at the same time. The role of the adaptive search systems is to retrieve as many relevant tweets as possible without introducing too much noise.

Therefore, more advanced techniques that consider correlation of keywords to the underlying event or those based on text content similarity measures are applied to capture promising query keywords that preserve relevant content. In this paper, we present a novel adaptive crawling approach for Twitter which can be used to track a particular event in real-time. The adaptive crawler starts with a set of seed keywords given manually by the user. In contrast to existing methods, it does not rely on the filtered stream generated based on this keyword set (and its modifications over time) alone. It complements this stream with a second stream, an unfiltered sample stream, which is used as a kind of "counter-stream" to help eliminate keywords from co-occurring events. A Bayesian framework is used to identify new keywords based on both streams.

The absence of a robust evaluation framework to compare the performance of alternative real-time adaptive algorithms is a challenge. There are no standard benchmarks to compare the performance of different adaptive algorithms. Especially, evaluating the coverage or recall of a method is difficult, since the size and speed of the Twitter stream makes it impossible to capture the whole data set for a time frame - besides the limitations enforced by Twitter on the publicly available tweets. We evaluate our approach, compare and contrast it with related work mainly on the Berlin Attack 2016 [1]. For this crisis, we systematically constructed the ground truth in order to evaluate the various adaptive crawling methods. The method can be employed for creating further ground-truth data sets in an effective, semi-automatic fashion. The evaluation considers two dimensions, the temporal aspect demands the algorithm to adapt new relevant keywords as soon as they emerge. The other dimension includes the standard metrics; precision, recall and F1-measure of the retrieved relevant tweets.

In this work, we address the real-time adaptive search task within crisis management context. Our choice is motivated by several reasons. First, the proposed system has been developed within a research project dedicated to communication concepts during crises. Hence, we were able to involve practitioners from aid organizations into our requirements analysis, development and evaluations, strengthening the evaluation results. The outcome is an application called **Sover!** short for Social media observer (Hadgu, Abualhaija, et al. 2018). The system has been tested in real scenarios. Second, crisis management is an extremely important and challenging application with a growing role for social media (Castillo 2016). The temporal aspect is very important and the reliability of crawling results is weighed by the sensitivity of critical decisions made, at least partially, based on these results.

In summary, our main contributions are:

- An effective real-time adaptive search algorithm that leverages simultaneously both the public one percent Twitter stream and the Twitter filter stream and combines them using a Bayesian framework for improving recall as well as precision.
- A simulation environment to experiment with real-time adaptive search algorithms on Twitter in a reproducible manner.
- A well-defined strategy on how to construct a ground truth specific to evaluate the performance of real-time adaptive search algorithms on Twitter.

RELATED WORK

The work in this paper builds on two distinct yet complementary tasks. The first is how to search for relevant content to a specific event in social media. The second is how to apply these methods for a real application context, crisis management in our case. Therefore, we describe the related work corresponding to each task separately.

Real-time Adaptive Search. In (Wang, Tokarchuk, Cuadrado, et al. 2013), the authors proposed an adaptive crawling algorithm, Refined Keyword Adaptation (RKwA), by developing a recall-oriented query that exploits the emerging popular hashtags in the crawling method. In their follow-up (Wang, Tokarchuk, and Poslad 2014), the authors proposed an adaptive crawling method that monitors hashtags and rates them by their similarity to the initial seeds using TF-IDF weighting. In (Magdy and Elsayed 2014; Magdy and Elsayed 2016), the authors developed an unsupervised adaptive method to track tweets for a dynamic topic. A binary classifier is trained and updated automatically and regularly to detect more relevant tweets from the stream. Another work, relevant to ours, is (Sadri et al. 2016), the Tweet Acquisition System (TAS), a system that follows an iterative process to automatically change and adapt the query representing a temporal topic aiming at maximizing the recall. The main difference between **Sover!** and these approaches is that while all these methods rely on a filter stream, to do the adaptation, **Sover!** uses simultaneously the sample stream to better estimate relevant keywords.

[1] https://en.wikipedia.org/wiki/2016_Berlin_attack

Social Search for Crisis Communication. Several tools have been developed to monitor social media for Crisis Communication. Let us have a brief look at the ones that are closest to our work. Rogstadius et al. proposed CrisisTracker, an online real-time system that tracks keywords on Twitter during disasters and creates stories using clustering. The Twitter Streaming API is used to collect tweets based on some keywords provided by the user. Twitcident (Abel et al. 2012) is a web framework that relies on the emergency broadcasting services to enable detecting an incident automatically and monitoring relevant information diffused on Twitter. XHelp in (Reuter et al. 2015) is a cross-social-media application that supports volunteers in responding to disasters. It is implemented as an embedded Facebook application. Magdy developed TweetMogaz, a news portal of tweets in the Arabic regions including Syria and Egypt. TweetMogaz provides a summary of the public response in Twitter towards ongoing events. The Emergency Analysis Identification and Management System (EAIMS), proposed by by McCreadie et al., is a crisis tracking toolkit, that provides a real-time event detection as well as some other relevant functions like sentiment analysis, information credibility estimation and automatic time-line generation. **Sover!** builds on ideas from these applications. It starts with Twitter but expands to Facebook pages, YouTube links and news pages associated with the tweets, which are significant for relief organizations.

ARCHITECTURE

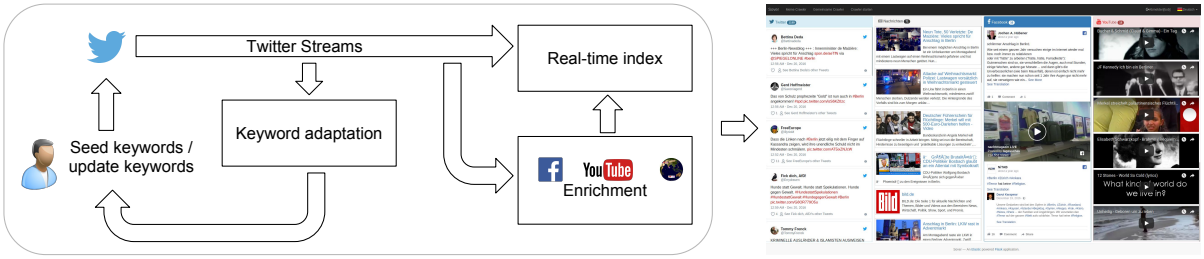

Figure 1. System Architecture of Sover!

In this section, we present the overall architecture (cf. Figure 1) and the various components of our adaptive search system **Sover!** . To start monitoring an event, a user begins the search by supplying a typically small set of initial seed 'keywords' that describe the event. E.g., to monitor social media feeds about the Berlin attack in German, one might supply 'Berlin Anschlag' ('Berlin Attack'). The system uses Twitter streams to search tweets containing these initial search terms initially. After a small time interval, the system dynamically changes the query keywords. The keyword adaptation module is used to compute these changes. A dashboard of social feeds from different platforms presents social media posts on the event to the user. A real-time indexing module and URL expansion and enrichment module support this dashboard. Each of these components is discussed below.

Twitter Streams. Sover! leverages the real-time Twitter streaming API to monitor events in real-time. This is mainly done through the **Filter Stream** [2] in combination with the **Sample Stream** [3]. The **Filter Stream** allows a searcher to supply parameters such as track to filter feeds by keywords, follow to filter by accounts or location to use bounding boxes to filter tweets from a specific area. These parameters can be changed in real-time to reflect the changing nature of an evolving event. Our system also supports searching past events. This employs data from Twitter Advanced Search [4]. The Twitter Advanced Search serves as a gateway to tap into the entire index of tweets. In order to obtain similar payload as a searcher gets from the **Filter Stream**, we combine this with the Twitter status look-up API [5]. We describe our implementation in the Evaluation Framework Section.

Keyword Adaptation. The main task of the keyword adaptation module is to take in two streams, the sample stream and filter stream and perform a statistical analysis on these collections in order to include new keywords that emerge from the collection to add in the next iteration or drop keywords from the previous query that are no longer relevant as search terms. The decision whether to update the query keywords or not takes place at discrete intervals. For instance, for a real-time event, after initialization through the user, we observe the stream for a time window, e.g., 5 min, then see if there are emerging keywords that should be included in the subsequent request to the stream. We also check if keywords in the search query are still relevant. The method behind this module is the main contribution of this paper. The keyword adaptation algorithm is presented in detail in the next Section.

[3] https://dev.twitter.com/streaming/reference/get/statuses/sample
[4] https://twitter.com/search-advanced
[5] https://dev.twitter.com/rest/reference/get/statuses/lookup

URL Enrichment. Twitter posts contain URLs to original sources such as images, videos that users upload from their devices but also shared links pointing to other social media platforms, news and other websites. Most of these URLs are shortened either by Twitter for display or by users using URL shortening services. Working with these shortened URLs is challenging. The URL enrichment module helps mitigate this problem. First it performs URL unshortening by performing an HTTP HEAD request. This not only serves as a way to check if the URL is valid but also to categorize links by domain. We mainly categorize domains as Twitter, Facebook, YouTube! and News Media. We use domains harvested from the GDELT project [6] to curate a list of news media domains. This helps to present content using an intuitive social feeds dashboard when monitoring events. For valid URLs pointing to news resources, this module also enriches the URLs with meta-data: such as article title, intro, and images if any to provide a snippet.

Real-time Index. We index the filtered and enriched streams of tweets on the fly using ElasticSearch [7]. We provide a mapping for tweets that makes it easy to recognize date-time, location fields etc. This helps to provide faceted search over all the Twitter fields as they get indexed in real-time from the social feed dashboard.

Human in the Loop. As the event a user is tracking unfolds, the keyword adaptation module provides new emerging keywords or omits those that are not relevant anymore from the set of search keywords. This happens automatically. Additionally, there is the option to bring the Human in the Loop: the user can intervene at any point via the user interface, if she thinks that the system adds noisy or irrelevant keywords or drops an important keyword. **Sover!** provides a user interface for the user to monitor and modify query keywords in a running crawler as necessary.

METHODOLOGY

Event tracking on Twitter is essential for many real-time applications. The dynamic nature of Twitter however makes real-time adaptive search challenging to achieve good coverage that guarantees gathering relevant tweets, without drifting away to other events happening at the same time. In this section, we present a novel adaptive search method for tracking dynamic events on Twitter and a simulation framework to evaluate such adaptive algorithms.

Real-time Adaptive Search

Let ς be a social media stream that consists of a set of social media feeds (posts) about a variety of events. Let us further assume that we can search this stream using query keywords $\varkappa$ to retrieve posts containing any of these keywords that describe an event ε that we are interested to track in real-time.

Definition 1 Filter Stream, F : a set of posts retrieved from ς using $\varkappa$.

Definition 2 Sample Stream, S : a random sample of posts from ς.

Problem Statement. Given the sub streams F and S, and a set of query keywords $\varkappa_i$ at a given time T_i, generate a set of query keywords $\varkappa_{i+1}$ to maximize the retrieval of posts relevant to ε at the next time step T_{i+1}.

First we generate candidate keywords $\varkappa_c$ from F. The keyword generation step is discussed in the Proposed Solution below. For each candidate keyword, k, we assign a score that quantifies how good this keyword is to ε. In information retrieval, tf-idf, is a commonly used numerical statistic that is intended to reflect how important a word is to a document in a collection or corpus. In our case, the score we are trying to compute for each k as a function of S and F is a tf-idf like metric. It assigns weights to keywords in F according to their frequency of occurrence. If we let $|F_k|$ be the number of posts containing the keyword k, we can give a similar estimate as follows:

$$P(k|F) = \frac{|F_k|}{\sum_i |F_i|} \tag{1}$$

Similarly, the second component assigns a score of how important a keyword k is for all other events in ς except ε ($= \varepsilon^c$). Since we can not observe ς directly, we can use S and $\varkappa$ to estimate ε^c. Let us denote posts in S that do not contain any of the query keywords $\varkappa$ as S^o, then Similar to Equation 1:

$$P(k|S^o) = \frac{|S^o_k|}{\sum_i |S^o_i|} \tag{2}$$

[6] http://www.gdeltproject.org
[7] https://github.com/elastic/elasticsearch

Finally, in order to incorporate prior information of keywords and change the probabilities as we gain more evidence over time as the event unfolds, we apply Bayes' theorem in order to compute the likelihoods given the priors and our current estimates. In the following, we provide a walk through of the pseudo code of our proposed solution given in Algorithm 1.

Algorithm 1 Keyword Adaptation

Input: $keywords$ at time T_i, $FStream$, $Sstream$, θ, min_freq, P
Output: $keywords$ at time T_{i+1}

```
for k ∈ Fstream do
    if freq(k) > min_freq then
        add k to candidates        ▷ generate candidates
    end if
end for
for c ∈ candidates do
    estimate P(h)
    estimate P(o)
    update likelihood P(c)
    if P(c) > θ then
        add c to keywords
        update P
    end if
end for
return keywords
```

Proposed Solution. Let E denote a particular event that we are trying to track on Twitter, e.g., Berlin Attack. Initially, this event is described by the set of tweets returned from Twitter as a result of our search containing the first query keywords – seeds. If we analyze the set of keywords, i.e., hashtags and word n-grams, in the initial response, it contains predominantly the initial search terms and other potentially useful query terms for future searches. The question is how to decide, which of the new keywords are useful as potential query keywords.

The main ingredient to our solution is to consider the global context instead of dealing solely with the resulting social feeds of a particular event that we are tracking in order to update the query parameters, i.e., including possibly other major events that are happening at the same time. Our insight is that we can leverage the one percent Twitter sample to get a sample statistic of the global context. This public stream gives us a random set of tweets covering all major global events (given they are big enough). By analyzing simultaneously both the random one percent sample of the entire Twitter stream and a focused stream of tweets about the event we are interested in, we can make better decisions about which keywords pertain truly to the event we are trying to track and which just co-occur because of another event or are just noise. This will help us to avoid keywords coming from other events thereby mitigating keyword drift and identifying emerging keywords in our filter stream that are not contained in the query keywords. In practice people use hashtags and phrases to perform searches about unfolding events. In our implementation we use hashtags and word bi-grams as candidate keywords.

Suppose r is the hypothesis that a given keyword is relevant for an event and can be used as a search keyword. We can quantify how good this keyword is as a search term for the event E by computing the fraction of relevant tweets that contain this keyword, $P(r)$ as given in Equation 1. The intuition behind this is that, a keyword that generates more relevant tweets for an event when used as a query term should get a higher probability of being used as a search query than a keyword that does not bring as many relevant tweets.

For the first iteration, this can be initialized in such a way that we penalize globally most frequent keywords such as #rt, #ff etc. with low probabilities, seed query keywords with high probabilities and the rest of the keywords with some small uniform probability. We can leverage past collection of tweets from the one percent Twitter sample to estimate these probabilities.

Similarly if we let o be the hypothesis that a given keyword is relevant for all other events, other than the event E that we're tracking, then $P(o)$ as given in Equation 2 quantifies how good this keyword is as a search query for all other events but E.

Concretely, we estimate $P(r)$ using the **Filter Stream** as the fraction of tweets containing the query keyword in our search result. In the same way, we estimate $P(o)$ from the **Sample Stream**. In particular, we take the fraction of tweets containing the keyword by taking all tweets from the Sample Stream except those that contain the query keywords that are used to retrieve the tweets for the event E at the current time-step. Finally, we update these probabilities in order to make potentially useful keywords get higher probabilities and those keywords that are in the query set but are not relevant anymore receive small probabilities so that they can be dropped in subsequent queries. For a given keyword, after computing the likelihood, we compute the ratio of the likelihoods to decide if a given keyword should be included as a query keyword in the next iteration. We set a threshold, θ that defines this cut off. Algorithm 1 gives the concrete steps for the computation.

Evaluation Framework

One of the challenges in evaluating algorithms for real-time tracking of event on social media is setting up a simulation environment, where one can run experiments multiple times and in a reproducible manner. This is in contrast to ad hoc approaches where one has to anticipate and monitor the social media platform as a particular event happens and then run competing algorithms against such collection. To enable reproducible experiments, we created a "simulation" environment to re-create Twitter streams. In this section, we describe exactly how we simulate the Twitter stream for evaluating real-time adaptive crawlers.

Simulation Real-time Stream. In a typical social search problem, one prepares training and test set collections for the retrieval problem. Real-time adaptive retrieval systems are then evaluated on such setup for comparison. However, this setup is limited in the sense that one must have collected the social feeds corresponding to every event we care about as they happened beforehand. This makes reproducibility challenging. Instead of explicitly building a test collection that maintains relevant and non-relevant feeds, we create a simulation environment that can help us play back past events.

The Twitter Advanced Search is a rich query interface that exposes all Tweets through the complete Tweet index [8]. Access is done via search operations using query words (such as exact phrases, any key words, exclusion words or hashtags), people (e.g., tweets written to or from accounts and mentioning accounts), places and dates. Thus, a searcher can go back in time and filter feeds by combining these parameters, and by replaying, this essentially gives us the best way to simulate real Twitter streams.

Of course the Twitter Advanced Search is not exactly the same as the Twitter real-time stream. There are a couple of drawbacks, when using Advanced Search. First, this only gives back organic tweets, i.e., retweets are not included and some of the tweets might have been deleted. Second, there is no official API that supports this. We solve the latter problem by writing a wrapper around this interface to mimic the same way a user invokes the Twitter real-time stream through Twitter Public Stream, e.g., **Filter Stream**. Each crawler in our experiments gets its tweets from the end point we described earlier. Our implementation of this query interface is Publicly available [9] for others to reproduce our work and use it for similar social search tasks.

Optimizing the Environment. This simulation framework gives each algorithm the same end-point and is not constrained by the tweet collection procedure common in previous works, i.e., this approach is not prone to leakage of one's approach to generating the real-time stream for evaluation in the first place and an adaptive approach that may leverage techniques from the generating process. It cleanly separates the evaluation framework from competing adaptive algorithms.

In the experiments, a user initiates an algorithm to track a given event with a starting seed query, the algorithm uses the Twitter Advanced Search wrapper and its task is to modify the query as appropriate at different time windows as time goes.

In our experience, this could be slow if for instance a crawler suggests a generic term (with lots of tweets) at the early stage of the event. To overcome this, we perform two optimization measures. Early stopping and caching.

- Caching: to avoid repeating the same query to Twitter, we have a caching step, that indexes tweets and query parameters as the query progresses. Only when a query was not yet seen does the algorithm fire an actual interaction to the Twitter Advanced Search. This simple caching technique reduces the experimentation time from potentially several days to minutes.
- Early Stopping: For a given past event, a crawler e.g., can perform the following GET request to track the keyword 'berlin' from 19:20:00 to 19:24:59 on December 19 2016. Instead of going all the way from the the last minute of the day of December 19th to the beginning. We stop after retrieving tweets at 19:20:00.

EXPERIMENT

In this section, we will describe our ground-truth generation approach. Besides, we will disucss the evaluation protocol and results of our experiments to validate (i) the simulation environment to compare real-time adaptive search algorithms and (ii) how well our proposed algorithm performs compared to existing methods.

Ground truth Data

In most previous work, the common way to evaluate different adaptive algorithms has been to run several competing algorithms and then annotate a subset of the returned tweets using crowd sourcing. This raises the question what if the algorithms miss out a large fraction of the event? In the following we propose a novel ground-truth generation approach. The idea is to leverage the flexible simulation frame work we described in the Evaluation Framework Section that allows us to look ahead and back. This gives an advantage that real-time adaptive crawlers do not have.

Approach. There are existing approaches, e.g., (McMinn et al. 2013), to build Twitter collections for events on Twitter. McMinn et al. proposed a methodology for generating Twitter corpus for event detection. This is however limited to a small number of tweets, up to 1000, per event. Our approach to building the ground-truth data mimics running a temporal adaptive crawler with relevance feedback of tweets from user annotations. Concretely, we start with seed keywords to collect the first tweets that describe the event. After this iteration, we generate candidate keywords of up to 400 keywords, a limitation imposed by Twitter, and label which keyword is relevant. In order to determine whether a given keyword is relevant or not, we look-ahead the tweets containing this keyword in the next iteration and assess it with the following two metrics.

1. Information Gain: What is the gain in terms of potential relevant tweets that are not covered by the query set in the current iteration? A potential keyword is considered a candidate keyword if it brings about at least a minimum number of tweets (e.g., 10) that wouldn't be generated with our current keywords.
2. Signal to Noise Ratio: Checks how many of the additional tweets from the candidate query, i.e., not covered by our current keywords, are relevant and how many are non-relevant? Here we use human annotators to inspect sample tweets and label the tweets as relevant or not. A potential keyword is included for the next iteration, if the relevance of the additional tweets meets a certain threshold, 70%.

Since no real-time adaptive search algorithm has the possibility to look-ahead into the future, we can guarantee that this is indeed the best choice a real-time adaptive algorithm can achieve.

Implementation. Concretely, we build a ground truth data for Berlin Attack. This has two desirable properties to test adaptive social search algorithms on. First, this is a big world wide event. This means, the algorithm has to deal with a big scale event. Second, there were other big global events happening on the same day. This creates a challenge for an algorithm to drift away from the event of interest.

Evaluation and Results

We compare the performance of our proposed approach with RKwA (Wang, Tokarchuk, Cuadrado, et al. 2013). Even though TAS (Sadri et al. 2016) would be another candidate, it is not easy to faithfully replicate as the results change drastically depending on the news article used to guide the search. RKwA and our system have the same setup in that they do not require any external dependency other than starting the search process with a set of seed query keywords. The experiment was to gather as many relevant tweets to the 2016 Berlin Attack as possible by modeling the query keyword dynamics of the event, i.e., by adding new relevant keywords and dropping obsolete ones. This is done every five minutes for the first two hours of the event. The ground truth data is constructed by manually simulating the adaptive crawler processes with the help of a crowd sourcing task. We used the seed keywords: #berlin, berlin christmas market, berlin weihnactsmarket. The ground-truth as well as the adaptive algorithms were run since: '2016-12-19 19:05:00' until: '2016-12-19 20:55:00.

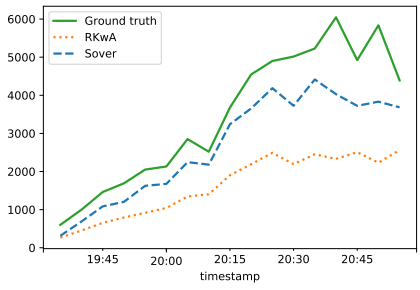

Figure 2. Number of relevant tweets gathered by (i) Sover! (ii) RkWA and (iii) the annotated ground-truth over the first two hours since the start of the event.

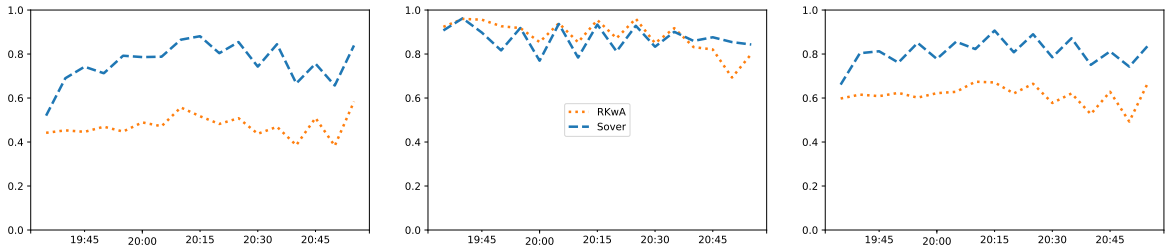
Relevance. This measures the total number of relevant tweets retrieved. In this case, the number of tweets that are about the Berlin Attack 2016. Figure 2 shows a comparison of the number of relevant tweets retrieved by the different algorithms. We see that **Sover!** performs better.



(a) Recall **(b) Precision** **(c) F1-score**

Figure 3. Evaluation of Real-time Adaptive Crawlers for Berlin Attack 2016 during the first two hours of the event.

Recall. is the fraction of relevant tweets that have been retrieved over the total amount of relevant tweets. Figure 3a shows that **Sover!** has significantly better recall than RKwA.

Precision. is the fraction of relevant tweets among the retrieved tweets. Figure 3b shows that **Sover!** achieves a higher recall without degrading on the precision.

F1-Score. is the weighted harmonic mean of precision and recall. Figure 3c shows that **Sover!** has overall better F1-Score than RKwA. It achieves a significant improvement with an average (over all five minute windows) F1 score of 0.81 for Sover! vs. 0.62 for RKwA.

Large-scale Crisis Simulation Exercise

Sover! was tested in a large-scale simulation exercise that was organized by the German Red Cross. The exercise was inspired by the 2013 European floods [10] crisis, in which Germany was affected. The main goal of the exercise was (1) to test communication methods, going beyond traditional means of communication and (2) to collect information from social media, mainly Twitter, using **Sover!** in order to enhance situational awareness. **Sover!** was particularly useful during the exercise to visualize the scale of the crisis through relevant posts that included images. This emphasizes the importance of visual content to enhance situational awareness. The keyword adaptation of **Sover!** was also useful. We observed that the keywords, e.g., #hochwasser ("flood") and #sturm ("storm") were added by the crawler automatically and reflected the exercise's scenario as the event was happening in the field.

CONCLUSION

In this work we presented the problem of real-time adaptive search. The challenges are: how to capture the evolution in the underlying vocabulary in order to dynamically change query keywords to track an unfolding event without adding too much noise. We proposed a method that solves this problem by leveraging simultaneously both a random sample of the Twitter stream and a focused stream about the event. The evaluation has shown that our method improves the performance of an adaptive Twitter crawler as compared to state-of-the-art methods. We also proposed a novel semi-automated ground-truth generation method in order to evaluate our proposed solution. This is also expected to bring the area forward by leading to more systematic approaches for evaluating adaptive crawling and social search technology. As a future work, we will explore how we can learn the ground-truth generation so that we can automate this process and apply it to similar events.

ABSTRACT

The "community" has played an important role in enhancing the regional disaster management capabilities in Japan. This paper proposes a Life-Area Broadcasting System (LABS) for usual and emergency cases. In order to realize very simple and easy management of LABS, we developed the Easy Contents Management System (ECMS). By this system, people can obtain life-area information related to their life support, small events and accident news occurring at their living area not only in emergency cases but also in normal cases by voice, images and text. Further, we developed some new Speaker Devices for unfamiliar users of ICT devices such as elderly users. Those users can receive the service of LABS as like as a television or a radio broadcast terminal anytime and every day. In this paper, we describe the concept of LABS and introduces the developed new systems and devices.

Keywords

Broadcasting, Artificial Voice, Emergency Information, Community Construction, Universal Design

INTRODUCTION

March 11, 2011, the East Japan Great Disaster and Tsunami occurred, and the authors experienced a lot of things about the disaster response, people action and information systems to a large-scale disaster. Murayama et al. (2015, 2016), and other related papers reports the experience in detail. After, regarding to the emergency information system, Murayama and Sasaki, et al. translated the book of Hiltz et al. (2009) "Information systems for emergency management" and published it in Japanese.

Through the above experience, we noticed that there were important issues in the information system for emergency management. One is the problem of government work difficulty of decision making in the emergency management and the other is the "digital divide" problem. In the case of a large-scale disaster, non-government

(community) activity such as self-help and mutual aid are more required than public help by government. Because, when a large-scale disaster occurs, the response capacity of the local government is lacking. In order to promote non-governmental (community) activities, everyone in the area needs to share information immediately. For that, it is important to solve the "digital divide" problem. In this paper, at first we introduce conventional researches for the public support, and we describe the importance of the non-government (community) activity and propose an information system to solved the "digital divide" problem.

CONVENTIONAL RESEACHES

In emergency case, the ordinary government work changed into a completely different mode. Especially, an organization transformation, a quick decision making and communication with many related people are required. There are many papers on the emergency management systems, the decision making and communication methods in the case of emergency. For example, Turoff et al. (2004) designed the Dynamic Emergency Response Management Information System (DERMIS), Tu et al. (2009) proposed some working flows of transformation in a self-organizing team for emergency responses, and Gonzales et al. (2016) constructed a simulation model of disaster response. Paltta et al. (2012) described the communication gap in disaster management. Regarding to using Social Media, there are some papers. For example, Hilts et al. (2014) proposed to use of Social Media for U.S. Public Sector Emergency Manager and Abdllah et al. (2017) discussed about the issues on information spreading by Twitter in the case of the disaster. Regarding to the decision making in emergency, Cesta et al. (2014) proposed the training for the decision making in crisis based on plan adaptation. Further, Bernabé et al. (2018) also studied the impact of warning situations for decision making in transportation companies through social media. For decision making in medical area, Sasaki (2017) proposed the patient transport decision making in multiple hospitals in a large-scale disaster.

Above problems are related with the "public support" in an emergency case. Not only in an emergency case but also in normal case, the "public support" has a limitation because of the budget and human resource limitation. Therefore, voluntary evacuation by citizen is important for emergency, and it is necessary for all citizens to share disaster information promptly. If there is an information gap by "digital divide", the risk of response delay for a disaster will be serious.

IMPORTANCE OF COMMUNITY

Recently in the advanced countries including Japan, the aging society has progressed rapidly. In order to provide living in the familiar area continuously, the Japanese Government is constructing the Comprehensive Community Care System (CCCS), which is an integrated care system of medical, nursing, and health care, and including living support. In the CCCS, the "public support" provide the medical, nursing and health care service to required people. The living support (housekeeping, housework and shopping support, etc.) is difficult for the Government to provide as the "public support" because of the budget problem. Therefore, the living support by "mutual aid" as well as "self-help" is necessary by such as volunteers and NPOs (without official fund) so that elderly people can live the region comfortably in the future.

We expect the "mutual aid" to reduce the cost of "public support" in not only the normal case mentioned above but also in emergency cases. To activate the "mutual aid", we focused on the function of "community". MacIver (1917) defined the "community", which was not association or State but a free, natural, spiritual, common sense and voluntary association for people to make a comfortable social life. Matsumoto and Yatabe (2008) studied the determination factor to continue the disaster prevention activities was the sense of community. The sense of community means "affection for the region" and "the spirit of self-devotion for the region". They concluded the sense of community means the "humanity and love for mankind within local resident" and it is the most important factor towards the continuous disaster prevention activities. Tsuburaoka et al. (2014) reported the community information as the living information is important to reconstruct and to keep the function of "community". They also described the problems of "digital divide" and "non-digital citizens".

In this research, we focused on the "digital divide" and "non-digital citizens" to re-construct the "community", which means regional community for safety social life. Further, this paper proposes a new information system to realize re-construction of the community with solving the problems of "digital divide" and "non-digital citizens".

BLIND SPOT OF INFORMATION SOCIETY

The "community" has played an important role in enhancing the regional disaster management capabilities in Japan. In other to keep the "community" function, people has been using various regional information systems such as newspapers, radio broadcasting and a cable broadcasting, television and Social Network Systems (SNSs) by the Internet. Those systems are useful for getting and sharing more wide area information, but they are still too

large for a person to get more near information related to their life support, small events and accident news occurring at their living area. The reason why the media covers wider area than the living area is the facilities' cost and the maintenance cost of broadcasting system and other related media are still too large to construct and keep the life-area information systems and services for required areas. As a result, there is a blind spot between Internet and other information media.

Figure 1 shows the image of the blind spot between in Internet and other information media. Our proposal of Life Area Broadcasting System (LABS) aims to eliminate this blind spot. Here, the size of the Life Area means the area where even the elderly can walk, or the range of a school or kindergarten (about a radius of 2-3 km). In addition, the blind spot includes not only elderly people but also people who are not good at information manipulation such as visual impairment, hearing impairment and dementia. For those people, excessive information from the Internet will be a flood of information and they will reject all information from the Internet. As a result, the "digital divide" and "non-digital citizens" are appearing and leads to the collapse of the community in current information society.

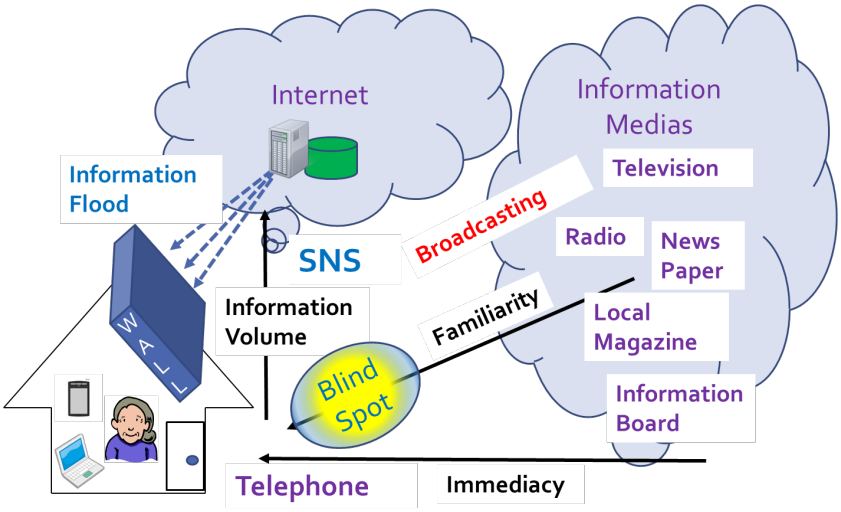

Figure 1. Blind Spot between Internet and other Information Media

CONCEPT OF LIFE-AREA BROADCASTING SYSTEM (LABS)

This paper proposes a Life-Area Broadcasting System (LABS) for usual and emergency cases. Figure 2 shows the concept of the proposed system of LABS. The feature of the system is as follows.

(1) **To provide both the formal information from Government Office such as emergency regional information and informal information from shops and community by the same system.** The conventional emergency system was for the government office and works in only emergency, but this does not connect to re-construct the community. Our proposal that the residents are receiving daily life information and sharing in the life area by LABS will connect the community re-construction. As a result, it leads to a high disaster responsible region.

(2) **To use our developed Easy Contents Management System (ECMS) described later in detail.** As the system distributes not only local government information but also private company or shop information, we consider that a non-profit organization (NPO) will manage the system. For this reason, we have developed an extremely easy-to-use contents management system so that even people without IT skills can manage the system.

(3) **To use new Speaker Device (SD) described later in detail.** In order to eliminate the "digital divide" and "non-digital citizens", we developed new speaker devices (SDs) for elderly people with weak hearing and vision and people who are not good at operating information terminals.

We also developed a smartphone application of the LABS for smartphone users. They can obtain the same service of LABS by using smartphone. The user can select the media of the information from voice, images, text (e-mail) and the combine of them. Smartphone users can directly obtain information from local government and stores not through LABS. Additionally by using the LABS, every users including non-smartphone users and smartphone

users can receive required life-area information every day as well as emergency information. By this system, all users in the same area can share the same information.

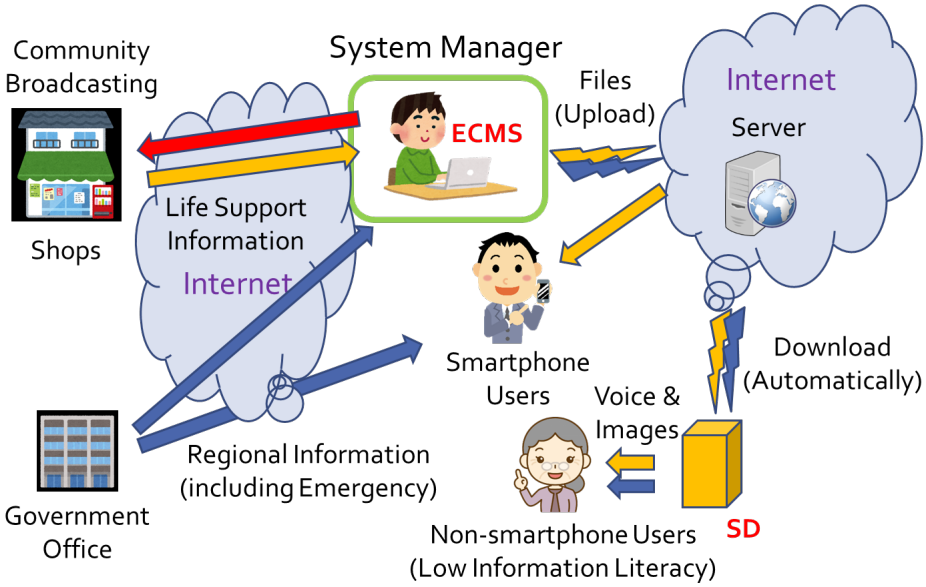

Figure 2. Concept of LABS

EASY CONTENTS MANAGEMENT SYSTEM (ECMS)

A feature of LABS is to use our developed Easy Contents Management System (ECMS). Figure 3 shows an example of the display of ECMS. The system manager of LABS for non-smartphone users uses this ECMS. The local government office sends their information directly to the smartphone users. The directly received information is still text (e-mail) and is not voice and images. Therefore, we developed an application which the smartphone users can receive the same information as that for non-smartphone users by the smartphone. The application provides the same information in voice or images or combine of them.

We divided contents of LABS into three classes, Emergency, Fixed Time and Optional Time. Each class has a specified time for the broadcast as follows,

- Emergency: one minute after the submit time,

- Fixed Time: pre-specified time in a day such as 7:00 am, 12:00 (noon), and 5:00 pm,

- Optional Time: depending on the contents.

For each classes, the system manager can select contents files and submit them to the system server. The contents files are voice files and image files. The system can send also text information as the image files. Recently, we can make the voice files from text files easily by using free software in the Internet. Further, the quality of the artificial voice becomes quite well, so we have not to use human resource to make the voice files. If the condition of the selected contents file is “open”, SD automatically downloads the file at the specified time. The user can delete the selected files and the user can change the condition of selected files from open to close anytime. There is an indicator of the number of downloads, the system manager can know the user’s terminal condition. As mentioned above, the ECMS has very easy human interface, so everyone can use it and everyone can be the system manager. There is no additional broadcasting facilities and it realize a very low cost broadcasting environment.

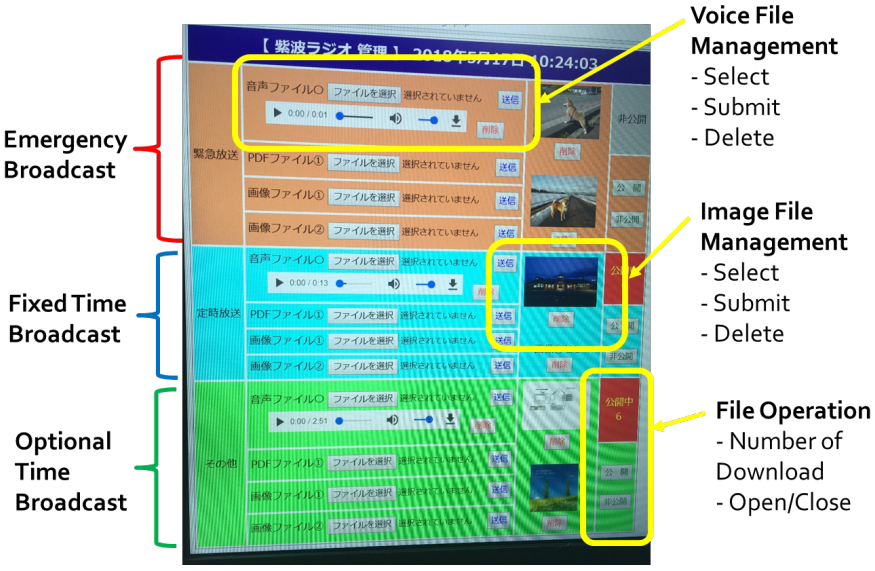

Figure 3. Display of ECMS

DEVELOPED SPEAKER DEVICES (SDs)

The other feature of LABS is to use our newly developed Speaker Devices (SDs). Figure 4 shows the photo of SDs. We developed two kinds of SD, one's name is "Radie" (Figure 4 (a)) which has a display and another's name is "Radita" (Figure 4 (b)) without display. We developed both of them using Raspberry Pi3. They can connect to Internet via WiFi and have file automatically download functions from the system server at the specified time mentioned above. After download the files, the SDs open the files and out the voice and image to the speaker and display (in the case of "Radie"). User can control the volume of the voice by turning the volume controller like a television or a radio. We developed the "Radita" (without display) by using the parts of conventional speaker terminals, which was for cable broadcasting. As a result, the "Radita" is very low cost and has a high-power speaker. This speaker is effective for the elderly with weak vision and slightly deaf ears.

In Japan, there are still many non-smartphone users. The most of them is elderly and needed the life-area information in the both of emergency and normal cases. We designed those devices for non-smartphone users. They require very easy use terminal like a television or a radio to get the life-area information. With this terminal, elderly and "digital divide" people can spend safely and convenient life because they can receive necessary life-area information automatically, and they not need to get information from themselves like the Internet.

Of course, as mentioned above, we also developed a smartphone application to receive and play LABS's contents by using regular smartphones. As a result, smartphone users and non-smartphone users are able to receive the LABS's service fairly. Namely, this will form a "universal designed" information community that no one will leave behind.

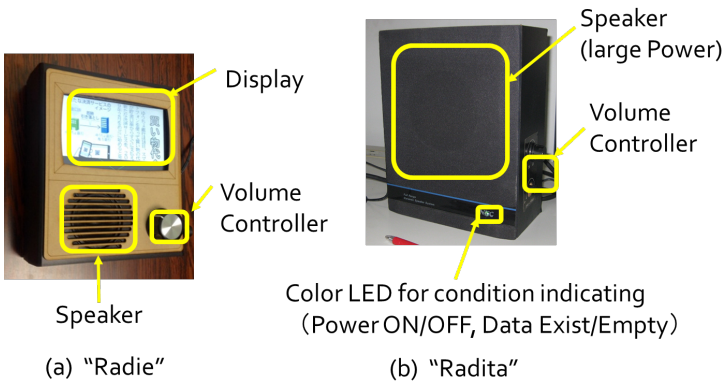

Figure 4. Developed Speaker Devices

CONCLUSION AND FUTURE WORKS

This paper proposed the concept of Life-Area Broadcasting System (LABS) for usual and emergency cases. To realize the LABS, we developed the Easy Contents Management System (ECMS) and some new Speaker Devices (SDs). We also developed a smartphone application to use the same service of LABS. By this system, every people including non-smartphone users and smartphone users can obtain life-area information related to their life support, small events and accident news occurring at their living area not only in emergency cases but also in normal cases by voice and images.

Using the LABS, we expect the re-construction of "community" by information sharing among the same life-area residents and increasing the communication opportunity at event in the life area. We believe the re-construction of "community" will connect to make a villages, a town and a city with high resilient to disasters.

The system introduced in this paper is still in the prototype stage. In the future, we have a plan that the actual elderly people and system managers use and evaluate the prototyped system. Then, improve the prototype system based on the evaluation results. After that, we have a plan of carrying out the field experiment on the effectiveness of the proposed LABS in Shiwa-town and Yahaba-town, Iwate Prefecture, Japan in 2019. Finally, we plan to establish an industry-government collaboration business model to operate this system and establish an NPO. By performing the continuous operation, we hope for the re-construction of "community", and the construction of a high disaster prevention, safety and secure region development.

ACKNOWLEDGMENTS

We would like to thank Mr. Seiji Sato, president of Sato Tax Accountant Corporation, I-O DATA Foundation and the financing of project TIN2016-75850-R from the FEDER Funds for support of this research.

ABSTRACT

In this paper, a scenario-based approach augmented with personas typically used in universal design and interactive design domains is used to illustrate the occurrence of situational disabilities in emergency situations, and to show how environmental factors can trigger these situational disabilities. With the help of personas representing selected archetypical characteristics and roles, the scenarios are further examined to show how these situational disabilities can affect the situational awareness of different stakeholders, not only in the command and control centers, but also first responders in the field as well as affected members of the public. This approach provides a better understanding of the importance of universal design of ICT for Emergency Management, not only for people with disabilities and the elderly, but for anyone.

Keywords

Situational Disabilities, Situational Awareness, Universal Design of ICT for Emergency Management.

INTRODUCTION

Attaining situational awareness (SA) is an important part of being able to take appropriate actions in catastrophic situations. It is equally important both for individual and closely related social groups in disaster events, as well as for all emergency responders that require shared or intergroup SA (Pogrebnyakov and Maldonado 2018; Seppänen et al. 2013). SA as a concept is introduced in the human factor domain in 1990s (Endsley 1995), especially in connection with the decision making and analyzing human errors and human performance (Endsley 2015). Scholars have explored, used and develop this concept into various domains in industrial automation, pilots, air traffic control and other high-risk activities in organizations or industries. The applicability of the use of SA concept in the area of emergency management has been explored, analyzed, used and demonstrated in some studies, e.g. for gaining common operational picture (Wolbers and Boersma 2013), development of information system decision support tool (Luokkala and Virrantaus 2014), emergency responder collaboration (Seppänen et al. 2013) and social media crisis communication (Pogrebnyakov and Maldonado 2018).

The concept of the perception – all human senses should work such as seeing, listening, smelling when it comes to establishing situational awareness in emergencies. One is supposed to use comprehension and cognitive capability to be able to understand and interpret all cues gathered by human sense, and to see the possible outcomes and to take actions. People also use tools and technologies to improve the human ability to sense and interpret the environmental cues that can also include either long or short numerical and written information and require a complex process before comprehending the information.

While we are aware of the importance of SA in disasters, the World Report on Disabilities states that the prevalence of disability is 15% and is increasing due to a global increase in chronic health in overall aging population. These catastrophic events not only increase the impairment incidence in certain regions but also may exacerbate medical conditions when disability-related health needs are not attended to appropriately. In the

disasters, people often need to be self-organized before the first responders come, and the ICT tools have been used to enhance the knowledge of the current situation. In this case, significant parts of the population have some kinds of disabilities that may prevent them from accessing relevant information and understanding quickly what happens, and what to do. Here, the role of the universal design of the ICT tools is important, as discussed by Radianti et al. (2017) and Gjøsæter et al. (2018). Also in the control room, universal design can play a role in supporting situational awareness (Gjøsæter and Radianti 2018).

In general, ICT is taking a bigger role in emergency management; and in the field, smart phones are becoming increasingly important as a first responder tells in his account of lessons learned during the hurricane Harvey[1]: *Smartphones are Extremely Powerful Tools*. "You can view maps, look up data and communicate effectively, as long as you keep your phone charged and functioning". However, we have to keep in mind that when introducing smart phones, we are also introducing the risk of encountering barriers to situational awareness through situational disabilities. The obvious cure for these barriers is Universal Design.

Universal Design concerns the design of products and environments to be usable by all people, to the greatest extent possible, without the need for adaptation or specialized design. A prerequisite for Universal Design is accessibility. According to WAI/W3C, for the web, accessibility means that people with disabilities can perceive, understand, navigate, and interact with websites and tools, and that they can contribute equally without barriers (Bennett et al.2017; Gjøsæter et al. 2018). In other words, accessibility and usability for the broadest possible diversity of users.

Universal Design is said to be "Necessary for Some and Good for Everyone". This means that Universally Designed solutions that are absolutely necessary for some people, can also be very useful for others in certain situations or contexts. For example, subtitles on video is not only useful for people with a hearing impairment or an ear infection, but also for commuters watching the video on the bus with lots of traffic noise and other auditory disturbances, or in the library where they have to be quiet. In addition, people with a limited knowledge of the language spoken in the video may also benefit from the additional assistance of subtitles. These situations can be thought of as temporary or situational disabilities (SD).

In this paper we will examine how situational disabilities are particularly relevant in Emergency Management, not only for the general public but also for first responders and other stakeholders. We aim at understanding how SD affects SA in emergency situations, and based on this understanding we will argue for the importance of Universal Design of digital systems for SA in diverse contexts within Emergency Management, to mitigate the effects of SD on SA.

The SD issue is one of the unexplored areas with respect to the Universal Design of ICT for Emergency Management, and can be considered as the main contribution of this paper. While people with disabilities in emergency contexts are equally important, the potential invisibility of people experiencing SD sometimes means they do not receive the support required to cope with disaster contexts until those conditions become apparent to others. SD can occur both for the first responders and public who are affected by the disaster in general. Another contribution that is worth to mention is the use of *personas* for scenario analysis in emergencies, which would help better understanding of individual persons when it comes to disabilities and SD. Personas are imaginary characters representing user archetypes that are frequently used in research in interaction design and universal design of ICT, to illustrate how common groups of users might interact with systems (Pruitt and Grudin 2003).

This paper is organized into five sections. After this introduction, in the theoretical concepts and related work section, we introduce some important terms in this area such as disabilities, situational disabilities, and universal design. We also try to introduce briefly the concept of situational awareness, including the situational awareness barriers. Next, we present our research questions and explain briefly our method. In the analysis and discussion part, we answer our research questions and explain how disasters can trigger situational disabilities that in turn can reduce situational awareness. In the conclusion part, we summarize this paper, reveal some limitations and the future work.

THEORETICAL CONCEPTS AND RELATED WORK

Permanent, Temporary and Situational Disabilities

In this section, we will present some basic concepts used in this paper. What is disability? In 1980's disability is a personal attribute: "In the context of health experience, a disability is any restriction or lack of ability (resulting from an impairment) to perform an activity in the manner or within the range considered normal for a human

[1] https://www.itstactical.com/intellicom/mindset/lessons-learned-first-responder-hurricane-harvey/

being." –World Health Organization (WHO). However, today the WHO defines disability as context dependent, and no longer consider it just a health problem, but a complex interaction between features of person's body and features on the society where he or she lives, covering wider context:

- *Impairments*: a problem in a body structure;
- *Activity limitations*: a difficulty encountered by an individual in executing task or action;
- *Participation restrictions*: a problem experienced by an individual in involvement in life situations.

People are more aware on the issue of disabilities, and more efforts have been made to remove the difficulties face by people with disabilities, including social and environmental barriers, sometimes, it can occur that people are in the situation that cause auditory, cognitive, physical speech and visual impairment, which often referred to *situational disabilities*.

For example, a short-term injury or context affects the way people interact with the world around them, Likewise, when people are wearing a cast or ordering dinner in a foreign country. People's ability can change as they move through different environment. Noisy sound background can reduce someone's hearing ability. New parents often do their tasks one-handed. A strong bright light when driving a car can cause visual impairment. An overwhelming day can cause sensory overload. What's possible, safe, and appropriate is constantly changing (Shum et al. 2016). To understand these situational disabilities, temporary disabilities and permanent disabilities, we cite the Persona Spectrum that can be used to understand the inclusive design as seen in Table 1.

Table 1. The Persona spectrum with respect to permanent, temporary and situational disabilities (based on Shum et al, 2016).

	Permanent	Temporary	Situational
Touch	One arm	Arm injury	New parent with a child on the arm
See	Blind	Cataract	Distracted driver
Hear	Deaf	Ear infection	Bartender in a noisy bar
Speak	Non-verbal	Laryngitis	Heavy accent that is difficult to understand

Using this "situational disabilities" perspective, we obtain a new understanding that many people may have experienced a sort of situational disabilities. When situational disability happens, the situational awareness may reduce significantly. For instance, in a noisy crowd or due to ear infection, the announcement of the likely evacuation due to fire may not be heard. In a strong light, or driving situation, one may not be able to read or see the alert message, e.g. on the likely flash flood ahead.

Situational Awareness (SA)

SA is essential in an emergency situation, for the general public affected by the emergency as well as for first responders and decision makers. In the literature, SA developed on an individual level and on a team level to comprehend a crisis situation. In addition, there are numerous definitions of SA derived from different application areas such as military, aviation, air traffic control, large-systems operations, navy, and psychology. Consequently, SA has been defined in different ways, for example "the results of a dynamic process of perceiving and comprehending events in one's environment may change and permitting predictions as to what the outcomes will be in terms of performing one's mission. In effect, it is a development of a dynamic mental model of one's environment" (Nofi 2000). Endsley (1995) proposes a three-level model to define SA. It is referred as "the perception of the elements in the environment within a volume of time and space, the comprehension of their meaning, and the projection of their status in the near future". These three SA concepts i.e. perception, comprehension and projection have been referred as Level 1, 2 and 3 SA respectively. When crisis management stakeholders and response team cooperate together in responding crisis, team SA would be equally important as the individual SA. However, the coordination would be very crucial as each team member may have a specific set of SA elements depending upon each member's responsibility in the team (Endsley, 1995).

Poor situational awareness has been considered as important factor that lead into poor team SA (Kaber and Endsley 1998; Stanton et al. 2001) such as failure to detect critical cues regarding the state of the system; or failure to interpret the meaning of information from monitoring technology. It can also occur due to misunderstanding of individual task and responsibilities, to communicate with other teams and with individual within other teams.

However, there are several factors that can affect the SA. Some of the factors that can affect SA are called *SA demons*. Eight categories of SA demons have been identified and each presents its own set of challenges to

maintaining SA (Bhatt and Güsgen 2012).

- *Attentional narrowing* - Humans are easily affected by attentional narrowing, systems need to support multitasking across multiple goals and decisions.
- *Requisite memory trap* – Humans tend to have limitation to hold short term memory and information and therefore systems should not rely on short term memory that is easily disrupted.
- *Workload, fatigue and other stressors* – Humans' capabilities decrease when having fatigue, stress and high workload. These factors all act to reduce already limited working memory and disrupt information acquisition.
- *Data overload* - The volume and rate of change of data in many systems can run faster than operators' abilities to keep up with it
- *Misplaced salience* - The overuse of prominent visual features such as bright colors and flashing lights overwhelm and misdirect operators' attention.
- *Complexity creep* – The more complex the system, the harder it is for operators to develop accurate situation comprehension and projection.
- *Errant mental models* – Humans tends to misinterpret data based on how a different part of the system works Without good mental models of how a system operates being triggered.
- *Out-of-the-loop syndrome* - Highly automated systems can leave operators with low awareness of the state of the system.

While the analysis of these situational awareness demons has helped us to understand what kinds of "disabilities" could happen to people in a stress condition, the discussions of these SA demons has been limited to those who work as operators in control rooms. Endsley (1995), e.g. has worked extensively on SA behaviors derived from very specific flight operations. While in this paper, we argue that in disaster situations, the SA is actually required for the general public (who receive lifesaving information), responders (who conduct lifesaving actions in a coordinated manner, uses various tools and technologies in the field to support the response activities), and the operators and decision makers in the command and control room (who collect information, use technologies and provide the decision supports). However, the discussion on SA of these three groups of important parties in crisis management, never fully discussed in depth, and especially their barriers to SA. We would like to portray the SA issue from the perspective of situational disabilities and eventually from the lens of the universal design.

Situational Awareness and Situational Disabilities

The Persona Spectrum shown in Table 1 have depicted that "disabilities" can also occur to everyone who is unnecessarily a part of the vulnerable groups due to specific, situational or temporary conditions. However, the effects of such situational disabilities may result in the same effects as those who are actually having disabilities. In other words, inclusiveness of crisis management should be understood in both cases: the vulnerable groups and situational disabilities as their abilities to survive disasters. Note that there are variations on the use of the term "vulnerable groups". Généreux et al. (2018) use "high risk population" to refer to "anyone who has functional limitations related to communication, housing, awareness, mobility/transportation, psychosocial factors, self-care/daily tasks, and safety/security that may put them at higher risk of negative impacts when an emergency or disaster occurs". We use the "vulnerable group" in the same meaning as the "high risk population". However, in this paper, we argue that the vulnerability goes beyond the "high risk population" only, as it can occur to anyone.

Indeed, we are aware of a recent concept of disaster resilience that has encouraged the all-of-society approach to survive disasters, i.e. by enhancing the capacity of individual, citizens and society at large to cope with, resist and respond to disaster. Généreux et al. (2018) propose a community resilience framework of the vulnerable groups, while O'Sullivan et al. (2017) use the stroke patients as a case study of a vulnerable group to derive keys for household resilience, which cover the social, physical, energy and personal characteristics as keys. Assistive devices such as lifeline personal alarms, lanyard/wristbands and mobile phones are the tool examples for reducing the individual vulnerabilities. While we acknowledge the efforts to increase disaster resilience to the household unit, even well-prepared plans can sometime fail, because of failing to understand the potential barriers when using assistive tools and the role of situational disabilities, where a person may be unable to operate the technologies that they use on a routine basis.

Previous studies have tried to explore barriers encountered by the vulnerable groups in disaster situations. For instance, Sullivan and Häkkinen (2006) argue that the historical evidence has documented significant numbers of population affected by disasters fail to take actions upon warnings of imminent disaster. People with disabilities become disaster victims due to trapped in a high-rise structure during the fire, crushed in collapsing structures during an earthquake, swept away in a tsunami or drowned in a hurricane storm surge are all examples how people

with disabilities can encounter barriers of receiving critical lifesaving information or mobility problems. Häkkinen and Sullivan (2007) analyze some assistive technologies to improve the effectiveness of the communication of warning and critical information, especially with respect to the speech-based delivery of critical information. Specifically, the authors suggest the accessible Web content and Digital Talking Books as means to convey urgent, critical messages. The authors also highlight the importance of communication that also applied for multi-lingual and multi-cultural environments which in our point of view can also be categorized as a form of situational disabilities.

On one hand, the efforts of linking the universal design with disability issue and situational awareness are evident such as in Häkkinen and Sullivan (2007) work, but the fact the "disabilities" can occur to anyone are missing in the current literature. For example, what factors that can lead into these situational disabilities, and why it is equally important to understand both vulnerable groups and situational disabilities. Would the SA demons' valid in the crisis management context, and especially when involving people with disabilities and situational disabilities? In the following, we will examine how emergency situations can cause situational disabilities which in turn can trigger SA demons.

RESEARCH QUESTIONS AND METHODS

Based on the identified issues above concerning situational awareness as it is affected by situational disabilities, we have defined the following research questions:

- RQ1: What kinds of situational disabilities will people typically experience (physically and mentally) in disaster situations?
- RQ2: How do these situational disabilities affect situational awareness in disaster situations?

We have applied a scenario-based analysis method to examine these research questions through different disaster scenarios and discuss how different categories of people can be affected by situational disabilities in these scenarios. The scenario-based analysis method is frequently used in software engineering to elicit requirements, and is here adapted for eliciting examples of SD and their effect on SA demons. We have enhanced the scenarios with simplified imaginary individuals, or *personas*. In addition to an invented name, personas will have relevant characteristics typical for an important group of users, and might also be supplied with less relevant information and a semi-realistic backstory to assist in making the scenarios more realistic. The personas were created based on literature analysis through which we have identified the main stakeholders, their activities and challenges in emergency situations.

SCENARIOS, PERSONAS AND ANALYSIS

RQ1: Situational Disabilities in Disaster Situations

To examine the occurrence of situational abilities in disaster situations, we provide some typical imaginary scenarios. These scenarios are organized from three categories in terms of stakeholders, actions and potential situational disabilities. In both scenarios, the stakeholders are represented by personas from four groups of stakeholders;

1. local members of the general public
2. non-local members of the general public,
3. first responders,
4. control room personnel.

Scenario 1: Earthquake in a city.

Earthquakes can contribute to triggering several situational disabilities, as the following imaginary scenario will illustrate.

In Reykjavik on Iceland, a strong earthquake strikes one day in late February, around 2AM in the morning.

Martin lives in a small 12th floor apartment in downtown Reykjavik. He is used to evacuating during fire drills, but this is different. He fights the panic as he awakes, puts on some warm clothes, grabs his smart phone, locks his apartment and quickly walks down the stairs among a crowd of other people, who are equally stressed and worried, and making a lot of noise. When he finally comes out of the building, he sees that some of the surrounding buildings have partly collapsed. He tries to check the news using his smartphone to find out more information

about what has happened, but although he is wearing warm clothes, his hands are still shaking from the cold combined with his high level of stress, so he has difficulty navigating the news. All the noise from the crowd and the still shaking ground is making it even harder to focus. His neighbor Alejandra is recently arrived to Iceland from Mexico to work on her PhD. In a panic, she didn't think of taking warm clothes with her as she left the apartment. Fortunately, she remembered to grab her smartphone on the way out. She is now very cold, and the noise makes it even more difficult to concentrate on finding safe shelter. There is a woman wearing a Red Cross uniform coming towards her, but she doesn't understand what she is saying. The woman is Anna. She has been a volunteer for Red Cross for several years, but this is the first big emergency she has been a part of. Although she has had a lot of training, she still feels unprepared for the challenge of finding, prioritizing and helping victims in such a disaster. Also, the emergency communication equipment is unfamiliar to her, and she is trying to remember the correct channel and how to communicate effectively. Olav works in the emergency control room communicating closely with different first responders in the field, including Anna. He is surrounded by monitors with warning messages and audible alarms. He is very stressed and overwhelmed by all the reports of collapsed buildings in his area of responsibility, and have a really hard time choosing how to distribute resources, gravely aware that his decisions can have severe consequences.

Stakeholders, actions and potential situational disabilities:

- Local member of the general public in the process of evacuating from the location of an earthquake ("Martin").
    - The person is trying to get an overview of the situation through his smartphone.
    - The person is trying to submit information about the situation to the local authorities through his smartphone.
    - Situational factors: stress, fear/panic (countered by some basic training in emergency response through earthquake drills), shaking ground, movement (running), crowds, noise.
    - Situational disability risks: hearing (noise from the crowd, collapsing buildings), dexterity (own and ground movement), cognitive (stress, panic).
    - Potential consequences: Cannot adequately use the smart phone because of SD.

- Recent immigrant in the process of evacuating from the location of an earthquake ("Alejandra").
    - The person is trying to get an overview of the situation through her smartphone.
    - The person is trying to use smartphone for translating some of the messages and information provided.
    - Situational factors: stress, fear/panic, shaking ground, movement (running), crowds, noise, lack of training in evacuation.
    - Situational disability risks: hearing (noise from the crowd, collapsing buildings), dexterity (own and ground movement), cognitive (stress, panic, language barrier).
    - Potential consequences: Cannot adequately use the smart phone because of SD. Do not understand messages and orders given, with potentially fatal consequences.

- First responder in the field during an earthquake ("Anna").
    - The person is trying help where it is most needed, and therefore needs to achieve SA through observation as well as communication equipment connecting them to the central control.
    - Situational factors: stress, crowds, noise, cognitive overload trying to prioritize victims. Ground shaking.
    - Situational disability risks: hearing (noise from victims, collapsing building), dexterity (own and ground movement), cognitive (stress).
    - Potential consequences: Cannot adequately use the mobile communication equipment because of SD. Risk of wrong decisions because of communication problems.

- Control room personnel during earthquake ("Olav").
    - The person is trying to continuously perform observation, analysis, decision-making, communicating orders.
    - Situational factors: Information overload through multiple information channels, stress from life-and-death-affecting decision making.
    - Situational disability risk: cognitive (stress).
    - Potential consequences: error in judgement caused by information overload.

Scenario 2: Fire in a multi-floor shopping mall.

Fire can contribute to triggering several situational disabilities, as the following scenario will illustrate.

Just before closing time, a fire breaks out in the "Galleriet" shopping mall in Bergen, Norway. It was caused by an accident in the kitchen of one of the ground floor snack bars. The fire alarm goes off, and evacuation begins. Bill is an American tourist on a one day visit from a cruise ship. He is a bit lost, but finds a map on the wall. To his dismay, the information is only in Norwegian. He tries using google translate to translate the text, but because of stress he gives up and rather follows the crowd to the nearest exit. Janne is on the top floor, and she is trying to use a smartphone indoor map of the mall to find the way to the nearest emergency exit. Along the way, she sees a person in a wheelchair who is unable to evacuate without assistance, and he is too heavy for her to carry. She sends a message about the trapped person to the local fire department using twitter, since the noise from the fire alarm is too loud for being able to communicate using the emergency phone number. Nils in the fire department control center is overwhelmed by all the messages about the rapid development of the fire, but sees the tweet from Janne, calls Petter the fire fighter over the emergency communication network, and Petter makes his way to the top floor and is able to help the trapped person out of the burning building.

Stakeholders, actions and potential situational disabilities:

- Local member of the general public in the process of evacuating the building ("Janne").
  - The person is trying to locate emergency exits through their smartphone indoor map.
  - The person is trying to notify the emergency responders about a person in a wheelchair trapped on the top floor by sending a tweet to the fire department through their smartphone.
  - Situational factors: stress, fear/panic (countered to some degree by regular training in building evacuation through fire drills), smoke, crowds, moving fast, noise (loud fire alarm).
  - Situational disability risks: vision (smoke in the eyes), hearing (loud alarm), dexterity (walking/running), cognitive (stress/panic).
  - Potential consequences: Cannot adequately use the smart phone because of SD.

- Tourist in the process of evacuating the building ("Bill").
  - The person is trying to use the smartphone to translate evacuation map text.
  - Situational factors: stress, fear/panic, smoke, crowds, moving fast, noise (loud fire alarm), lack of training in building evacuation.
  - Situational disability risks: vision (smoke in the eyes), hearing (loud alarm), dexterity (walking/running), cognitive (stress/panic, language barrier)
  - Potential consequences: Cannot adequately use the smart phone because of SD. Do not understand messages and orders given, with potentially fatal consequences.

- First responder in the fire ("Petter").
  - The person is trying help where it is most needed, and therefore needs to achieve SA through observation as well as communication equipment connecting them to the central control.
  - Situational factors: stress, crowds, noise, cognitive overload trying to prioritize victims. Smoke, heat.
  - Situational disability risks: vision (smoke), hearing (alarm noise), dexterity (fast movement, bulky protective equipment), cognitive (stress)
  - Potential consequences: Cannot adequately use the mobile communication equipment because of SD. Risk of wrong decisions because of communication problems.

- Command and control center's personnel during fire ("Nils").
  - The person is trying to continuously perform observation, analysis, decision-making, communicating orders
  - Situational factors: Information overload through multiple information channels, stress from life-and-death-affecting decision making.
  - Situational disability risks: cognitive (stress).
  - Potential consequences: error in judgement caused by information overload.

RQ2: How SD can Feed the Demons of SA in Disaster Situations

The following overview shows which SD will feed the different SA demons (Bhatt and Güsgen 2012). First, we adapt the Persona Spectrum from Table 1 (Microsoft, 2016) in Table 2 (for issues in the field) and Table 3 (issues in the control room) with disaster-specific situational disabilities, as well as several additional types of disabilities including cognitive and dexterity/fine-motorics. For clarity, we divide the tables into two types of disabilities; sensing and perception-related, and action-related.

Table 2. Situational Disability Triggers in the field

		Situational Disability Triggers
Perceive		
	Touch	Hot/cold/wet/protective gear leading to loss of feeling
	Vision	Dust and/or smoke
	Hearing	Noise/alarms
	Cognitive (understand, interpret)	Language barriers, information overload
Action		
	Speaking	Dust and/or smoke in the throat, language barriers
	Moving	Protective gear, crowds, panic
	Fine-motorics /dexterity	Panic/stress, protective gear
	Cognitive (plan – act)	Information overload, confusion (wrong communication channel, forgetting protocol)

Situational awareness demons encountered in the field (effects that are not among the established demons are shown in parenthesis, while the situational awareness demons are marked with bold italic):

- Touch SD: (Not detecting haptic feedback/vibration).
- Vision SD: ***Data overload***; ***Misplaced Salience***.
- Hearing SD: ***Data overload***; ***Misplaced Salience***.
- Cognitive (understanding) SD: ***Attentional narrowing***; ***Requisite memory trap***; ***Workload, fatigue and other stressors***.
- Speaking SD: (Language barrier, too much noise to be heard).
- Moving SD: (Blocked, slowed or redirected movement),
- Dexterity SD: (Barrier for access to ICT-based SA tools).
- Cognitive (act) SD: ***Attentional narrowing***, ***Requisite memory trap***, ***Workload, fatigue and other stressors***.

Table 3. Situational Disability Triggers in the Control Room

		Situational Disability Triggers
Perceive		
	Touch	
	Vision	Many screens and blinking lights
	Hearing	Noise/alarms
	Cognitive (understand, interpret)	Information overload
Action		
	Speaking	
	Moving	
	Fine-motorics /dexterity	Stress
	Cognitive (plan – act)	Information overload, confusion (wrong communication channel, forgetting protocol)

In the control room scenarios, the following situational disabilities map to the following SA demons (effects that

are not among the established demons are shown in parenthesis, while the situational awareness demons are marked with bold italic):

- Vision SD: ***Data overload***; ***Misplaced Salience***.
- Hearing SD: ***Data overload***; ***Misplaced Salience***.
- Cognitive (understanding) SD: ***Attentional narrowing***, ***Requisite memory trap***, ***Workload, fatigue and other stressors***; ***Data overload***; ***Misplaced Salience***.
- Dexterity SD: (Stress affecting ability to manipulate control room equipment).
- Cognitive (act) SD: ***Attentional narrowing***; ***Requisite memory trap***; ***Workload, fatigue and other stressors***.

We notice that several of the effects are outside the scope of the demons of situational awareness, in particular when it comes to situational disabilities triggered in the field. Thus, the situational disabilities are not aligning well with the demons of SA, beyond the control room parts of the scenarios above. This makes sense since the demons of SA were defined in the context of control room SA.

From this research, we find that the demons of SA are not sufficiently general to cover the issues met by the general public and first responders. They cover mainly cognitive overload in control room situations, but not so much situations in the field with mobile equipment. This is a major issue that will be investigated in future work.

CONCLUSIONS AND FUTURE WORK

In this paper we adopted scenario-based analysis with simplified personas to identify situational disabilities among stakeholders in disaster situations and the demons of situation awareness. We have found that the Demons of SA (Bhatt and Güsgen 2012) are not adequately covering the issues of loss of SA caused by situational disabilities for major groups of stakeholders in typical disaster scenarios, such as the general public and first responders. Further studies should be performed to examine this issue in more details and provide a more complete picture of the demons of situation awareness, and we are currently working on extending the "Demons of SA" so that they cover other contexts as well.

In our scenarios, we see that ICT in addition to providing opportunities for increased situational awareness, can also introduce barriers to situational awareness through situational disabilities which can further hinder effective actions. It also becomes clear that not only obviously vulnerable groups like the elderly and people with disabilities needs special consideration when designing ICT tools for EM. We wish to highlight that Universal Design of ICT tools for emergency management can play an important role in removing these barriers and make the tools usable for a broader range of users, even those affected by situational disabilities (Gjøsæter and Radianti 2018; Gjøsæter et al. 2018; Radianti et al. 2017). Further research should focus on how Universal Design principles and guidelines can be used in the development process of ICT tools for Emergency Management, and a process model to illustrate the use of universal design principles in the design of ICT systems to support SA is part of ongoing work. This model is built upon the process model for information system of SA (Luokkala and Virrantaus, 2014) and demonstrate the adoption of UD in the whole process of ICT systems for SA.

ABSTRACT

Risk assessment aims at improving prevention and preparedness phases of the crisis management lifecycle. Qualitative risk assessment of a system is important for risks identification and analysis by the various stakeholders and often requires multi-disciplinary knowledge. We present an automatic approach to qualitative risk assessment in metropolitan areas using semantic techniques. In particular, users are provided with a computational support to identify and prioritize by relevance risks of city services, through generation of semantic descriptions of risk situations. This approach is enabled by a software system consisting of: TERMINUS, a domain ontology representing city knowledge; WS-CREAM, a web service implementing risk identification and ranking functions; and CIPCast, a GIS-based Decision Support System with functions of risk forecast due to natural hazards. Finally we present the results of a preliminary validation of the generated risks concerning some points of interest in two different areas of the city of Rome.

Keywords

Risk assessment, geographic information system, conceptual modeling, ontology, computational creativity.

INTRODUCTION

Recent disasters in urban areas have caused an increasing interest in risk assessment. Knowing the possible risks for a specific area could increase the level of prevention and preparedness of a community to a crisis. Two types of approaches are commonly used for risk assessment of systems. Qualitative risk assessment involves system stakeholders to identify risk situations and prioritize them. Quantitative risk assessment, which may follow the qualitative approach, is performed by analysts to provide forecast of the impact of predefined risks, whenever

the relevant event and system data are available. Examples of quantitative approaches include estimation of cascading failure propagation in electric power system (Baldick at al., 2008) and those devoted to compute the losses due to an earthquake (Silva et al. 2014). The qualitative approach for risk assessment is especially useful to identify possible new risks for an area, as the so-called *black swan* events. However current practices of qualitative risk assessment are heavily based on human judgment and experience, and this may weaken completeness and reliability of the results. Therefore, as a new research, we are facing the problem of how to automatize some human activities of qualitative risk assessment by exploiting Artificial Intelligence techniques.

In this context we propose an automatic approach to qualitative risk assessment in urban areas that aims at conceiving new risks for points of interest (POIs) in metropolitan areas and at prioritizing them. Examples of points of interests are hospitals, police stations, museums and restaurants. The approach is enabled by a software system that, in particular, generates conceptual models of risks, named risk mini-models (Coletti et al. 2017), and locates them on a map. The system consists of three main components: TERMINUS (Coletti et al. 2018), a domain ontology formalizing knowledge concerning environment, city services and infrastructures and related risks; WS-CREAM, a web service implementing the computational support for automatic risk identification and ranking, by querying the ontology and using context data; and CIPCast, a GIS-based tool for critical infrastructures protection, enhanced with forecasting and decision support functionalities.

The TERMINUS ontology was built by means of ontology design patterns. An ontology design pattern is a reusable conceptual structure with the aim of supporting the ontology engineering process (Gangemi and Presutti, 2009). WS-CREAM implements semantic queries automatically built from pre-specified ontology patterns[1].

Then we present the guidelines to perform qualitative risk assessment by means of the proposed software. The activities concern both the system set up and the actual qualitative risk assessment process.

As a case study we present the experience we had on qualitative risk assessment in the city of Rome. In particular, we focused on two areas with different characteristics. The former, the area close to Ponte Milvio, is located in the city center and close to the Tevere river. The latter, close to Colli Albani, is located nearby a lake and it is threatened by earthquakes. We discuss a preliminary experts' validation of the generated risk mini-models concerning the points of interest of these two areas.

The rest of the paper is organized as follows. The second section presents relevant work in the area. The third section describes the proposed software system for qualitative risk assessment. The fourth section presents the guidelines to perform qualitative risk assessment using the system. The fifth section describes the preliminary results of a case study of qualitative risk assessment in the city of Rome. Finally the last section presents conclusions.

RELATED WORK

This paper deals with risk assessment for metropolitan areas. As stated in Introduction the most common approaches for this purpose are quantitative and qualitative risk assessment. Among the existing works on quantitative risk assessment we cite: the seismic vulnerability and risk assessment performed by (Vicente et al., 2011) for the city of Coimbra in Portugal; the earthquake risk assessment for Istanbul metropolitan area treated by (Erdik et al., 2003); and the quantitative risk assessment performed by (World Health Organization, 2014) that, among the different causes of death, includes also costal flood mortality. Among the existing works concerning qualitative risk assessment we cite (Rinaldi et al. 2001) that discusses the risks due to interdependencies of critical infrastructures, With respect to these works our proposal addresses both approaches as CIPCast is mainly devoted to quantitative risk assessment whereas WS-CREAM, together with CIPCast, addresses qualitative risk assessment.

There are different initiatives in the literature devoted to building ontologies related to risk assessment. One of the first initiatives is the vulnerability upper model and the VUM ontology presented by (Coletti et al., 2016). The VUM ontology includes concepts as risk, threat, system, stakeholder, severity, and vulnerability Then this ontology was extended to build the first version of the TERMINUS ontology presented in (Coletti et al., 2018). After these, other initiatives include the common ontology of value and risk presented by (Sales T.P. et al. 2018) and the ontology of emergency managing and planning about hazard crisis presented by (Gaur, M. et al. 2018).

At the best of our knowledge, our is the first approach devoted to automatizing human activities of qualitative assessment and linking risk descriptions to system components on a map to the purpose of analysis.

[1] Similarly to an ontology design pattern, in the following, an ontology pattern is a reusable semantic model, based on the ontology that supports the definition of queries.

SOFTWARE SYSTEM FOR QUALITATIVE RISK ASSESSMENT

The automatic approach for qualitative risk assessment is realized within a wider system whose architecture is illustrated in Figure 1. Specifically, such a system realizes interoperation of two pre-existing applications, such as an ontology-based CREAtivity Machine Web Service (WS-CREAM) and CIPCast, a GIS-based Decision Support System (DSS) for critical infrastructures protection with a web interface. A middle layer, such as the Semantic data Integrator, was realized to manage communication between the two independent back-end components. In summary, for a user selection of an urban area and of a natural hazard from the WebGIS interface (i.e. CIPCast front-end), TERMINUS ontology, representing city knowledge, together with context data managed by CIPCast geodatabase, are used by WS-CREAM to generate ranked lists of risk descriptions for the services belonging to that areas. These risks, after off-line validation, are shown on the map as result.

A more detailed description of the system components follows.

The CIPCast Decision Support System

CIPCast is a novel Decision Support System (DSS) (Giovinazzi et al., 2017) able to produce a real-time operational risk forecast of CI in a given area due to natural hazards. The main functionalities of CIPCast are: (i) real-time monitoring of natural phenomena; (ii) prediction of natural events (if predictable); (iii) prediction of damage scenario on critical infrastructure components; (iv) prediction of impacts on critical infrastructure services and impacts on citizens and (v) definition of efficient strategies to support decision-making operator processes.

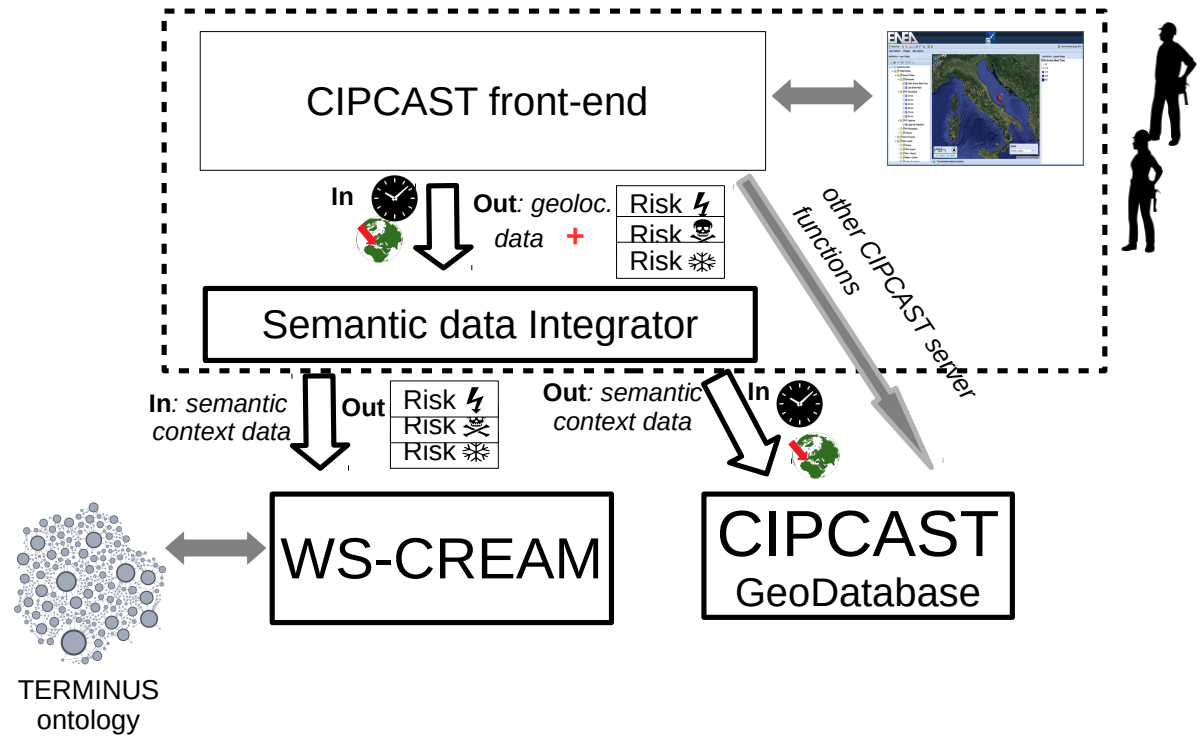

Figure 1 Illustration of the software architecture and information flow

CIPCast was conceived as a combination of free/open source software (FOSS) environments including Geographic Information System, GIS features, which play a major role in the construction of such a tool. Multisource data and GIS-integrated analysis can contribute to a better emergency planning, providing fundamental information for immediate response. The creation of this information consultation tool, enriched by the geospatial component, implies the adoption of a specific and suitable GIS architecture (commonly indicated as SDI, Spatial Data Infrastructures). In order to store and share all data and information available (base cartography, risk maps, CI features data, data from sensors, scenario produced, etc.), a PostGIS[2]-based

[2] https://postgis.net/

Geodatabase for data storage and management was implemented. The Geodatabase can be directly accessed by means of different desktop GIS software suites (e.g., QGIS). In addition, by means of the server stratum, composed by GeoServer[3], data can be accessed via web by using OGC standards[4] (WMS, WFS and WCS services).

Moreover, CIPCast provides a user-friendly geographical interface, implemented through a specific WebGIS application[5], for querying and analysing geographic data and thematic maps, execute processes and simulations, produce and evaluate scenarios, etc. Thanks to the WebGIS interface, the main results produced within CIPCast can be easily accessible to the users and exploitable for further analyses.

An Ontology for Territorial Management and Infrastructures

TERMINUS (TERritorial Management and INfrastructures ontology for institutional and industrial USage) is a domain ontology including knowledge representing environment, critical infrastructures and related hazards, risks and threats. An ontology is a formal specification of a shared conceptualization (Gruber, 1993) (Borst, 1997). It defines concepts, relationships, and axioms relevant for representing a domain of interest. TERMINUS has been built by extending some ontology design patterns. At the current stage, TERMINUS has been built by deriving concepts from the *vulnerability upper model* (VUM) design pattern (Coletti et al., 2016), from the *system aspect* design pattern presented by (Coletti et al., 2018) and from the *risk of system service* design pattern that is presented in the following. It also includes knowledge related to interdependencies between critical infrastructures (Rinaldi et al., 2001). In particular the *risk of system service* design pattern allows representing risks for city services due to catastrophic events as earthquakes, floods, and landslides. This ontology design pattern is depicted in Figure 2. It consists of five upper level concepts: `Hazard`, `Critical_event_of_system`, `Functional_vulnerability`, `System_service`, and `Stakeholder`. The descriptions of these five upper level concepts is presented in Table 1 whereas the descriptions of the relationships between them is presented in Table 2.

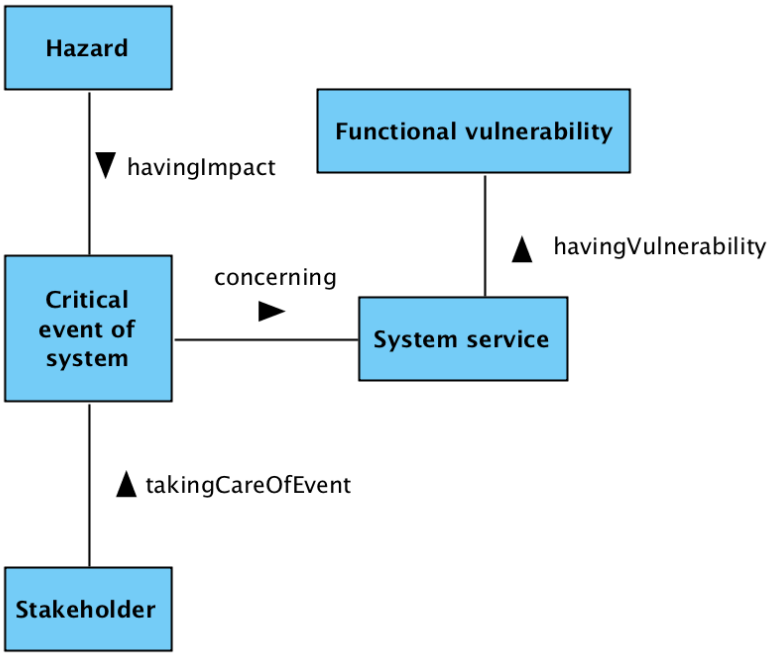

Figure 2. UML class diagram of the risk of system service ontology design pattern

[5] Developed exploiting the GeoPlatform FOSS suite: https://github.com/geosdi/geo-platform

Table 1. Description of the five upper level concepts belonging to the *risk of system service* ontology design pattern

Concept name	Description
`Hazard`	Climate-related event or trend or their impacts on geophysical systems (e.g., floods, droughts and sea level rise) with likely detrimental consequences to human systems (Mora et al. 2018).
`Critical_event_of_system`	Event representing one or more effects on systems from exposure to a hazard; effects are mediated by the strength of the hazard and the vulnerability of the exposed system (Adapted from the Impact concept description in Mora et al. 2018).
`Functional_vulnerability`	The propensity of a system function to be adversely affected. This results from the balance between sensitivity and adaptive capacity (Adapted from the Vulnerability concept description in Mora et al. 2018).
`System_service`	Service provided by system.
`Stakeholder`	A person or organization that is interested in a system or its subsystems.

Table 2. Description of the relationships between the concepts belonging to the *risk of system service* ontology design pattern

Object property name	Description
`havingImpact`	Conceptual relationship between a `Hazard` and a `Critical_event_of_system`.
`concerning`	Conceptual relationship between a `Critical_event_of_system` and one of its provided services (i.e. `System_service`).
`havingVulnerability`	Conceptual relationship between `System_service` and one of its function vulnerabilities (i.e. `Functional_vulnerability`)
`takingCareOfEvent`	Conceptual relationship between `Stakeholder` of a system and `Critical_event_of_system`.

Figure 3 shows an excerpt from TERMINUS ontology showing a fragment of the taxonomy related to the `System_service` concept.

WS-CREAM

The CREAtivity Machine (CREAM) Web Service is a software application that, more generally, is capable to automatically generate semantic descriptions of future situations that may be significant in some given application domain to the purpose of analysis. These situations refer, for example, to possible emergencies in a city or to risks for infrastructures or enterprises. The aim is to support a user, such as a risk analyst or a city planner, to imagine possible futures and identify those relevant for her final objectives, including city emergency management and/or risks mitigation. Indeed, this component provides an automatic ranking of the generated situations, based on context information, a useful function to speed up the subsequent qualitative assessment activity by the user, .

From a technical perspective, WS-CREAM has been realized to be independent from the specific application (risk assessment or emergency scenarios planning), hence to be adaptable to different uses by means of some configuration information.

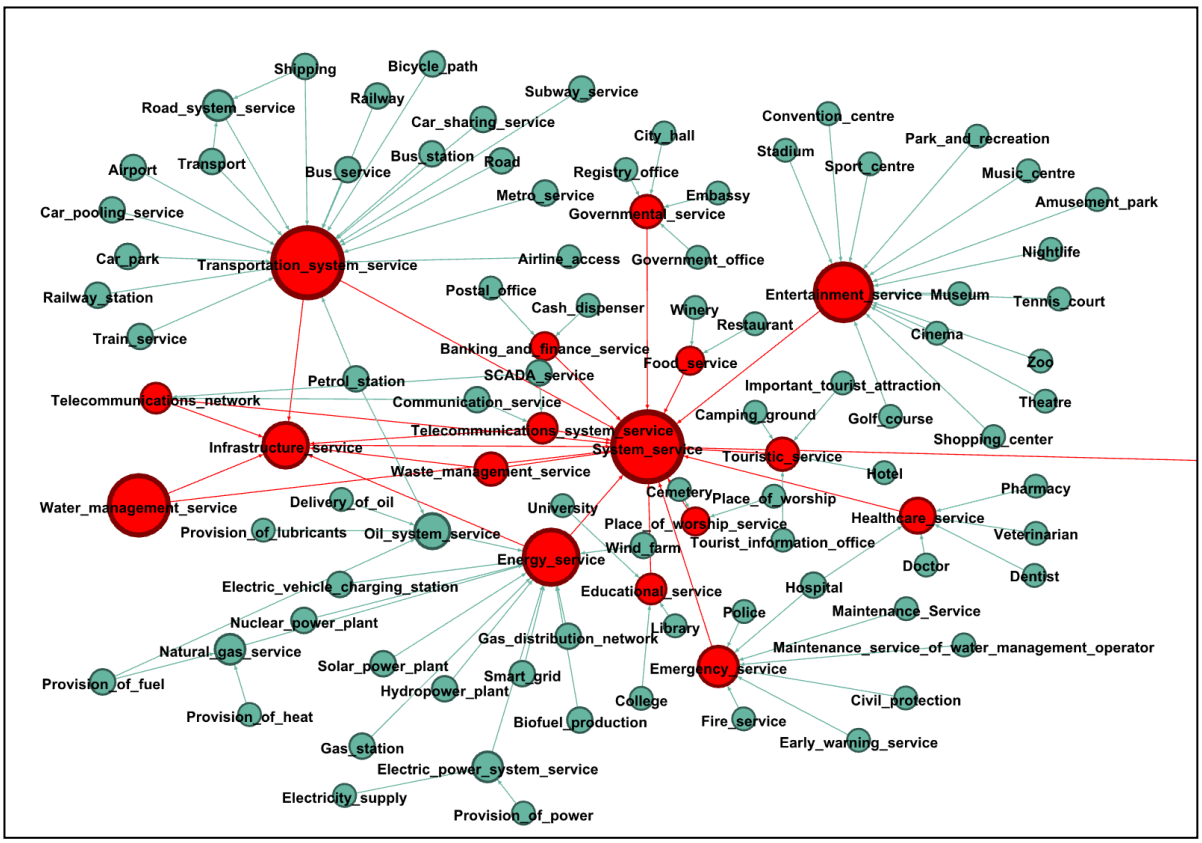

Figure 3. Excerpt from TERMINUS ontology showing a fragment of the taxonomy related to the `System_service` concept

In this work, WS-CREAM uses the following input configuration specifying:

- the **application domain**, here represented by the TERMINUS ontology;
- the **semantic structure** (by means of a formal ontology pattern) of the information on the situation to be represented. Here such a structure is described in OWL and it is based on the ontology design pattern described previously. The output risks will be described as records of the following table.

  [*System service*, *Hazard*, *Functional vulnerability*, *Critical event of system*, *Stakeholder*] (1)

- a **ranking formula** to be applied to order by relevance level the generated risks for each city service. Such a formula is defined by the metrics: context-specific properties of the service, such as its relevance as point of interest in the given city, its physical exposure to risks caused by the given hazard; and context-independent properties of the service, such as the service criticality compared to other services of a city (e.g., hospital versus monument). The formula also specifies the aggregation operations of those variables.

For the application presented in this paper, as a trial, the ranking formula is the *average* of the relevance levels attributed to some components of the ontology design pattern, that is: the *relevance* of the specific service in the city, such as its *value* or *criticality* in the city, associated with the *System service* component in (1); the *risk level* from a natural hazard, referred to the geographical location of the service, associated with the *Hazard* component of (1); the *criticality level* of the described impact of the natural event on the service, compared to other types of impact, associated with the *Critical event of system* component of (1); the *relevance level* of the functional vulnerability, compared to other known vulnerabilities, associated with *Functional vulnerability*.

Given such a configuration, WS-CREAM provides a function that takes as input a list of semantically annotated services present in a user selected urban area, their contextual properties; and possibly the type of hazard with its associated properties. A SPARQL query (Coletti et al., 2017) is automatically built from a pre-defined ontology pattern addressed in the configuration file, which is run on the TERMINUS ontology to retrieve a list of semantic descriptions of possible service risks as records of (1). These records are built with concepts of TERMINUS, where the *System service* component specifies the type of service provided as input, and, possibly, the *Hazard* component specifies the type of chosen hazard. For each city service, WS-CREAM computes a relevance level of each generated risk (in a ordinal scale from 1 to 5), using the ranking formula. The output will

be a set of associations of the city services with their ranked lists of risks.

GUIDELINES FOR QUALITATIVE RISK ASSESSMENT

In our proposal qualitative risk assessment requires six activities. The first three activities are related to the system set up, whereas the last three concern the actual qualitative risk assessment process.

1. **Points Of Interest (POI) identification.** This set up activity consists in identifying points of interest located in the area considered for the analysis, like restaurants, hospitals, cinemas and governmental offices.
2. **Semantic annotation of the POIs**. This set up activity consists in providing a formal meaning to the points of interest identified in step 1. So each point of interest is associated with a formal expression. For instance, POI:`Stadio_Olimpico IS_INSTANCE_OF TERMINUS:Stadium` specifies that *Stadio Olimpico* of Rome is annotated by the `TERMINUS:Stadium` ontology concept.
3. **Definition of the ranking mechanism**. This set up activity consists in deciding the ranking formula and collection of the required data to prioritize the generated risks.
4. **Risk mini-model generation for a selected area**. This activity consists in using the system to generate ranked risk descriptions, named risk mini-models (RMM), for the POIs of the selected area.
5. **Risk mini-model validation**. This activity involves experts to assess RMM usefulness and relevance.
6. **Geolocalization of risk mini-models**. This activity consists in using the system to visualize the valid risk mini-models on a map.

CASE STUDY: QUALITITATIVE RISK ASSESSMENT IN ROME (ITALY)

This case study is related to qualitative risk assessment concerning two areas of Lazio (Italy): the area near Ponte Milvio, in the center of Rome and close to the Tevere river, and Colli Albani, an area on the hills in the south-east of Rome. For these areas we identified the points-of-interests.

Ponte Milvio

Considering the morphology of this area and its proximity to Tevere river, our study focused on the alluvial event that, historically, has frequently occurred in this area. The points-of-interests located in this area are all located inside buildings and mainly include medical offices, dental offices, restaurants and are homogeneously located throughout the territory. Some of such points-of-interests are particularly relevant due to their high occupancy rate. These include the Olympic stadium, the Auditorium Parco della Musica, the Palazzetto dello Sport and the IUSM University of Rome. Regarding the presence of points-of-interests not included into buildings, these include petrol stations and tennis courts.

Colli Albani

This area, including a portion of territory between the lakes of Albano and Nemi, has suffered damages following seismic events in history. The points-of-interests are all located inside buildings and, mainly, include restaurants, medical offices, veterinary offices, dental clinic, museums, hotels and libraries.

In the following we present a risk mini-model for the Ponte Milvio area and another one for the area of Colli Albani. These were selected by experts as representatives of the most relevant risk mini-models. Each risk mini-model is followed by a description written by the expert, in the form of an imagined story or report of a known situation. The purpose is to provide context-based interpretation of the risk mini-model and to support risk plausibility. This method follows the approach to stimulate creativity presented by (De Nicola et al., 2019).

Ponte Milvio risk mini model

```
Functional_vulnerability: People_inside

System_service: Nightlife

Critical_event_of_system: Health_and_physical_consequences

Stakeholder: Unspecified_person

Hazard: Flood
```

Description
A flood occurred in the center of Rome; it hits a very popular nightclub of the area while this was registering its maximum capacity of customers. The water caused physical damages and also health consequences to people inside the nightclub. Indeed, the panic of the mass generated fights to exit the structure resulting in several injured persons.

Colli Albani risk mini-model
`Functional_vulnerability: Presence_of_electric_elements_potentially_dangerous`
`System_service: Doctor`
`Critical_event_of_system: Economic_damage`
`Stakeholder: Manager`
`Hazard: Earthquake`
Description
It is 9:00 am on a weekday. The waiting room of a medical office is, as usual, full of: patients waiting for their turn; secretaries; doctors and staff involved in their work. At 9:15 a strong earthquake causes breakage of machinery and electrical tools that begin to fall dangerously over the patients; moreover, the general panic in the waiting room grows as the large neon lights come off the supports, creating some injuries. A few minutes later the medical office is evacuated, but the general chaos produces considerable damage to electrical equipment and specialist instruments, computers and printers, the general electrical panel, lights, etc. These damages have an economic impact on the medical service .

In the following we present the analysis of the results after the experts' validation of the risk mini-models generated by WS-CREAM. Table 3 shows the number of relevant risk mini-models with respect to the overall set. It shows that, for the two considered areas, the percentages of relevant risk mini-models are 37.77% and 53.88%. As a future work, discarded risk mini-models will be used to learn rules to improve precision of the generative function of WS-CREAM.

Table 3. Number of relevant generated risk mini-models according to the expert's judgment. This analysis considers the type of system service.

Area	Relevant risk mini-models	Overall risk mini-models	Percentage of relevant risk mini-models
Ponte Milvio	431	1141	37.77%
Colli Albani	534	991	53.88 %

Table 4 shows the degree of relevance of generated risk mini-models according to the expert's judgment. It should be noted that the numbers of risk mini-models are higher with respect to those presented in Table 3 as here these numbers include POI instances. This means that there could be more than one medical office in the selected area.

Table 4. Degree of relevance of generated risk mini-models (by POI) according to the expert's judgment. This analysis considers the different POIs (there could be more POIs for one type of system service).

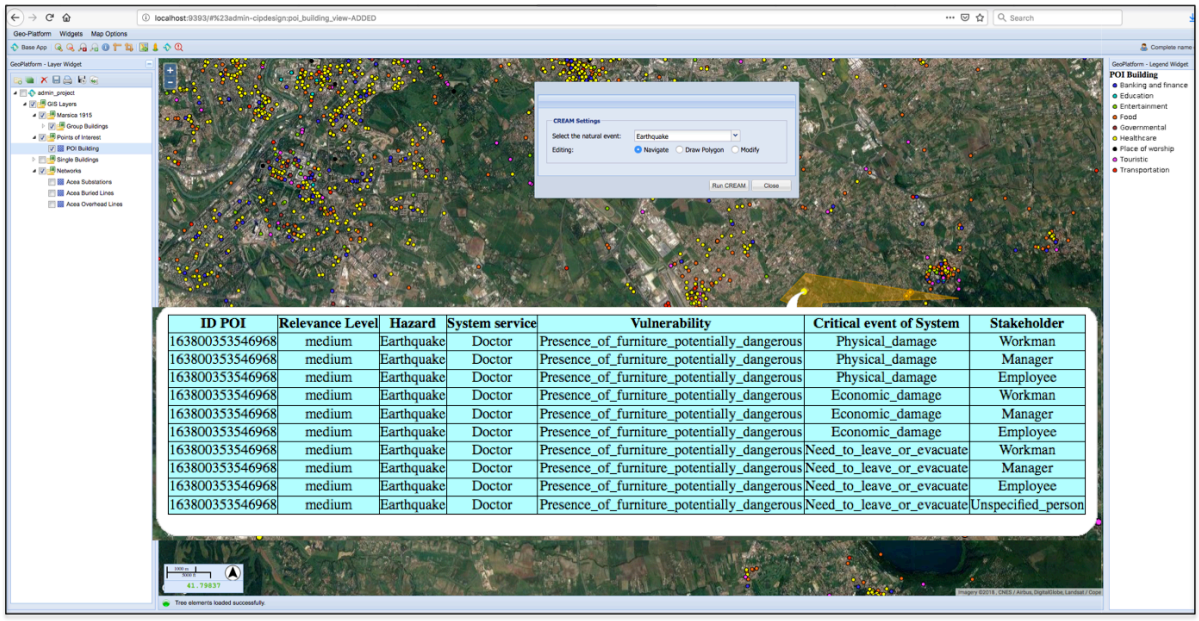
Area	Number of relevant risk mini-models	High relevance	Medium relevance	Low relevance
Ponte Milvio	827	124 (14.99%)	431 (52.12%)	272 (32.89%)
Colli Albani	809	343 (42.39%)	162 (20.02%)	304 (37.58%)

Table 5 shows the degree of relevance of generated risk mini-models according to WS-CREAM ranking.

Table 5. Degree of relevance of generated risk mini-models (by POI) according to WS-CREAM ranking. This analysis considers the different POIs (there could be more POIs for one type of system service).

Area	Number of relevant risk mini-models	High relevance	Medium relevance	Low relevance
Ponte Milvio	2122	1180 (55.61%)	942 (44.39%)	0 (0%)
Colli Albani	1472	0 (0%)	1320 (89.67%)	152 (10.33%)

Then we compared the relevance level assigned by the experts to risk mini-models with that assigned automatically by WS-CREAM. We found that the expert and the software judgments were the same for 210 out of 809 risk mini-models (25.96%) in case of the area of Colli Albani and for 373 out of 827 risk mini-models (45.10%) in case of the area of Ponte Milvio. Again we expect to improve these numbers in the near future, for instance, by gathering more accurate context-specific and context-independent data and experiencing different ranking formulas. Finally Figure 4 shows a screenshot of CIPCast including the risk mini-models generated by WS-CREAM for the point of interest doctor in case of flooding.



ID POI	Relevance Level	Hazard	System service	Vulnerability	Critical event of System	Stakeholder
163800353546968	medium	Earthquake	Doctor	Presence_of_furniture_potentially_dangerous	Physical_damage	Workman
163800353546968	medium	Earthquake	Doctor	Presence_of_furniture_potentially_dangerous	Physical_damage	Manager
163800353546968	medium	Earthquake	Doctor	Presence_of_furniture_potentially_dangerous	Physical_damage	Employee
163800353546968	medium	Earthquake	Doctor	Presence_of_furniture_potentially_dangerous	Economic_damage	Workman
163800353546968	medium	Earthquake	Doctor	Presence_of_furniture_potentially_dangerous	Economic_damage	Manager
163800353546968	medium	Earthquake	Doctor	Presence_of_furniture_potentially_dangerous	Economic_damage	Employee
163800353546968	medium	Earthquake	Doctor	Presence_of_furniture_potentially_dangerous	Need_to_leave_or_evacuate	Workman
163800353546968	medium	Earthquake	Doctor	Presence_of_furniture_potentially_dangerous	Need_to_leave_or_evacuate	Manager
163800353546968	medium	Earthquake	Doctor	Presence_of_furniture_potentially_dangerous	Need_to_leave_or_evacuate	Employee
163800353546968	medium	Earthquake	Doctor	Presence_of_furniture_potentially_dangerous	Need_to_leave_or_evacuate	Unspecified_person

Figure 4. Risk mini-models associated to points of interest located in the area of Colli Albani (Rome) in case of flooding.

CONCLUSION

Qualitative risks assessment for metropolitan areas is a complex activity due to uncertainties on hazards and to the variety of systems. WS-CREAM is a novel software system aiming to provide descriptions of relevant risk situations with semantic reasoning applied to a domain ontology. As risk assessment requires data on the geographical areas and on the societal and infrastructures' characteristics of the specific system under analysis, WS-CREAM has been integrated with CIPCast, which is a GIS-based tool for CI protection, enhanced with forecasting and decision support functionalities. In this work, we presented how these two systems interoperate to perform qualitative risk assessment for metropolitan areas. We presented also preliminary validation results of the approach. These results provided us future work directions to improving selectivity of the risk mini-models generation function and precision of the automatic assessment.

ABSTRACT

Modern early warning systems (EWSs) use Internet-of-Things (IoT) technologies to realize real-time data acquisition, risk detection and message brokering between data sources and warnings' destinations. Interoperability is crucial for effective EWSs, enabling the integration of components and the interworking with other EWSs. IoT technologies potentially improve the EWS efficiency and effectiveness, but this potential can only be exploited if interoperability challenges are properly addressed. The three main challenges for interoperability are: (1) achieving semantic integration of a variety of data sources and different representations; (2) supporting time- and safety-critical applications with performance and scalability; and (3) providing data analysis for effective responses with personalized information requirements. In this paper, we describe the "SEmantic Model-driven development for IoT Interoperability of emergenCy serviceS" (SEMIoTICS) framework, which supports the development of semantic interoperable IoT EWSs. The framework has been validated with a pilot performed with accident use cases at the port of Valencia. The validation results show that it fulfils the requirements that we derived from the challenges above.

Keywords

Early warning system, Internet-of-things, semantic interoperability, emergency service.

INTRODUCTION

An Early Warning System (EWS) is a distributed information system that is able to monitor the physical world and issue warnings if it detects abnormal situations (Waidyanatha 2010). A multi-hazard EWS (MHEWS) is a special type of EWS that integrates two or more EWSs in order to be able to detect and react upon different types of situations (UNISDR 2015). EWSs can benefit from Internet-of-Things (IoT) technologies (Poslad, Middleton et al. 2015) to realize (near) real-time data acquisition, risk detection and message brokering between data sources and information receivers, comprising both humans (e.g., emergency managers) and machines (e.g., sirens).

Interoperability is crucial for effective EWSs to enable the integration of EWS components, e.g., sensors, devices and platforms, and the interworking among EWSs (Wächter and Usländer 2014). Although IoT technologies can potentially improve the EWS efficiency and effectiveness, this potential can only be exploited if interoperability challenges are addressed (Middleton, Zlatev et al. 2013). In this paper, we focus on how to improve the semantic interoperability of IoT EWSs, i.e., how to enhance the ability of two or more EWSs (or EWS components) to share data elements in a precise format (syntax) and well-established meaning (semantics).

In a literature review on interoperable EWSs (Moreira, Pires et al. 2018), we identified three major challenges: (1) semantic integration of a variety of data sources that adhere to different standards, ontologies and data models; (2) near real-time processing in time- and safety-critical applications; and (3) data analysis for effective situation awareness and decision support.

This paper describes the "SEmantic Model-driven development for IoT Interoperability of emergenCy serviceS" (SEMIoTICS) framework. SEMIoTICS enables the model-driven development of interoperable IoT EWSs in different domains, so that an IoT EWS can act as a cloud-based semantic broker for situation-aware decision support. SEMIoTICS is leveraged by ontology-driven conceptual modelling for situation-aware applications (Moreira, Ferreira Pires et al. 2015), covering both EWS design-time and runtime.

SEMIoTICS was validated with a case study performed in the H2020 INTER-IoT project (Ganzha, Paprzycki et al. 2016). The case study involves a semantic interoperable IoT EWS developed to detect truck accident risks at the Valencia port area. The case considers a variety of data sources and processing requirements for safety-critical applications, and applies existing domain-specific ontologies and standards, along with their serialization formats. Accident risks are assessed by monitoring the truck drivers' vital signs with electrocardiogram (ECG) wearables, and the trucks' position with speed and accelerometer data, using mobile phones as gateway. The detection targets health issues of drivers and collisions of trucks with dangerous goods. The IoT EWS is able to provide personalized emergency notifications to multiple target groups with distinct information requirements.

BACKGROUND

The term "IoT EWS" (Balis, Kasztelnik et al. 2011, Du and Zhu 2012, Poslad, Middleton et al. 2015) denotes EWSs supported by IoT technologies. Interoperability is crucial for the effectiveness of IoT EWSs and is impacted by data variety. The level of interoperability depends on the standardization of interfaces, data exchange formats and protocols (Wächter and Usländer 2014). A MHEWS usually needs to use and integrate standards from different domains to support seamless integration of distinct IoT EWSs (Keeney, Buan et al. 2012).

Early Warning System Reference Architectures

A conceptual architecture of an interoperable *Standard-Based EWS* was introduced in (Wächter and Usländer 2014), in which three consecutive steps have been identified: *Upstream Data Acquisition, Decision Support* and *Downstream Information Dissemination*. The *Upstream Data Acquisition* component is responsible for pre-processing and storing streaming data acquired from sensor systems in an internal *Context Database*. *Models* are used to represent an emergency situation identification mechanism, which can be either specification-based or learning-based. The *Decision Support* module applies the intrinsic rules of the models over the context data, supporting decision making by allowing the EWS administrator to configure actions according to the situation identified, usually with support of a workflow management system. Notifications are sent according to the pre-configured actions to different target groups through the *Downstream Information Dissemination* component, which is responsible for message brokering. The target groups can be either humans, who receive alerts through mobile applications or low-frequency radio, or actuators for automatic emergency response.

OASIS EDXL is a common standard for downstream data representation for interoperable EWSs (Chronaki, Kontoyiannis et al. 2011, Dogac, Kabak et al. , Lendholt, Esbrí et al. 2012, Poulymenopoulou, Malamateniou et al. 2012, Wächter and Usländer 2014, Barros, Kislansky et al. 2015). The *Standard-Based EWS* architecture allows the integration of EWSs through event-based message-oriented middleware (MOM), which can play the role of either a context broker or a service broker. The main limitation of this approach is that it neglects semantic interoperability.

Most of the semantic EWS approaches (Balis, Kasztelnik et al. 2011, Du and Zhu 2012, Poslad, Middleton et al. 2015, Roy, Sarkar et al. 2015, Battistini, Rosi et al. 2017) extend the *Standard-Based* architecture by using semantic technologies to represent data, both upstream and downstream, taking advantage of inference capabilities. Usually, the concept of a common information space is exploited, linking semantic technologies to SOA (Balis, Kasztelnik et al. 2011). Performance tends to be a drawback, which makes scalable time-sensitive data exchange and processing from heterogeneous data sources quite challenging.

The *Semantic IoT EWS* approach (Poslad, Middleton et al. 2015) improves semantic interoperability with a scalable solution for data exchange and processing, by providing a balanced way to use lightweight and heavyweight ontologies. Lightweight ontologies are used in *Upstream Data Acquisition* and *Downstream Information Dissemination* to reduce the message payload during data exchange and processing. Heavyweight (formal logic based) ontologies are used in *Decision Support* to add additional semantics to the data, enriching the fusion of new and historical data by enabling the discovery (inference) of new knowledge. This new information is serialized as lightweight (association based) semantics to be included in the warning messages that are brokered through the downstream information dissemination component. This balance of heavyweight and lightweight ontologies enables scalable time-sensitive data handling from heterogeneous sources with effective responses.

The *Semantic IoT EWS* approach introduced a heavyweight ontology by reusing terms from the W3C Semantic Sensor Network (SSN) and incorporates terms from the OGC Observations and Measurements (O&M) standard. W3C SSN is the most popular lightweight ontology in the IoT domain, founded on the OGC SWE standards. Upstream sensor data are annotated only with SSN predicates. Annotation is applied at the broker (gateway) level, since sensors only need to interoperate with a control centre via a sensor's access node.

Internet-of-Things Platforms

An IoT platform enables ICT solution engineers to bridge the gap between device sensors and connected applications through suites of components. All big players in cloud services provide a general-purpose IoT platform, such as Microsoft (Azure IoT), Google (IoT), IBM (Watson IoT) and Amazon (AWS IoT). Some IoT platforms are domain-oriented, such as Google Fit and Apple Health for healthcare. The enabling technologies underlying an IoT platform include: sensor networks and cloud computing, RESTful microservices (usually with JSON), relational and NoSQL databases, distributed Complex Event Processing (CEP) engines and message/event-oriented middleware.

MyDriving[1] is the open source[2] use case of the Azure IoT platform, which provides a starting point for scalable, high-performance and cross-platform IoT implementation. *MyDriving* targets users who want to increase their awareness of their driving habits and improve safety and long-term vehicle performance. Real-time telemetry data are collected from the vehicle, such as location, speed, instantaneous acceleration, distance, fuel consumption, temperature and RPMs. These data are processed both locally in the field and in the cloud, providing meaningful information that can be accessed through various types of interfaces. A mobile phone plays two roles in this application: (1) it collects and transmits data as an IoT "field gateway"; and (2) it provides data visualization with maps, both real-time and past trips. The solution can be leveraged by using an On-Board Diagnostic (OBD 2) sensor, which is able to send more accurate vehicle telemetry data to the mobile phone via Bluetooth. Data are aggregated at the field gateway and published into the Azure message-oriented broker (IoT Hub) in JSON format. A RESTful microservice subscribes to the data, storing in parallel JSON documents in a blob database ("warm path"), and in a relational database ("cold path"). The solution makes use of *Streaming Analytics*, a kind of distributed CEP engine that subscribes to receive all data published in the IoT Hub, being able to integrate historical data in the warm path. It also allows to apply machine learning in the cold path to identify driving habits.

Some of the research-oriented IoT platforms include semantic technologies, such as FIWARE with the Sense2Web for RDF, the universAAL internal semantic models, and the OpenIoT with an ontology extended from SSN. In this context, we mention the INTER-IoT project, which aimed at designing, implementing and experimenting with interoperability among heterogeneous IoT platforms (Ganzha, Paprzycki et al. 2016). The project was driven by use cases from e-Health and transportation/logistics at the port of Valencia, addressing semantic integration among IoT artefacts. INTER-IoT developed the Inter-Platform Semantic Mediator (IPSM) tool to support the semantic integration at runtime when multiple-ontology translations are required (Ganzha, Paprzycki et al. 2017).

Challenges and Requirements

In an earlier work (Moreira, Pires et al. 2018), we concluded that the cross-disciplinary nature of the emergency field made it necessary to match conceptualizations and combine multiple domain ontologies, in order to provide a higher level of interoperability for EWSs that acquire data fusion from multiple sources. *Semantic Gateways* address this issue by enabling the execution of semantic translations that can tackle specific semantic integration problems, such as semantic overload, ambiguity and information distortion (Kim, Kang et al. 2012).

To the best of our knowledge, approaches with *Semantic Gateway* that support the whole lifecycle of semantic translations (specification, implementation, and runtime configuration) have not been exploited yet in any EWS initiative. Although some researchers point out that such approaches are needed in order to more effectively apply the use of semantic models within EWSs (Poslad, Middleton et al. 2015), results are still lacking in the literature. A particular need that emerged for EWSs is the ability to interoperate with health monitoring systems that support medical emergency services (Clinton, Zollo et al. 2016) using *e-Health* standards.

The *Semantic IoT EWS* includes an approach that can handle multiple ontologies to support compound EWS semantics and ontology commitments. However, this approach lacks support to the development of alignments between domain ontologies that can be configured at runtime, i.e., it does not provide a mechanism for

[1] https://azure.microsoft.com/en-us/campaigns/mydriving/

[2] https://github.com/Azure-Samples/MyDriving

describing and executing semantic translations. Furthermore, efficiently publishing large volumes of semantically rich sensor data is a major architectural challenge due to inefficient data exchange caused by the overhead imposed by the encoding schemas of the current semantic models, e.g., OWL or RDF serialized as XML, requiring research especially for EWSs (Middleton, Zlatev et al. 2013).

Our ambition is to enable EWS semantic interoperability for disaster risk reduction by considering not only IoT ontologies, but also addressing cross-domain relationships through the alignment of multiple domain ontologies. Therefore, our research goal is to improve the semantic interoperability of emergency services for IoT EWSs. We identified the following challenges to achieve this goal, along with the corresponding requirements to the supporting framework:

(C1) Semantic integration of a variety of data sources

(Req1) Enable the development of an EWS core context model as a well-founded ontology, taking into account existing data representations and possible restrictions from the EWS requirements.

(Req2) Enable the development of an EWS data acquisition component to be able to process data from different sensor types described with different semantic models, i.e., provide syntactic and semantic interoperability.

(Req3) Enable a data fusion mechanism for EWS, allowing it to combine incoming real-time data with historical data, both for situation identification and for upstream information dissemination.

(C2) Processing in time- and safety-critical applications

(Req4) Enable the EWS to provide adequate performance, in terms of total processing time, which depends on the specific safety-critical restrictions regarding minimal response time. If the EWS requirements explicitly restrict the minimum time thresholds, the EWS should be able to process within this threshold.

(Req5) Enable the EWS to be scalable according to the data input volume and velocity, i.e., be able to allocate resources according to the number of data sources, their input frequency and message size.

(Req6) Enable a dynamic and adaptive mechanism to modify the EWS at runtime, minimizing the effect on the running instances.

(C3) Data analysis for effective responses

(Req7) Offer modelling capabilities for the representation of temporal relations among different types of events and situations. In particular, it must enable the EWS to use interval relationships, such as Allen's operators, to relate events for situation identification.

(Req8) Enable the representation of complex rules over context data, such as multivariate functions (risk, odds, rate and prevalence) and temporal existential rules (sliding time windows).

(Req9) Enable the EWS to issue warnings, as semantic enriched messages, to multiple targets through multiple channels (e.g., broker, e-mail, SMS). In particular, enable the modification of the information requirements of the targets at runtime through an UI.

SEMIoTICS FRAMEWORK

Our SEMIoTICS framework aims at improving the semantic interoperability of EWSs and their components, and addresses the interoperability challenges mentioned above. The first version of SEMIoTICS was reported in (Moreira, Ferreira Pires et al. 2015), which evolved to the architecture presented in (Moreira, Pires et al. 2018). SEMIoTICS consists of an architecture, which is illustrated in Figure 1, IoT platform technologies and MDE methodology guidelines. The MDE methodology guides the choice and application of the technologies according to the reference architecture.

Reference Architecture

The architecture consists of components that address the activities of the EWS workflow for real-time data processing. *Subscriber REST/RDF* and *Input Handler* are responsible for the *sense* activity, thus, implementing the *Upstream Data Acquisition* component of the *Standard-Based* architecture. Data are acquired by the EWS by subscribing to a context broker, which should provide data in RDF, either directly from the sensors or from a semantic gateways, which can be deployed in the field (e.g., in a mobile phone) or in the cloud (e.g., in a semantic web application). *Input Handler* is responsible for checking whether the EWS is capable of

understanding the data, i.e., if the data messages comply with the EWS ontology profile represented by *Context Model*. If the data cannot be understood, then *Input Handler* should check the pre-defined ontology alignments to execute semantic translations to transform the data.

If the EWS is capable of understanding the data, the (translated) messages are forwarded to *Context Data Manager*, which is responsible for storing the data in context database(s) and to forward them to *Situation Identification Manager*, which uses *Situation Type Rules* that can be executed by CEP engines. This situation identification mechanism addresses the *detect* activity of the EWS workflow. *Situation Model* uses data elements of *Context Model* for defining situation types at an abstract level.

Once the CEP engine detects a situation, it sends the related data to *Situation Reaction Manager*. *Situation Model* is linked to emergency response processes through *Action Model*, which specifies the procedures to react to the situation, usually derived from emergency plans. *Action Model* specifies the targets that need to receive the emergency notifications, considering the information requirements of each target and the channels to broker the messages. This approach enables personalized response activities, improving the emergency response effectiveness. Therefore, *Situation Reaction Manager* performs the *decide* activity of the EWS workflow.

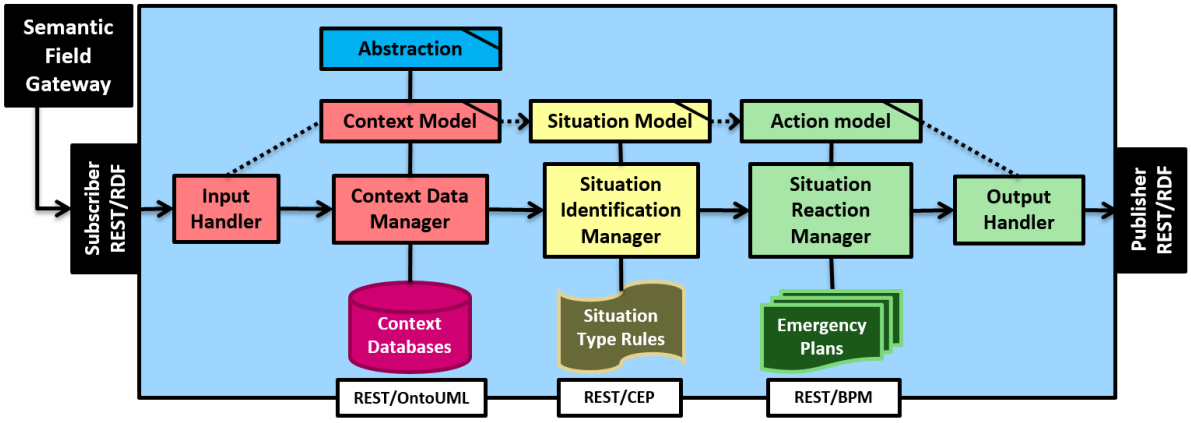

Figure 1. SEMIoTICS reference architecture

The *broker* activity is performed by *Output Handler* and *Publisher REST/RDF*, which together implement the *Downstream Information Dissemination* element of the *Standard-Based* architecture. Data are represented with standard-oriented emergency semantics, using the EDXL-CAP standard extended with the required contextual information structure (derived from *Context Model*). These messages are made available for the targets by publishing the data in a service broker, as an emergency notification publisher, and through other channels, such as e-mail and SMS.

Data stored in *Context Database(s)*, *Situation Type Rules* and *Emergency Plans* can be accessed through RESTful services. Both *Situation Type Rules* and *Emergency Plans* allow the management of the pre-defined linked situation and action models (emergency procedures). They provide data according to appropriate languages: ontological language, event processing language and business process language, respectively. Therefore, SEMIoTICS allows an EWS to share not only the data, but also all its "internal knowledge", namely: raw and processed data (for perception), situation rules (for comprehension) and reaction plans (for projection of future status).

Semantic Model-Driven Methodology

SEMioTICS follows a semantic Model-Driven Engineering (MDE) approach. The SEMIoTICS MDE methodology prescribes specification and implementation phases at design-time, considering the EWS deployment at runtime. The design-time level is organized in three interrelated parts: (1) Conceptual: presents the definition of real-world constructs in a foundational ontology, with temporal and structural aspects being addressed by extending the Unified Foundational Ontology (UFO). (2) Specification: covers the EWS design, adopting improved modelling languages as graphical modelling languages for context, situation and reaction. (3) Implementation: realizes the specification as executable pieces of software with IoT platform components.

Therefore, the conceptual part supports the modelling language constructs of the specification part, which is mapped onto the appropriate technology implementations by our model-driven engineering process, through model transformations. As usual in MDE, the implementation is (partially) generated by model transformations that integrate models and generate code for each component of the architecture according to use case requirements. Horizontal (same abstraction level) exogenous (different languages) transformations are applied at

the specification level, from the context model, represented with OntoUML, to the situation model, represented with the Situation Modeling Language (SML), and from the situation model to the action model, represented with BPMN, as described in (Moreira, Ferreira Pires et al. 2015, Moreira, Ferreira Pires et al. 2017).

In SEMIoTICS, we applied *ontology-driven conceptual modelling* to represent the occurrence of hazardous events and their relation to emergencies in situation-aware applications (Moreira, Ferreira Pires et al. 2017). The modelling languages used to specify these applications must support not only the design of structural aspects, but also temporal aspects and their relations (Costa, Mielke et al. 2012). Our ontology-driven conceptual modelling relies on ontological analysis based on UFO. Using UFO one can produce a well-founded core ontology that provides a precise definition of a specific field, being independent of a domain application (Scherp, Saathoff et al. 2011). This ontological approach supports common understanding among parties, addressing the semantic interoperability problem from the EWS specification to its implementation.

The SEMIoTICS framework also provides ontology alignments between the main standardized IoT ontologies (SSN/SOSA and SAREF), which can be used for semantic translations (Moreira, Daniele et al. 2017). OntoUML models have been incorporated in the SEMIoTICS core ontology[3], which is an extension of OntoEmerge (Ferreira, Moreira et al. 2015) that has alignments to other semantic models, such as the EDXL-CAP produced by the RESCUER project[4]. The SEMIoTICS core ontology represents the *Context Model*, which can be easily extended for specific application domains.

VALIDATION DESIGN

The validation design of SEMIoTICS included two activities: (1) developing an IoT EWS with a case study composed of emergency use cases as an instance of SEMIoTICS reference architecture; and (2) testing the IoT EWS developed by checking the fulfilment of each requirement.

Detecting accident risks with e-Health and logistics data

The INTER-IoT project developed a scenario to decrease the risk of fatal accidents at the port of Valencia. This scenario requires integration between logistics and health domains. The goal was to exploit how e-Health can use IoT platforms dedicated to logistics to prevent the occurrence of accidents and to support evacuation or attention in case of emergency situations (Ganzha, Paprzycki et al. 2016).

The main involved actor is the truck driver, who works for a haulier company that transports goods to/from the port. This company has a *haulier IoT platform* that tracks the trips made by the trucks and monitors the health of the drivers. The scenario features another IoT platform, the *port IoT platform*, for monitoring the data provided by the haulier IoT platform, integrating logistics and health data, and providing the emergency notifications to be consumed by the port emergency command centre. This emergency centre is simulated in two ways: (1) an UI based on Google Maps, able to plot the data in real-time; (2) a third-party partner provides an emergency management system that consumes data from the port IoT platform and integrates with the emergency notifications, being able to coordinate the emergency response. The scenario validation steps are described as functional and non-functional capabilities:

(IIOT-FC1) IoT platforms should be able to coordinate with emergency systems by detecting accidents and risks with trucks within the port area. The EWS should be able to identify vehicle collisions and severe changes of the driver's cardiac behaviour, alerting their urgency and severity to multiple targets through emergency interoperability standard(s).

(IIOT-FC2) The haulier IoT platform and the port IoT platform should be able to share cardiac information about the driver, monitored in real-time through an electrocardiography (ECG) device. The solution should be able to provide both raw and calculated data, e.g., ECG sequence (time series) and heart rate. These data need to be integrated such that the port emergency control system can consume them in conformance with emergency interoperability standard(s).

(IIOT-NFC1) IoT platforms should be semantically and syntactically interoperable. The solution should be able to integrate the involved IoT platform(s) in a way that their data syntax and semantics are understandable, i.e., can achieve common understanding among the participating parts.

(IIOT-NFC2) E-health and logistics should be integrated at the INTER-IoT application and semantics level, including primitives for data interpretation of medical and logistics data by using semantic models to represent e-health and logistics data within the IoT use cases (listed below).

[3] https://github.com/jonimoreira/SEMIoTICS
[4] http://fpc.ufba.br/ontologies/edxl_cap

(IIOT-NFC3) The energy consumption (battery level) of the devices being used for the situation identification mechanism should be monitored.

Use Cases and Situation Types

Four use cases were defined to validate these capabilities:

(IIOT-UC01) Vehicle collision detection

The EWS monitors the truck's instantaneous acceleration and location, being able to monitor the truck behaviour within the port area. The data are provided by both the mobile phone and by the ECG device, which enable the detection of possible vehicle collisions. Use cases like this are performed by using tri-axial (x, y, y) accelerometer sensor(s), deployed within the vehicle, to collect data about the vehicle's acceleration, allowing the calculation of the G-Force over time. The detection mechanism compares if the G-Force computed is above a certain threshold to detect a collision, which is usually 3G for devices deployed in the vehicle chassis and mobile accelerometer (Sulochana and Babu 2014). Collision detection is supported by computing the instantaneous cross-axial energy function (Equation 1) and comparing it to the threshold.

Equation 1:

$$CrossAxialEnergy = x^2 + y^2 + z'^2$$
$$z' = z - 1G$$

where *x, y, z* are axial accelerations measured in m/s^2. 1G = 9.806 m/s^2

The severity and urgency of the collision detected is calculated based on a deterministic distribution according to four ranges, as shown in Table 2. Variable *A* represents the cross-axial energy computed when the accident was detected, while variable *B* represents the threshold.

Table 2. Ranges of emergency severity and urgency

Range	Urgency	Severity	Colour
B < A <= B * 1.2	Minor	Expected	Green
B * 1.2 < A <= B * 1.4	Moderate	Immediate	Yellow
B * 1.4 < A <= B * 1.6	Severe	Immediate	Red
B * 1.6 < A	Extreme	Immediate	Black

In this use case, situation types are computed both at device and cloud levels, e.g., (UC01.ST01) collision detected based on one acceleration observation (from ECG unit) with cross-axial function and identification computed at the field gateway level; and (UC01.ST02) based on one acceleration observation (from ECG unit) with cross-axial function and identification computed at the cloud level.

(IIOT-UC02) Cardiovascular risk detection

The EWS is able to detect occurrences of arrhythmia of truck drivers, issuing alerts according to the possible cardiovascular emergencies. By detecting cardiovascular emergencies with truck drivers, it is possible to reduce the risk of an accident at the port area. The EWS monitors the cardiac behaviour of the driver, tracking the heart rate during the trip within the port area. The heart rate data are provided by the ECG device as a processed measurement from a function, which measures the intervals between R waves from the QRS complex of the ECG time series. Both processed heart rate and raw ECG data are made available to the EWS, which must adhere to health data privacy best practices, complying to the EU General Data Protection Regulation (GDPR).

Thresholds used by the detection mechanism should be based on classifications to detect health risks, both regarding bradycardia and tachycardia[5]. For example, the heart rate below 50 bpm is a bradycardia and above 99 bpm is a tachycardia. The heart rate score reflects the urgency and severity levels of the situation, e.g., for heart rate of 115 bpm, the score is 2, similar to the classification of severity and urgency of the previous use case. Figure 2 illustrates a more complex pattern covered by the UC02.ST03 situation type, which is activated when three consecutive bradycardia (UC02.ST02) are detected within an interval of 20 seconds.

[5] http://www.mayoclinic.org/diseases-conditions/bradycardia/diagnosis-treatment/diagnosis/dxc-20321665

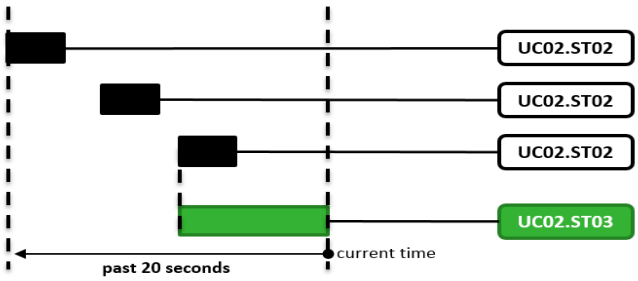

Figure 2. Complex event pattern that triggers the situation type UC02.ST03

(IIOT-UC03) *Correlation of vehicle collision and cardiovascular risks*

This use case exploits the possible temporal relations between UC01 and UC02 for detecting accidents that involve both collision and cardiovascular risk detection. This approach identifies that a collision is followed by an arrhythmia, which can represent a possible injury of the driver after the accident occurrence, as well as the other way around, i.e., an arrhythmia followed by a collision, which can represent that the accident occurred because of a health issue. For example, if a truck collision is detected from the mobile accelerometer data (UC01_ST03) and within 20 seconds a bradycardia is detected (UC02.ST01), then there is a high probability that the driver is injured and requires urgent medical support. This use case demonstrates the integration of both data sources and how to execute complex behaviours that rely on temporal relationships. The situation types defined for this use case include (UC03.ST01) collision followed by bradycardia within an interval of 20 seconds.

(IIOT-UC04) *Accident involving dangerous goods*

This use case extends UC01, UC02 and UC03 by monitoring the type of goods being transported (logistics data), taking into account the dangerous goods classification of the United Nations Economic Commission for Europe (UNECE): Explosives, Gases, Flammable liquids, Flammable solids (substances liable to spontaneous combustion; substances which, on contact with water, emit flammable gases), Oxidizing substances and organic peroxides, Toxic and infectious substances, Radioactive material, Corrosive substances, Miscellaneous dangerous substances and articles, hazardous substances. When detecting an emergency, the IoT EWS informs the type of dangerous goods being transported, warning the need of adequate equipment to deal with the material transported for effective response. This use case demonstrates the integration of data from both domains (health and logistics). Three situation types were defined for this use case according to each prior use case: (UC04.ST01-3) vehicle collision, cardiovascular risk, and vehicle collision with cardiovascular risk, respectively, with dangerous goods being transported, informed by the mobile app.

VALIDATION RESULTS

To tackle the three main challenges for semantic interoperable IoT EWS and to implement the envisioned INTER-IoT use cases, we developed the INTER-IoT-EWS[6] solution. INTER-IoT-EWS enables semantic data streaming with standardized ontologies serialized as JSON-LD, improving existing solutions for vehicle tracking and ECG monitoring.

Reusing Solutions: Vehicle Tracking and Real-Time Electrocardiogram (ECG) Monitoring

Many open source IoT solutions are able to track vehicle trips. We chose to apply the *MyDriving* solution discussed before to reduce the development time of INTER-IoT-EWS. The *MyDriving* architecture adheres to the SEMIoTICS framework. It uses a cloud gateway (*IoT Hub*) to broker data provided by IoT devices. The field gateway (*MyDriving* mobile app) provides data as JSON messages and, thus, can benefit from JSON-LD to serialize RDF for brokering semantic data. The main idea was to change *MyDriving* data interfaces, using specific ontologies to represent both logistics and e-Health. The *MyDriving* Android application, the *IoT Hub* and the application service with its database service were reused.

Real-time outpatient ECG monitoring is known as mobile cardiac telemetry and can stream data continuously to caregivers. Mobile cardiac telemetry is leveraged by IoT technologies, which offer opportunities to abnormal situation detection with support of medical wearables and cloud infrastructure. Modern ECG units can transmit

[6] https://github.com/jonimoreira/INTER-IoT-EWS/

the records of the electrical signals measured from the skin through wireless communication (e.g., Bluetooth), and are becoming smaller, more comfortable and energy-efficient. There are several examples of industry-oriented four-lead ECG devices for real-time outpatient monitoring, such as Shimmer3 ECG[7], and advanced stick-on ECG devices. To the best of our knowledge, none of the ECG monitoring solutions support real-time semantic data streaming, which became necessary due to the combination of requirements IIOT-FC2 (monitoring real-time ECG) and IIOT-NFC2 (e-Health semantic model).

A study was performed to select an industry-oriented four-lead ECG device for real-time outpatient monitoring. The main characteristics needed were: (1) to be a recognized and affordable solution (less than 800 EUR) and a reliable four-lead ECG for outpatient-monitoring; (2) to record high-frequency, e.g. 256/516Hz; and (3) to provide configurable sensor module and open-source API for data acquisition in a mobile environment. Shimmer3 ECG covers all these needs and was developed with the same technology as the *MyDriving* mobile app. Shimmer3 ECG has high accuracy and usability, being able to transmit data from the ECG device to a mobile phone application (Android) through Bluetooth. In addition, the Shimmer3 ECG solution provides an API for mobile environment with implementation examples, including the *ShimmerCapture*[8] mobile app (Android). Therefore, Simmer3 ECG solution was chosen to be integrated with *MyDriving*, playing the role of health data provider, requiring an e-Health ontology. Both logistics and e-Health ontologies require to be integrated with an IoT ontology such as SAREF or SSN/SOSA.

INTER-IoT-EWS Solution Architecture

The *MyDriving-LD* app along with the Shimmer3 ECG device represents the haulier IoT platform. Since the *MyDriving* app does not represent data as RDF, changes in the mobile app were required to transform the app to a *MyDriving for Linked Data* (*MyDriving-LD*). MyDriving-LD plays the role of the *Semantic Field Gateway* component of SEMIoTICS, providing logistics data, thus, requiring an ontology that represents transports, trips, location, acceleration and the goods transported. The *MyDriving-LD* should be integrated with the Shimmer3 ECG device, using the *ShimmerCapture* solution as example. For health data, we developed a SAREF extension called SAREF4health (Moreira, Pires et al. 2018), and for logistics data, we used the ontology modules developed by TNO[9] (LogiCO/LogiServ/LogiTran).

The cloud components (*Input* and *Output Handlers*, *Context Data*, *Situation Identification* and *Reaction Manager*) implement the accidents detection and warning brokering mechanism. Processing vehicle collision (IIOT-UC01) and hazardous health changes (IIOT-UC02) are performed at the cloud level, where the EWS implements the situation identification mechanism, including the composition use cases (IIOT-UC03 and IIOT-UC04). The solution also performs situation identification at device level, such as UC01-ST01.

Figure 3 shows the solution architecture. The Shimmer3 ECG device collects data from the truck driver and sends them to the *MyDriving-LD* application, aggregating and publishing JSON-LD messages in the *IoT Hub* (in the cloud). *Input Handler* subscribes to receive all messages published in *IoT Hub*, checking the TBox of each message, whether the domain is IoT or e-health or logistics, and checks if semantic translations are necessary to harmonize the data with the SEMIoTICS core ontology. If so, *Input Handler* requests the translations from IPSM, forwarding the input message and the alignment required (pre-configured) for executing the translations. The IPSM is responsible for syntactically and semantically translating the data streams: from JSON-LD to the INTER-IoT JSON-LD syntax, which is a structured JSON-LD with middleware (INTER-MW) information. Our INTER-IoT-EWS solution also provides an internal translation mechanism, which is a standard approach using SPARQL to query input data harmonizing it with the context model.

The syntactical translation mechanism for *sosa:Observation* objects creates observation instances according to the measurement property. For example, if the property is the vehicle collision computed by the ECG device or the mobile, then the method creates a *semiotics:VehicleCollisionDetectedObservation* instance, adding this translated observation to the ordered list of observations (according to the observation timestamp) that are sent as events to the CEP processor. After executing the translations, the *Input Handler* sends the non-structured ("raw" JSON-LD) data to *Context Data Manager*, and the structured data are represented as object-oriented classes, such as Plain Old C# Object (POCO) classes implemented by *Situation Identification Manager*, exposed through microservices. *Context Data Manager* annotates the data with the core ontology terms, providing heavyweight semantics by adding predicates from the foundational ontologies, storing the data in two ways: (1) inserting the JSON-LD messages in a document-based (NoSQL) database (MongoDB) for historical data storage; and (2) inserting the RDF in a triplestore (Virtuoso) for querying semantic data.

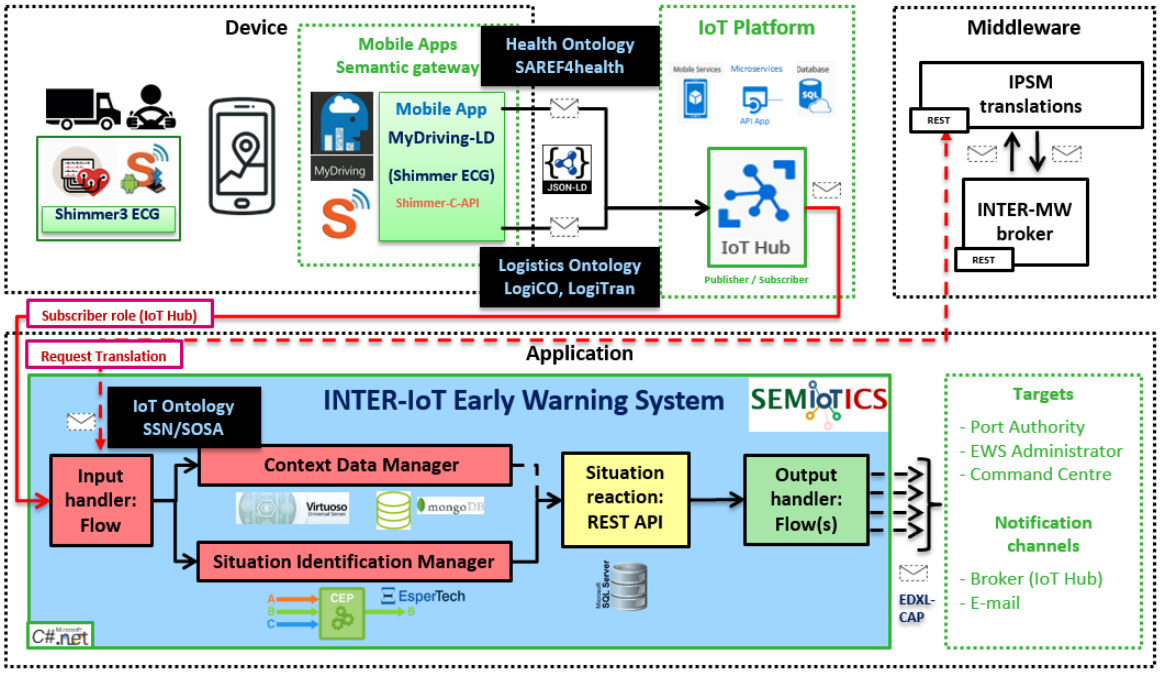

Figure 3. Solution architecture of the IoT EWS to detect accident risks and accidents

INTER-IoT-EWS is also aligned to the *MyDriving* architecture in terms of real-data handling ("hot path") and historical data handling ("cold path"). Both real-time data and historical data are used by the *Situation Identification* component, which was implemented with NESPER event processing server[10], taking advantage of the SQL-like approach of Event Processing Language (EPL)[11]. Therefore, *Situation Types Rules* are implemented as EPL statements, which uses the POCO classes as internal data model. Each *Situation Type Rule* is linked to a response process, i.e., the specific workflow to be executed once a situation is identified. When the CEP server identifies a situation type by matching the EPL pattern, the CEP server triggers an event handler method, forwarding the data to *Situation Reaction Manager*, which executes the workflow that includes the activities (tasks) for message brokering. *Situation Reaction Manager* checks the information requirements of each alert target, passing this information to *Output Handler* when a brokering message activity is executed. *Output Handler* is responsible for transforming the data to semantically compliant EDXL messages, brokering the notifications as JSON-LD messages. An UI application shows the alerts issued by the EWS with its severity, urgency and other information.

Laboratory Tests and Pilot in the Port

The validation plan checked whether the requirements were realized. The functional validation activities included factory acceptance tests (FAT) and site acceptance tests (SAT) through a pilot in the port of Valencia, where accidents were simulated in accordance with the port emergency exercises. Both FAT and SAT assess whether the system works for the intended risks' detection and warnings. FAT were performed to check completeness and requirements verification, simulating each of the situation types of each use case. Test hooks included data injection to increase the instantaneous acceleration data for the collision detection and to change the processed heart rate to below the bradycardia threshold and above the tachycardia threshold, as well as other more complex data patterns. Figure 4 shows a screenshot of the UI prototype we developed to perform the tests, with some results from the execution of emergency exercises in the port.

In total, 44 test cases were performed, of which 43 have been successful (97.7% test coverage). IIOT-FC1 was realized, since INTER-IoT-EWS enables an IoT platform (Azure IoT) to interoperate with emergency systems through the most appropriate interoperability standards for input data, through SSN/SOSA or SAREF, and for emergency notification, through EDXL-CAP. IIOT-FC2 was covered by the haulier IoT platform providing cardiac data of drivers in real-time, both raw ECG and processed heart rate data being available through a context broker (IoT Hub). Identification of cardiac issues was covered by the arrhythmia situation types. IIOT-NFC1 was covered by addressing both syntactic and semantic interoperability in the INTER-IoT-EWS component. Semantic interoperability was improved by the adoption of the standardized ontologies and, in

[10] https://github.com/espertechinc/nesper
[11] http://www.espertech.com/esper/

particular, the development of SAREF4health (Moreira, Pires et al. 2018). Syntactic interoperability was covered by the adoption of JSON-LD, while semantic translations were tested using two approaches, the "raw" SPARQL (internal to INTER-IoT-EWS) and IPSM (external to INTER-IoT-EWS). IIOT-NFC2 was also covered by the integration of the health and the logistics ontologies at application level. Finally, IIOT-NFC3 was covered since the battery level of the ECG device was provided (in real-time) to the EWS.

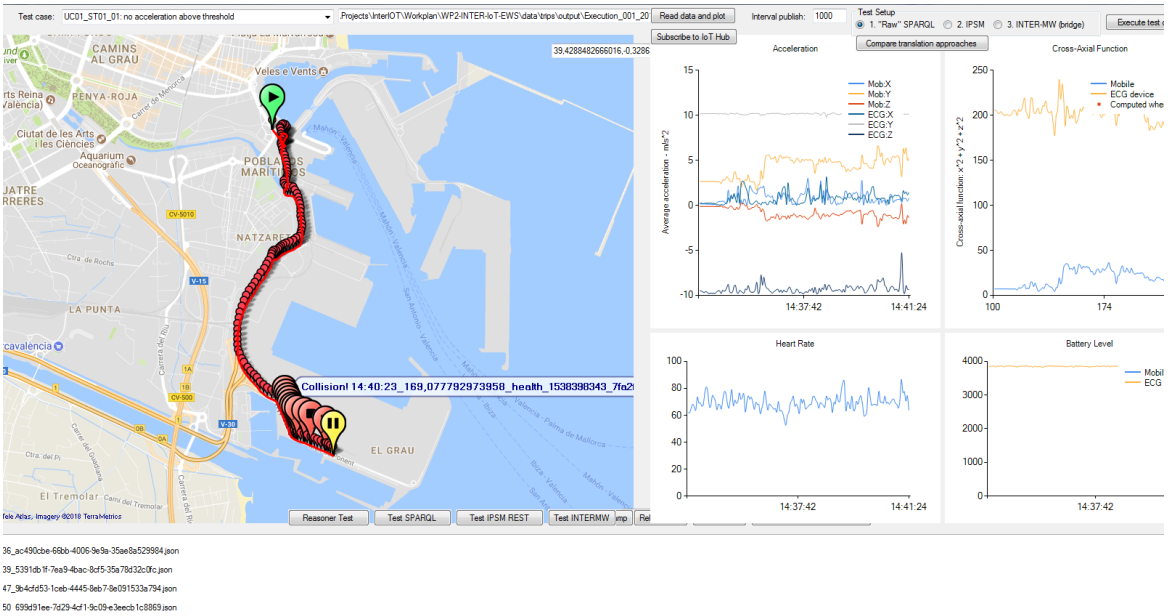

Figure 4. UI prototype simulating a command centre receiving data at real-time (tests in the port of Valencia)

This overall validation showed that SEMIoTICS can integrate data from different sensor types described with different semantic models, addressing Req2. It also enables data acquisition using semantic technologies (Req2) and addresses the integration of historical data with real-time data (Req3).

Performance Analysis

The performance validation showed that SEMIoTICS can address the processing time (Req4) and the scalability requirements (Req5), being able to change the situation types at runtime (Req6). The adoption of SML for specification and situation identification implementation with CEP technology, generated from SML to CEP transformations addressed Req7 and Req8. Personalized information requirements for the emergency notifications addressed Req9, allowing each target to configure the EDXL-CAP elements should be considered in the warnings received.

The overall INTER-IoT-EWS performance analysis included the measurement of the total transaction time for the whole EWS workflow. We followed a similar validation method of the *Semantic IoT EWS* approach for scalability and resilience: (1) test the upstream data acquisition and situation identification, measuring the total transaction time from *Input Handler* to *Situation Identification Manager* for each test setup; (2) validate data storage and query performed by *Context Data Manager*; (3) validate the multi-brokering multi-cluster approach, by investigating whether an industry-oriented cloud infrastructure, such as MS Azure, is able to multiply the throughput threshold of 700 msg/sec achieved by the Semantic IoT EWS applied for tsunami detection in the TRIDEC project (Middleton, Zlatev et al. 2013).

Storing the JSON-LD in MongoDB and querying data with JQuery showed to be extremely complex and inefficient, in terms of semantic features and total time. Since data are already formatted as RDF (JSON-LD), we tested storing the data in a Virtuoso server to benefit from SPARQL. In contrast with the MongoDB behaviour, the triplestore was slower for data insertion but efficient for querying. Therefore, for long-time historical data storage purposes, such as backup for audit, MongoDB seems to be the best option.

Concerning the efficiency of publishing semantically rich sensor data with a multi-broker approach similar to the *Semantic IoT EWS*, we conclude that the threshold of 700 msg/sec/unit, with message size of 6Kb, thus, 4.200 Kb/sec/unit, is easily reached with the Azure cloud infrastructure. According to the *IoT Hub* quotas and throttling[12], the throughput of publishing sensor data (termed "device-to-cloud") can reach 6.000 msg/sec/unit,

[12] https://docs.microsoft.com/en-us/azure/iot-hub/iot-hub-devguide-quotas-throttling

with message size of 4Kb, thus, 24.000 Kb/sec/unit. Therefore, the cloud infrastructure can scale up to five times the broker throughput of *Semantic IoT EWS* approach. Furthermore, Azure provides a limit of 50 brokers (*IoT Hub* instances) per subscription, thus, allowing a multi-broker approach deployed either in a single cluster (an Azure "resource group" deployment) or multiple clusters, as the federated cluster deployment.

We stress that the SEMIoTICS approach is even better because the *Semantic IoT EWS* approach splits data and metadata, separating the sensor data as key-pair values (serialized as XML messages) from the semantics (metadata), which is incorporated only on the server side (cloud level). In contrast, the SEMIoTICS provides a more efficient approach to enrich the semantics of sensor data at the field gateway level, which decouples the solution to the specific IoT platform and cloud infrastructures. However, this high efficiency has a high cost, namely €42,17 (unit/month). A crucial characteristic that impacts the performance and costs is the operating time requirement. Considering that the *MyDriving-LD* app publishes health messages (~30Kb) and logistics messages (~6Kb) each 3 seconds (12 Kb/sec), and each driver uses the solution for 8 hours/day, then each driver consumes ~42 Mb/h (337.5 Mb/day). The IoT Hub cost for a haulier company would be more €8,43 per driver per month.

CONCLUSION

Current IoT EWS approaches only partially address the semantic integration of a variety of data sources along with processing in time-critical applications and data analysis for effective responses. This paper describes the SEMIoTICS framework, which is a conceptual architecture for the development of interoperable IoT EWSs. The SEMIoTICS framework guides the use of different modelling languages, ontologies and IoT platform technologies towards the improvement of interoperability within and among IoT EWSs. The SEMIoTICS architecture combines different theories and technologies, such as ontology-driven conceptual modelling with foundational ontologies, Endsley's situation-awareness theory, IoT platforms, microservices architecture with JSON-LD, RDF implementation best practices for IoT, leveraged by the two main standardized IoT ontologies (W3C SSN/SOSA and ETSI SAREF) and their alignments for semantic integration with the most common standard for emergency systems (EDXL-CAP). SEMIoTICS was designed to be general enough for various types of emergency, and is not limited to a specific domain.

SEMIoTICS was validated through INTER-IoT-EWS, an instance of the SEMIoTICS reference architecture, in an emergency use case for the port of Valencia. INTER-IoT-EWS is able to monitor trucks delivering goods at the port and the drivers' vital signs, integrating logistics and health data for accident detection. The validation of INTER-IoT-EWS showed that SEMIoTICS is able to cover all identified requirements, enabling semantic integration of a distinct data sources with adequate processing performance and providing data analysis for effective responses with personalized warnings. The prototype test execution covered 97.7% of the test cases, the architecture showed to be scalable and perform better than the baseline.

The main disadvantage of SEMIoTICS is the high cloud infrastructure costs necessary to run the system with critical operating times. The framework also lacks a mechanism to cope with quality of information at the network level, such as a Grubbs' test for outlier detection.

ABSTRACT

A crisis is a complex situation, difficult to manage by the actors. Some of them are under stress it is difficult to deal with problems when consequences cannot be predict. The human conditions (concerning familial and life) and, the influence of the environment related to politics, economic, and media pushe the actors to lose control of the crisis situation. The question we face in this paper is: "is it possible to use the fuzzy theory for predicting the stress impact in crisis?" Our main hypothesis to represent experience feedback in a situation prediction in order to show negative consequences and correctness actions is taken account. Fuzzy theory concept is used in prediction in order to generate several situations.

Keywords

Crisis management, Fuzzy Theory, Ontology, Collaboration, Stress.

INTRODUCTION

A crisis situation generates a collective stress. This kind of situation request an organization to manage it and, to make pertinent decisions with the aim to reduce the effects in a short time with minimal damage. This paper shows us, how is possible to generate a predict stress impact situation by using fuzzy sets and knowledge management. This can help crisis management actors to learn by exploring different situations due to stress impacts. So, the main questions can be: Is it possible to use the ontology in the prediction of the impact of the stress during a crisis situation? Is it possible to use the fuzzy theory for predicting the stress impact situation in crisis? In this paper, some answers to this question are explored, especially, the generation of the stress impact situations by using the experience feedback and the fuzzy theory. Firstly, a description of the uncertainty and the fuzzy theory were addressed. Then, the crisis management as a collaborative situation and the impact of the stress during the crisis that can generate some uncertainty situations is studied. Also, an otology is identified for our study. And then, the use of the fuzzy theory in the representation of the stress impact during a crisis situation is discussed and a representation of the structure of the fuzzy generator called "NOE" is proposed.

THE FUZZY THEORY AS UNCERTAIN REASONING TOOLS

The uncertainty is a situation of inadequate information. It can be of three sorts: inexactness, unreliability, and borders with ignorance (Funtowicz, Ravetz 1990). For Zadeh, "Uncertainty is an attribute of information" (Zadeh 1997). It can prevail in situations where a lot of information is available (Van Asselt, Rotmans 2002). A new information or knowledge can decrease or increase the uncertainty. Some researchers suggest that uncertainty may be an important mediator of the impact of role stressors on the stress (Beehr 2000; Beehr, Bhagat 1985; O'Driscoll, Beehr 1994). The uncertainty concern all phenomena or systems whose behavior is generally disordered and irregular, which can often appear unpredictable and random.

Fuzzy Theory Principles

It is a mathematical theory of Zadeh (Zadeh 1996) based on intuitive reasoning. This theory considers the subjectivity and the imprecision. It may treat digital literacy; non-measurable values and for a linguistic issue (Bouchon-Meunier, Yager, Zadeh 1995). Fuzzy sets provide techniques to represent subjective and uncertain reasoning. Its goal is to build a formal system that it can make a qualitative reasoning (Rosental 2004). The fuzzy sets are used in different domains like pattern recognition, robotics, biology, economy, medicine, ecology, etc. (Zimmermann 2010). From this theory, we used the linguistic modifiers for using adverbs. The linguistic modifier permeate to attenuate or amplify the initial meaning of a number of attributes by the action of adverbs such as: very, more, at least, slightly. And, we use the multi-objective decision-making. It involves a selection of one alternative from a universe of alternatives given a set of criteria or objectives. For this study, we seek a decision that simultaneously satisfies all of the decision objectives.

THE CRISIS MANAGEMENT AS COLLABORATIVE ACTIVITY

During a crisis management, actors come from different organizations. They work, communicate, cooperate, coordinate and, exchange their own experiences. Their main common objective is how to deal with the crisis for reducing its effect? In this relationship, is noted that multiple actors are interdependent in their work. They interact each other to improve the state of their common field. They use resources like computers; plans; procedures; schemes; etc. This distributed activity can be represented as Triple C (Communication, Coordination, Cooperation). Several papers in the literature mention the role of Triple C in crisis management, and their interdependence (Martin, Nolte, Vitolo 2016). The interdependence of the 3C is affected by the regulation. Indeed, the regulation adjusting consists of sending or to receiving information, giving a warning (Communication); using means (Coordination); and to use the procedure, decision and organization (Cooperation).

REPRESENTING CRISIS SITUATION BY USING ONTOLOGY

Ontology is generally defined as a conceptualization of entities used in a specific domain (Gruber 1995). There are three levels of ontologies: Top, domain and applications (Guarino 1998). Identifying different concepts that represent crisis situations is needed before dealing with uncertainty in this type of situation. Related ontologies are then studied in this aim. For our study we choice the ontology named ResOnt (CHEHADE, Samer; Matta, Nada; POTHIN, Jean-Batiste; COGRANNE 2018) for rescue operations. In these ontologies, entities like tasks, actors, roles, organizations, materials, infrastructures are defined. These entities are specialized to answer our specific needs: representing main factors that influence uncertainty in crisis situations. Firstly, physical objects are distinguished from mental ones as recommended in top-level Ontology as Dolce (Guarino 1998) and SUMO (Niles, Pease 2001).

- Physical Objects emphasize Means, Persons, etc. (Fig. 1)
- Mental Constructs specify Task, roles, Influence, etc. (**Erreur ! Source du renvoi introuvable.**)

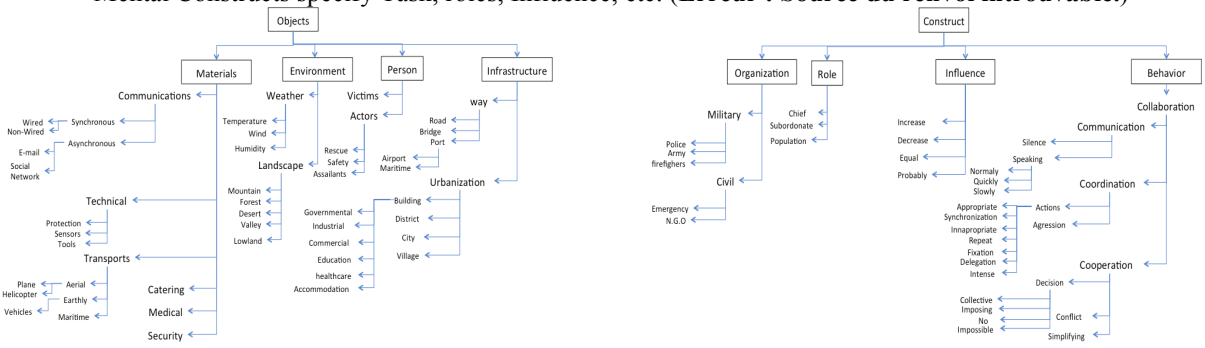

Fig. 1. Physical Object and Mental construct Ontology

Relationships between these concepts are then identified in order to reflect the dynamicity of crisis situations. Sediri propose to represent this dynamicity using state and events (Sediri, Matta, Loriette, Hugerot 2013). Crisis situations can be then seen as a sequence of events modifying states (0).

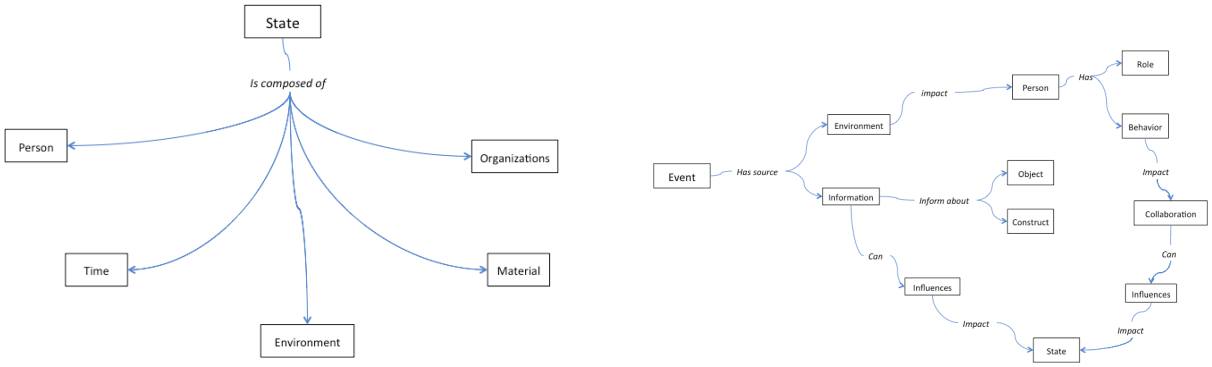

Fig. 2. State and Event relationships

These relationships are used in "NOE" situation generator that we defined (Teffali Sammy; Matta Nada; Chatelet Eric 2018). It is based on fuzzy theory.

APPLICATION ON STRESS IMPACT DURING A CRISIS MANAGEMENT

The Stress

The stress is an important factor in the success or the failure of the decision-making in a situation of crisis management. It is a particular relation between an actor and his specific environment. Its evaluation can be weak or exceed the actor resources and can be endangered his well-being (Lazarus, Folkman 1984). It was noticed that "Some policymakers reveal resourcefulness in crisis situations seldom seen in their day-to-day activities; others appear erratic, devoid of sound judgment, and disconnected" (Hermann 1979). Several approaches for the stress have been proposed, in the case of this study, the transactional approach is chosen (Cox, Griffiths, Rial-González 2000). It is related to cognitive and emotional processes, which gives interaction between a person and his environment (Boswell, Olson-Buchanan, LePine 2004). This indicates that the individual and the demand are two components. Indeed, an actor possesses personal characteristics that differentiate him from others. He is under the influence of environmental variables. He uses the coping. Lazarus defined the coping as "the overall cognitive and behavioral efforts, continuously changing, deployed by an actor for managing specific internal and/or external requirements, which are evaluated as consuming or exceeding his resource" (Lazarus, Folkman 1984). There are different studies that propose training and mental preparation methods to help actors to face the stress in crisis management (Ducrocq, Vaiva, Cottencin, Molenda, Bailly 2000; Pauchant, Mitroff, Lagadec 1991). This paper focus on the impact of stress on decision-making in order to promote learning from fails and guides based on experience feedback.

The Stress Impact During a Crisis

Boswel present four classes of indicators that influence stress conditions (Boswell, Olson-Buchanan, LePine 2004). (1) Task conditions: workload, etc; (2) relational conditions: conflict, harassment, etc; (3) job conditions: Mobility, no promotion, etc; (4) interaction private/profession: husband, children, family, etc. Different observable indicators of the stress are considered in psychology as manifestations of stress. Some of these are mainly noted: Speech rhythm (Siegman, Pope 2016), repetition of expressions and words (Kasl, Mahl 1965), using specific words (Kasl, Mahl 1965) etc; super activity, inadequate movement (Dittmann 1962) etc; silence (Weintraub, Aronson 1967); ambivalence, self-confidence (Aronson, Weintraub 1972); hostility and aggression (Gottschalk, Winget, Gleser, Springer 1966); inappropriate behavior and actions (Mehrabian 1968a, 1968b). Other studies have shown some manifestations of stress impact on decision-making as: Situation and context simplification (Lazarus et al, 1966); fixation on one possibility without any flexibility and alternatives (De Rivera 1968); consulting several opinions without concluding on a decision (Cooper et al., 1988); imposing a decision without measuring the impact and the consequences (Holsti 1972); missing decision-making and actions (Schlenker, Miller 1977). In this work, some of these indicators that can be measured directly from crisis management actions feedback are selected: super activity and imposing decision without considering the impact; silence, missing decision and actions; speech rhythm, aggression, and conflict of opinions and decisions; simplification of the situation and inadequate means and actions. Based on this study of stress impact, an expert dealing with military crisis situations has been interviewed in order to identify the influence types related to stress impacts. Ontologies entities previously defined are used as a guide in these interviews; the experts are solicited to specialize these entities and especially relationships between events and states.

INTEGRATING ONTOLOGY IN FUZZY THEORY APPLICATION

The advantage of the fuzzy theory is to use the linguistic value and to give for this value a mathematical sense. The main characteristic of this theory is the quantification of the uncertainty. As we know, the human reasoning in different areas is based on uncertainty. One of our principal preoccupations is how to interpret the impact of the stress in crisis situations using the human behavior and reasoning. The preferred method is to use the natural language. This is most comprehensive and simplest to interpret it. Our proposition is so to use the natural expression or words with fuzzy theory and especially the fuzzy sets. For that, we used a real situation lived as a case studied to apply the fuzzy theory.

Architecture of the Stress Impact Generator

Considering all these components, and the fuzzy logic theory we imagined a fuzzy generator called "NOE" who can generate state by introducing event. In the beginning we feed all the components mentioned above in a knowledge base. The information contained in the event is introduced in the generator. By using the fuzzy theory and the knowledge base, "NOE" generates the output state. For the next phase of this study, we are going to give more precision about some components that will enable us to use this theory.
We define for the first time a number of the sets:

- A is a universe of three actions: $A = \{a_1, a_2, a_3\}$ (1)

  Where $a_1 = \text{Communication}; a_2 = \text{Coordination}; a_3 = \text{Cooperation}$

- B is a universe of n actors: $B = \{b_1, b_2, \dots, b_n\}$ (2)
- C is a universe r places: $C = \{c_1, c_2, \dots, c_r\}$ (3)
- D is a universe of j data:

D includes different kinds of information as weather (w); crisis-place (cp); victims (v); population (p); morphology-of-land (m); assailant (as): infrastructure (in); and crisis-situation (cs). Then the function D is represented as the intersection of r-tuples noted: $D(w_j, v_j, cp_j, v_j, p_j, m_j, as_j, in_j, cs_j)$ (4)

- F is the universe of q means : $F = \{f_1, f_2, \dots, f_q\}$ (5)
- T the set of I time : $T = \{t_1, t_2, \dots, t_i\}$ (6)
- The linguistic modifier is a set of atomic terms defined and in relation to the feedback experience of the expert: $G = \{\text{equal}, \text{increase}, \text{decrease}, \text{probably}, \}$ (7)
- The State is defined as a function composed by actors (b), place (c), means (f) and data (d).

$$\text{State} = \{(b_1, c_1, f_1, d_1), (b_2, c_2, f_2, d_2), \dots., (b_n, c_r, f_q, d_j)\} \quad (8)$$

- The function event is composed by the couple action (1) or data (4), and by actors (2).

$$\text{event} = \{(a \text{ or } d_1, b_1), (a \text{ or } d_2, b_2), \dots, (a \text{ or } d_j, b_n)\} \quad (9)$$

$$\text{For all } a \in \{a_1, a_2, a_3\}.$$

The objective is to define the impact-stress function O composed by the functions state (8), events (9), the sets of the time (6) and the linguistic modifier (7).

$$O = f(\text{state}, \text{event}, T, G) \quad (10)$$

By using the impact-stress function O we can generate several situations during a crisis situation.

"NOE" THE GENERATOR OF THE SITUATION

The generation of situations with "NOE" can be illustrated on a study of a real case.

Example of Stress Impact During a Crisis Situation

A real case is studied in a crisis management situation. The author's observation can reveal some aspects of the impact of the stress during this event. It also provides, a timeline for actors' reaction with a general view on errors committed, means used, the places where the event was reported and, different information and data known. For this, a retired officer of the Algerian Army has been interviewed (as an expert) about one of crisis situations he dealt with. This case is about a terrorist attack on two villages in the Algerian mountain. The case analysis shows us some impact of the stress: (I) Imposing a decision without measuring the impact and the consequences. (II) Repetition of expressions and words. (III) Silence, missing decision and actions. (IV) Simplification of the situation and inadequate means and actions.

Generate Situations From the Case Studied by Using "NOE"

For our study, we apply the generator "NOE" to the scenario cited upper. We observe how some data like victims, place, and assailants using the linguistic modifiers can change. These help the manager to have the best understanding of the situation and to take the best decision in managing the crisis situation. Applied the fuzzy generator on the same example, we can also note that for the same state and for the same action, communication (silence), the fuzzy generator can generate three situations (**Erreur ! Source du renvoi introuvable.**). Otherwise, for the same state we can use other actions and with the fuzzy generator, we can generate a considerable number of states.

CONCLUSIONS

The present study suggests a crisis situation predicts, which generate a number of states of crisis. This is based on the stress impact representation by using experience feedback during a crisis. An experience is presented and modeled as specialization of existing crisis management ontologies. Based on that, we answer the main question. A representation is illustrated in a real case study in order to verify its applicability. The predict system is based on the Fuzzy theory that helps to deal with uncertainty and dynamicity of situations. So, for the same state and for the same action, the predict-system can generate a variety of situations. The natural progression of this study is to implement "NOE" generator in a learning system. This can help the crisis manager to explore different situations of the crisis and discover stress consequences to deal with.

ABSTRACT

During rescue operations, being aware of the situation is very critical for rescuers and decision-makers to reduce the impacts. This work aims to support situation awareness amongst actors participating in rescue operations by adopting an ontology-based approach. An application ontology is proposed based on existing related ontologies and operational expertise collection. It will help to ensure common situation representation and understanding between different actors. After that, a knowledge-based system will be developed and integrated in actors' environment to support decision-making. Our preliminary results are shown in this paper.

Keywords

Application Ontology, Common situation representation, Rescue of people, Situation awareness.

INTRODUCTION

Rescue of people consists in saving their life in case of particular situations by applying responsive operations. In France, it is described as precise duties to be achieved by several public services in order to ensure the protection of people by allowing them to escape from dangers, securing intervention sites, providing medical help, and finally, making sure the evacuation to an appropriate place of reception (Diederichs et al., 2006). These services have to deal with several flows of information coming from many sources. They have to make decisions based mainly on these information. They also have to cooperate and each one should be aware of actions and environment's perception ensured by the other even if they are not in the same place. A shared situation representation between different involved actors is thus required. The aim of sharing a common situation representation between actors is to ensure situation awareness.

Semantic representation techniques (Sowa, 2000; Studer et al., 1998) and ontologies (Gruber, 1993) can be very helpful in order firstly to represent main situations entities and then to guide situation's perception sharing between actors (Nunavath et al., 2016). In this paper, we present our work done toward the definition of an application ontology to represent rescue operations in France as well as information and data flow between actors. This ontology will help to share common situation representations between different actors. It responds to situation awareness requirements, which necessitate having a global vision of main elements, aspects and dimensions in a given situation. This paper is divided in three sections:

1. Definition of rescue operations and actors involved in France
2. Situation awareness and rescue operations
3. Ontology for situation representation, a methodology to build it and related existing ontologies

RESCUE OF PEOPLE

Also called emergency rescue, *rescue of people* is one mission of medical services and firefighters. It consists in ensuring the safety of victims and patients by making them able to escape from a danger, sending adapted means and securing interventions sites, applying first aid gestures, and, finally, ensuring the evacuation and transportation to a suitable place of reception. In France, two main services are engaged in rescue operations and emergency care to the population: Emergency Medical Assistance Services (SAMU) and Departmental Fire and Rescue Services (SDIS) (Diederichs et al., 2006). A common referential has been elaborated in order to make responsibilities clearer and delimit missions (Comité quadripartite DDSC et DHOS, 2008). The mission of SDIS is to ensure protection, prevention and firefighting. They are also responsible of the rescue of patients or victims of disasters and accidents as well as their evacuation (Chehade et al., 2018; Comité quadripartite DDSC et DHOS, 2008). Whereas, the mission of SAMU is limited to providing medical assistance in emergency situations. This task can be divided into five subtasks: 1) Provide permanent medical listening, 2) choose and trigger responses according to the nature of the calls, 3) make sure the disponibility of the means of hospitalization adapted to the patient's or victim's condition, 4) prepare victims transportation using a private transport company or another public service and, 5) make certain the victim's admission. Other centers and services also participate in rescue operations. They are attached to the two previous ones and are responsible of receiving alerts and calls, transferring received calls to the good actor as well as ensuring a good information exchange and communication between SDIS and SAMU. Each SDIS possesses Health and Medical Rescue Service (SSSM) that assists, in particular, in emergency relief missions. Moreover, it has a Fire and Rescue Departmental Operational Center (CODIS) responsible for coordinating the activity of fire and rescue services. Add to that, it has one or several Alert Processing Centers (CTA), responsible for receiving, reorienting and processing requests and alerts. On the other hand, each SAMU has a Center of Receiving and Regulating Calls (CRRA) responsible of receiving alerts and calls and transferring them to a SDIS when there is a need of participation of this latter in a rescue operation. They are also connected to Mobile Service of Emergency and Reanimation (SMUR), which provides care for victims or patients whose conditions require, urgently, special medical care.

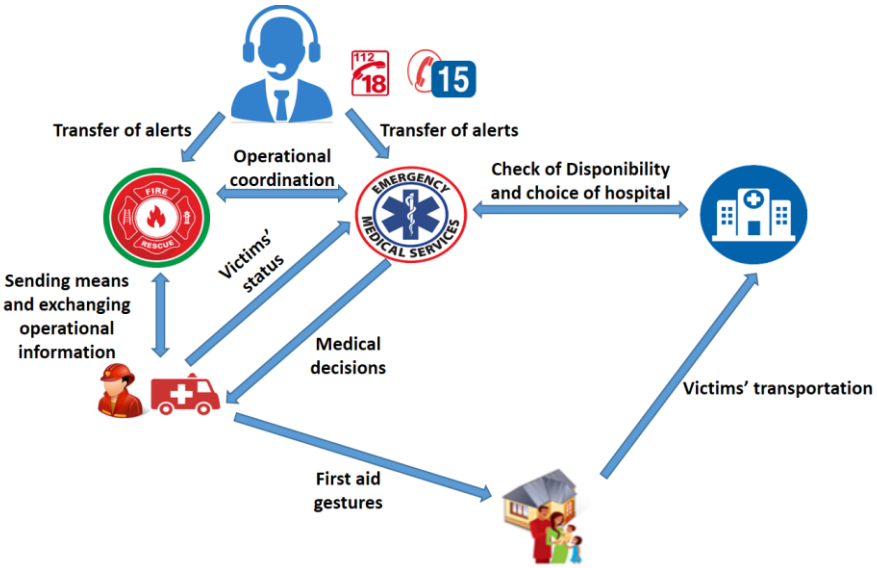

Figure 1. Involved actors and flow of information during rescue of people

An example illustrating the multiplicity of engaged actors during an operation is shown in Figure 1. In this example, we took the case of a medical rescue operation. As we can see, participating actors exchange a sheer volume of information such as operational information or victim's status. This plurality of sources and the important volume of exchanged information during an operation can lead to overcharge and make it challenging for actors to understand provider's intentions. Sharing situations' perception between actors can be important in order to solve this problem and ensure situation awareness. Ontologies can help in order to ensure sharing same perception of situations.

SITUATION AWARENESS

Nowadays, the term of situation awareness is widely used; it serves as a foundation of overall performance throughout many different domains, such as education, military operations, air traffic control, driving, search and rescue, and crisis management (Endsley, 2006). Endsley in (Endsley, 1995) defined it as *"the perception of elements in the environment within a volume of time and space, the comprehension of their meaning and the*

projection of their status in the near future". In addition, she defined steps to achieve human situational awareness and divided them into three levels. The first level of situation awareness is the perception of the situation elements, their status, their attributes, and their dynamics. After that, level two consists in the comprehension of the elements and the current situation. This comprehension depends on understanding the meaning of elements perceived in the first level as well as the relation between these elements and the objectives. Finally, the third level involves making predictions about the future status and actions of the situation elements based on the first two levels. From the above definition, we can say that situation awareness is the result of understanding of what is happening around us and is the basis for decision-making. Researchers in different areas have determined that expert decision-makers start with classifying and understanding a situation, and proceed then to decision making (Endsley, 2006; Kulyk et al., 2008). Furthermore, situation awareness has a vital importance in vital collaborative environments since it can improve team performance by improving the quality of made decisions (Endsley et al., 1995). Rescue domain is one of these environments.

Problems of Situation Awareness in Rescue Operations

In rescue operations, being aware of the situation is very important for cooperation of participating teams and decision makers in order to reduce negative impacts such as loss of a victim's life. However, ensuring a high degree of situation awareness is one of most difficult components of many jobs and one of the most vital and challenging duties for many rescue actors (Endsley, 2006). In fact, multiple actors coming from various organizations participate in a single operation as it was shown in Figure 1. These actors are from various backgrounds with distinct missions, experiences, expertises and goals. Thus, it is difficult for decision-makers to understand the situation perception of actors and other-decision makers. During a rescue operation, a large number of information is exchanged between actors during an operation. These actors have to interpret these information in order to develop an overall picture of the situation since their decisions are based on understanding the situation first. This interpretation can differ from an actor to another since they are from different backgrounds and are presents in different places. For example, a decision-maker has to make his/her decisions based on the received information from another actor and his understanding of the situation. S/he has to be aware of the exact situation because any misunderstanding of the situation can lead to its misinterpretation and thus to bad decisions and actions (Nunavath et al. 2016). Moreover, the dynamicity of situations and the continuous evolution of their status is another problematic in face of enhancing situation awareness. According to these problems, we decided to work on sharing a common situation representation and environment perception between different actors, which can lead to ameliorate awareness of the situations.

Related Work

In recent years, rescue operations and emergency responses have merged technologies of computer, communication, artificial intelligence, system engineering and knowledge engineering. These technologies aim to support the coordination, cooperation, communication and decision making of actors. Several systems and applications were developed recently in order to support information sharing and enhance situation awareness in critical and dynamic domains such as rescue operations and crisis management. Some researchers focused on studying situation awareness in robot-assisted rescue operations (Larochelle et al., 2011; Riley and Endsley, 2004) while others studied the effect of using mobile devices and tabletops in these operations (Bergstrand and Landgren, 2009; Engelbrecht et al., 2011).

On the other hand, research on ontology-based situation awareness has enormously increased during the past and current decades. Several ontology-based situation aware systems were successfully developed such as "AKTiveSA" (Smart et al., 2003) and "BeAware" (Baumgartner at al., 2010). An important number of studies confirm the importance of using ontologies in order to ensure this awareness (Kokar et al., 2009; Kokar and Endsley, 2012; Matheus et al., 2003). They also afford high-level ontologies to capture situation descriptions. These ontologies can be specified and contextualized in order to define more domain specific ones. Javed el al, (Javed et al., 2011) developed a system for enhancing shared and team situation awareness in emergency management domain by using ontologies. They created an ontology by extending the Core Ontology for Situation Awareness (Matheus et al., 2003). Authors in (Nunavath et al., 2016) proposed representing and sharing domain knowledge through domain model in order to support situation awareness. To do that, they developed an ontology in order to unify concepts between actors. However, their work was restricted to a specific kind of emergencies that is the fire building. Ashish et al, (Ashish et al., 2009) worked on situation representation in crisis management domain. The aim of this representation was to support situation awareness through the support of multiple applications such as monitoring, analyzing and planning. They based their work on event-based approach to represent the state and the evolution of crisis, the progress of response process, and the state of crisis site. To do that, they constructed an ontology and they proposed an *event management system* as a framework for representing

situations. However, it is limited since the representation depends on the occurrence of events and makes it difficult to represent all the required information such as the availability of resources or hospitals.

As discussed previously, we found that several ontologies have been defined in order to support situation awareness in crisis and emergency response domain. However, none of these ontologies covers all aspects, dimensions and elements in emergency management, which is necessary to ensure situation awareness and representation. Add to that, we did not find any ontology that aim to ensure situation awareness in traditional rescue operations. Based on this problematic, we propose to construct an ontology for representing situations during rescue operations. The principle objective of this ontology is to respond to situations awareness requirements. The first requirement of situation awareness is to have a global vision of a situation. In other words, this ontology take into consideration all aspects, elements and tasks in order to promote situations perception between different actors and to support situation awareness.

ONTOLOGY FOR COMMON SITUATION REPRESENTATION

As cited above, our aim is to build an application ontology related to rescue operations in France and to be more specific, to the organization, communications, responsibilities, flow of information and processes during a rescue operation. This ontology will be used for representing situations and sharing these representations between different actors. In this section, we give details about ontologies, their categories and the methodology we followed in order to construct the proposed ontology. This ontology will help to emphasize main elements to share between actors especially when operating and solving a problem. It will be used in communication and problem's perception support systems.

Definitions

Ontology is defined as *"an explicit specification of conceptualization"* (Gruber, 1993). Ontologies can serve on two levels: (1) as a vocabulary that makes use of appropriate terms to describe entities and agents of a domain, as well as interactions and relationships between them and (2) as a knowledge base for a particular domain. In rescue operations domain, ontology can grant a shared perception of a situation by actors. This reduces the chances of misunderstanding and the rescuers as well as decision-makers can fully understand the evolution of situations. Generally, there are three categories of ontologies. This classification depends on the level of generality of the ontology, and are separated into *application ontologies*, *domain ontologies*, or *generic ontologies*, also called *top-level ontologies*. Generic ontologies are domain independent. They contain general concepts such as action, space, time, object, event and many others that can be used in different domains. Examples of these ontologies are DOLCE defined by its authors as an ontology of particulars (Gangemi et al., 2003), the Suggested Upper Merged Ontology (SUMO) (Pease et al., 2002) and OpenCyc ontology (Matuszek et al., 2006). Domain ontologies are related to a specific domain such as rescue operations. They are specification of generic ontologies. A specification of domain ontologies can be done in order to construct application ontologies that describe specific concepts in a specific domain and specific associated tasks. Good examples of domain ontologies are that related to emergency response and crisis management domain (Li et al., 2008; Yu et al., 2008). Moreover, a huge number of application ontologies have been constructed from which we cite EDXL-RECUER (Barros et al., 2015), SHARE-ODS (Konstantopoulos et al., 2006), and EMERGEL ontology (Azcona, 2013) developed to support RESCUER (Villela et al., 2014), SHARE (Konstantopoulos et al., 2006; Velde et al., 2005), and DISASTER (Azcona, 2013; Schütte et al., 2013) projects respectively.

Methodology

To construct ontology, we adopted the methodology proposed by (Bachimont et al., 2002). This methodology consists of three main steps: Normalization, Formalization, and Operationalization. The advantage of this methodology is that it details steps to build the ontology starting from identifying units until having a complete ontology with rules and relations passing by structuring taxonomies.

Normalization

This step consists in identifying terms and units in a domain, extracting their meanings, giving complete definitions to these terms, and then expressing differences and similarities of each term or unit with respect to its parents and siblings. The result of this step is a first taxonomy of notions, which can be modified during the definition of properties and relations with other notions. This modification can occur in the Formalization step. In order to identify terms, a deep study of the domain is required. This study includes studying and analyzing the domain related documentation and conducting interviews with domain experts. Another key component in this step is to reuse other existing ontologies as much as possible since they may contain common concepts with their

definitions and relationships (Bouaud et al., 1995). To do that, we started by studying domain related documentation. In addition, we conducted an interview with a firefighter expert in France. The aim of this interview was to understand the organization and role of different actors and organizations. Questions turned on the different hierarchies of organizations, their roles and relations between them. We explored also the literature review about existing ontologies related to situation awareness and rescue operations domain.

During our literature review, we found and studied many ontologies defined in the domain of rescue operations. Some of these ontologies and not directly applicable in our case such as SHARE-ODS that does not cover all aspects in rescue operations (Konstantopoulos et al., 2006), while others are not publicly accessible. In addition, we found an ontology related to situation awareness that is the main interest of our work (Matheus et al., 2003). We also found several application and domain ontologies constructed in emergencies and crisis management domain. These ontologies cannot be used completely in our case because there is a difference between an ordinary rescue response and an emergency or crisis response. However, we used these ontologies as supports to borrow ideas and some defined concepts in order to build our ontology specific for rescue operations in France. In addition, many important concepts related to our particular context are not defined in previous ontologies. For instance, structures and actors organization, roles, dataflow, and many other concepts. From the ontologies that we found, we based our study on five ontologies that are the most applicable to our context. These ontologies are the emergency response ontology (Li et al., 2008), the emergency ontology (Yu et al., 2008), EMERGEL (Azcona, 2013), EXDL-RESCUER (Barros et al., 2015), and the situation awareness core ontology (SAW) (Matheus et al., 2003).

The first ontology we studied is the EMERGEL ontology (Azcona, 2013) defined in the context of the project "DISASTER" focusing on information exchange on a semantic level (Azcona, 2013; Schütte et al., 2013). It is an application ontology built to temporally describe a crisis or disaster situation. In order to construct this ontology, authors specified some generic classes defined in the top-level ontology DOLCE particulars (Gangemi et al., 2003). This ontology takes into consideration, **SPACE**, **TIME**, **OBJECTS** representing physical objects, **CONSTRUCTS** representing non-physical objects, and **ACTIVITIES** representing duties and missions to be achieved. Examples of concepts of this ontology are *Person*, *Equipment*, *Vehicle*, *Communication*, *SpatialPoint* and *Infrastructure*. The advantage of this ontology is that it covers different subjects in emergency response.

The second ontology we chose is the EXDL-RESCUER ontology (Barros et al., 2015) developed to support the project "RESCUER" designed to assist actors in emergencies by using crowdsourcing information (Villela et al., 2014). The aim of this application ontology is to construct a conceptual model corresponding to coordination and information exchange with other systems. It defines a group of message contexts and focuses on the type of exchanged data during an emergency. In this ontology, authors defined concepts correspondent to the type of exchanged messages such as Alert, MsgType, ResponseType, Info, etc.

The third ontology we consider is the emergency ontology constructed to enhance the reorganization of knowledge in decision-support systems (Yu et al., 2008). Authors developed this domain ontology by adopting the Activity First Methodology (Mizoguchi et al., 1995). This ontology contains four main classes: **EVENT** that can be a *disaster* or a *disease*, **SUBJECT** divided into *personal* and *actor*, **TASKS** consisting of *detection*, *prevention*, *rescue*, *evaluation* and *communication*, and **RESOURCE** that can be *artificial* and *inartificial*. Each class is also divided into several subclasses, each having many instances. We used this ontology since it gives the many general concepts that are in common between rescue operations and crisis management. This ontology has the advantage of covering multiple contexts in disaster response, ranging from events to tasks, passing by resources and subjects.

Moreover, we studied the 'Task Ontology' constructed in the aim of supporting the deployment of the evacuation planning system during emergencies (Li et al., 2008). This ontology defines a unique vocabulary usable by different actors and organizations regardless of the emergency nature. It defines four generic concepts that are Preparation, Response, Rescue, and Handling, divided each into several sub concepts. This ontology is restricted to the steps and tasks to achieve during an emergency. From this ontology, we reused some concepts that are in common with rescue operations such as communication, medical aid, and victim assistance.

Finally, we studied the core ontology for situation awareness (Matheus et al., 2003). Authors constructed this ontology as a reference for building ontologies for arbitrary situations. The generic concept defined in this ontology is **SITUATION** that is a collection of **SITUATIONOBJECTS**, **GOALS** and **RELATIONS**. SituationObjects represent entities in the world and they have attributes. One kind of SituationObjects is PhysicalObject. The main advantage of this ontology is that is takes into consideration the evolution of situations with respect to time and space. From this ontology, we reused several main concepts used for situation representation such as Situation, Time. However, we did not extend this ontology since it is a little bit specified to situation awareness and when we tried to extend it we were not able to cover all concepts and aspects in rescue operations. Another reason that prevented us from extending it is that there is a mix between Attributes, Relations and Properties and we cannot follow this mixing since we decided to use semantic networks for representations. Semantic Networks are one type of formalisms used for knowledge representation in which there is a difference and separation between an Is-a relation and other relations that are in general properties which makes inferences simpler (Sowa, 2008).

After studying the existing ontologies, the domain related documentation and conducting an interview with a firefighter expert, we identified notions. We gave then definitions and we classified these notions into a first taxonomy. We moved then to the next step: the ontology formalization.

Formalization

The second step is Formalization and consists in defining properties and relations between notions classified into the taxonomy obtained in the first step (Bachimont et al., 2002) and reorganizing this taxonomy in a way that it enables the addition of new concepts. At the end of this step, the taxonomy will become a true ontological tree and notions will become concepts with relations between them. To do that, we defined relations between concepts. However, we stayed with our relations at a high level without making relations between low-level concepts. The part related to relations and properties will be detailed in the Operationalization subsection.

Let us talk first about the main concepts and the final taxonomy of our ontology. First, we considered a rescue operation as an entity and we divided it into two generic concepts **OBJECTS** and **CONSTRUCTS** in order to make a first classification between different categories as it has been done in EMERGEL ontology (Azcona, 2013). These two categories represent physical and abstract defined in SUMO (Pease et al., 2002). We chose to follow the classification of SUMO since it is a top-level ontology that can ensure interoperability between lower level ontologies. **OBJECTS** are defined as a representation of physical objects in the real world. As shown in figure 2, the main category **OBJECTS** include three main concepts: *Environment, Persons and Material.* Each main concept contains several sub-concepts. *Environment* represents the context of operations. It contains Infrastructure that includes Ways, Ports and Buildings, Space that could be a Decision Space or an Intervention Site and Weather that is divided into Temperature, Wind and Humidity. *Person* represents people involved in a rescue operation. A person can be an Actor who is participating in an operation or a Victim who is being rescued. While in *Material*, we consider concepts concerning inartificial resources used during a rescue operation including Transport, Medical, Safety, Catering, Communication equipment and Technical equipment.

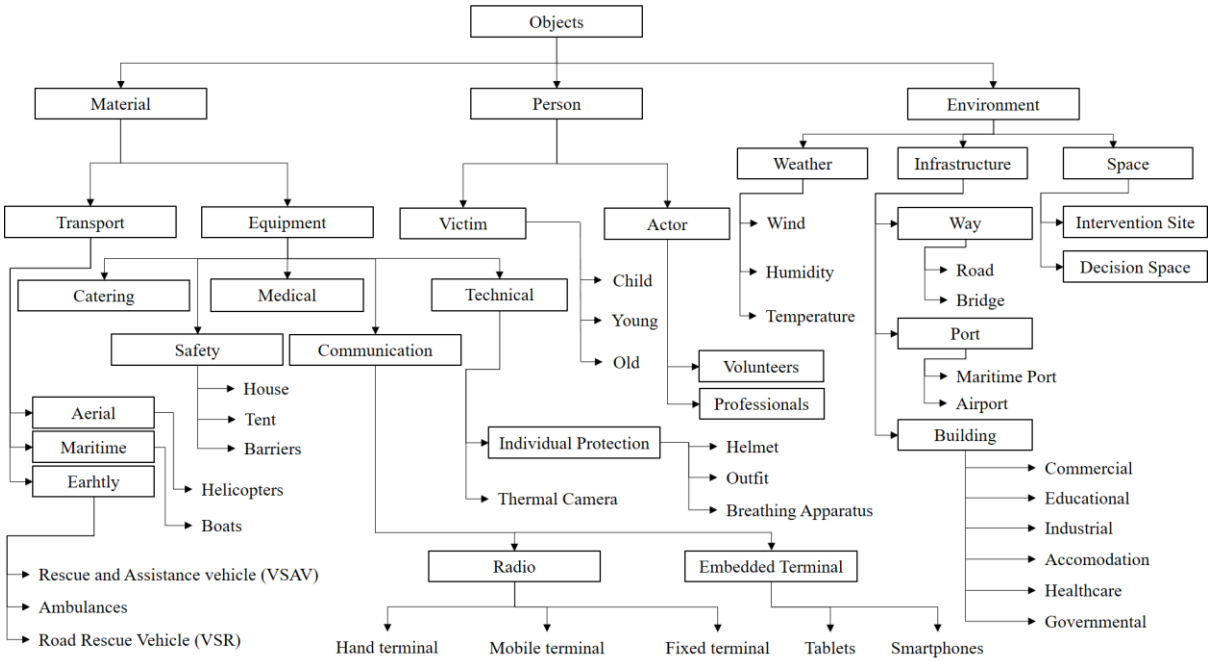

Figure 2. Hierarchy of Objects

On the other hand, **CONSTRUCTS** contain concepts related to non-physical objects. This category includes six main concepts that are *Tasks*, *Organization*, *Time*, *Characteristics*, *Data* and *Incident,* divided each into several sub-concepts as shown in Figure 3. *Organization* represents the organism involved in an operation. It can be a Military organization such as Army and Firefighters (SDIS) or a Civil organization such as medical services (SAMU) connected each to different centers. *Time* is used for sure since we talk about dynamic operations and situations and it contains Timeline. *Characteristics* are used to describe some objects and constructs. They are divided into main categories: Qualitative and Quantitative Characteristics. For example, Type and Form can characterize the exchanged Data. It can be a report in form of text. *Data* represents the exchanged information before, during and after an operation. It informs on situations and their evolution as well as occurring events during a situation. *Incident* represents the type of situation behind the intervention. It can be a disease, an accident, a fire or a natural event causing victims. Finally, *Tasks* represent the required missions and duties to ensure

effective operations. These tasks covers three main phases: 1) Preparation phase including tasks to be taken before an operation such as personal training and resources maintenance, 2) Response phase including tasks to be achieved during the operation such as Communication, Coordination, Cooperation and, 3) tasks to be taken at the end of the operation such as investigation, reporting and supplying social assistance to the victims. Due to a lack of space, we decided to represent the concepts related to Tasks in a separated figure of constructs as shown in Figure 4.

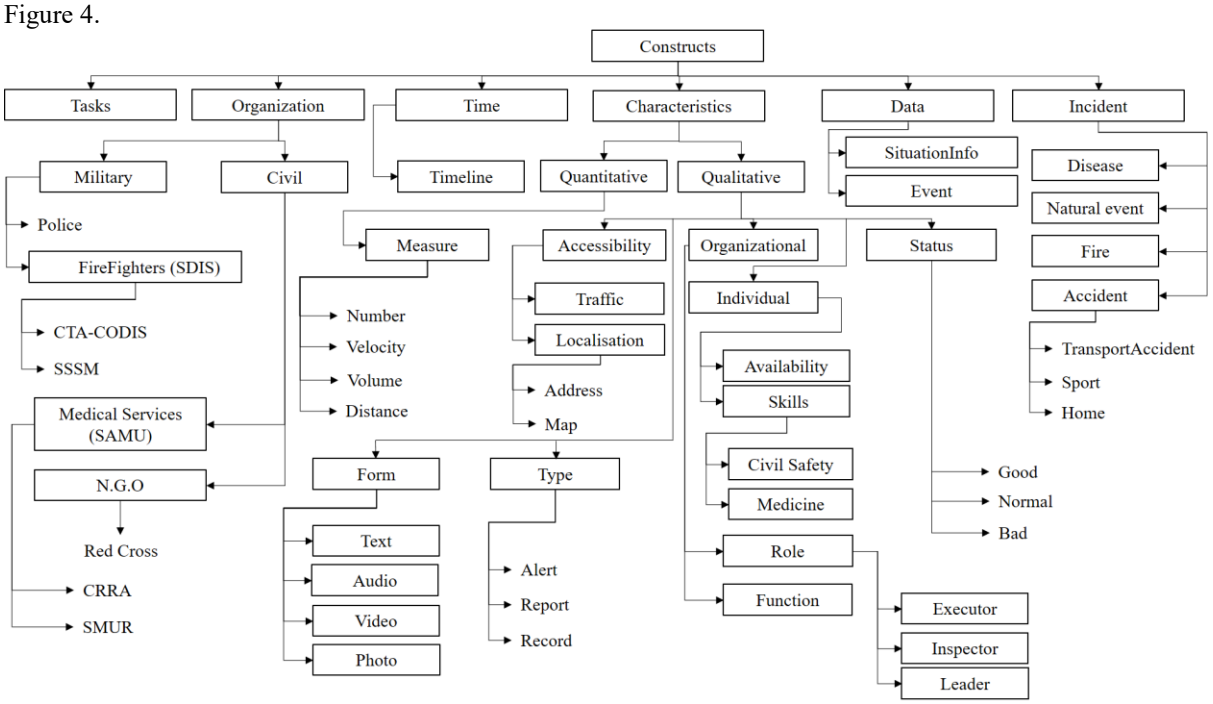

Figure 3. Hierarchy of Constructs

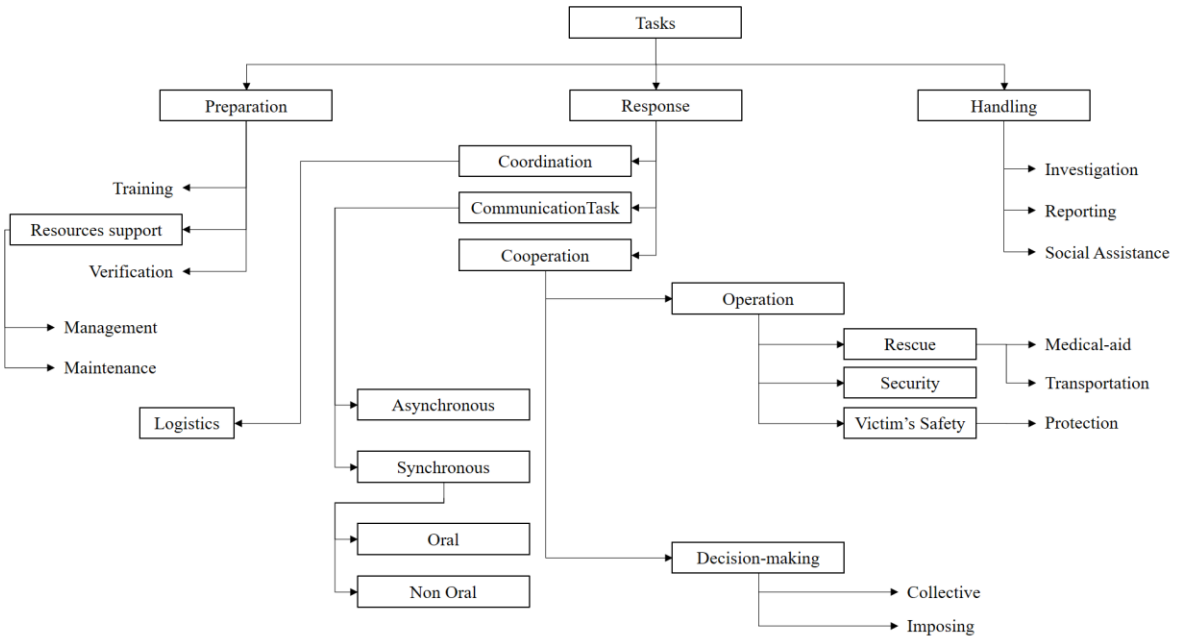

Figure 4. Tasks to be achieved

Finally, we moved to the last step: the Operationalization.

Operationalization

The last step consists in implementing the ontology in a system using a formal representation language. The result is called computational ontology (Bachimont et al., 2002). To do that, we used Protégé 5.2 (https://protege.stanford.edu/products.php#desktop-protege), which enables building OWL-based ontologies (Musen, 2015). The advantage of using Protégé is that it enables building ontologies, defining rules and doing

required inferences. In this step, we defined our concepts and sub-concepts as classes and sub-classes. Figures 5 and 6 show the classes defined under **OBJECTS** and **CONSTRUCTS** respectively.

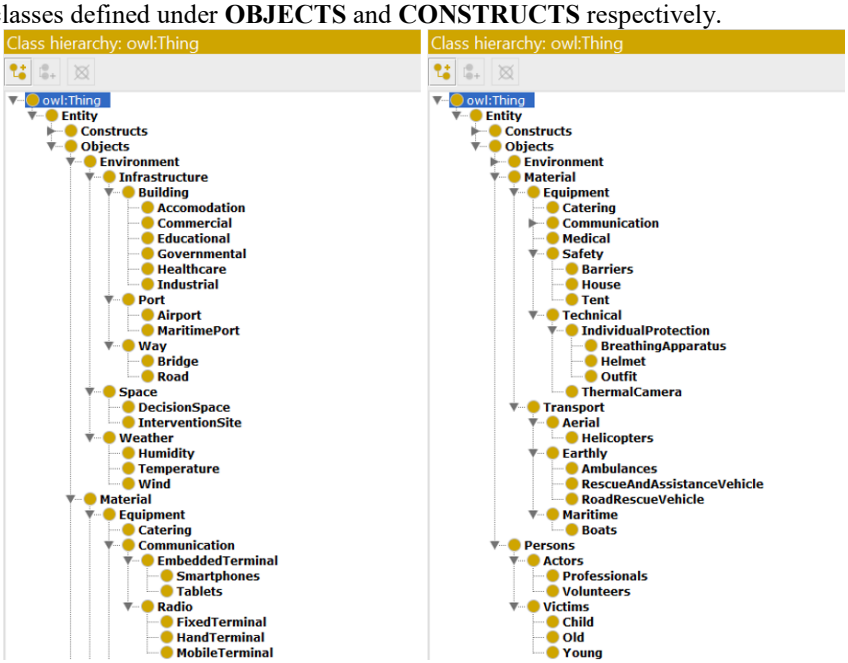

Figure 5. Classes of Objects

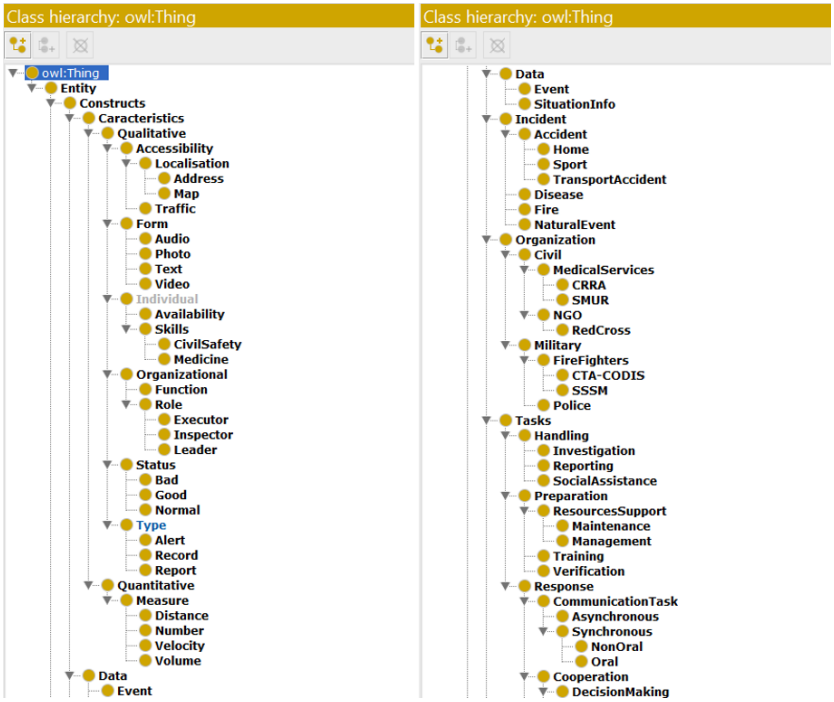

Figure 6. Classes of Constructs

After that, we identified properties of concepts. These properties are the relations between concepts. Figure 7 shows an example of properties defined for the concept Actors.

Figure 7. Example of Properties

After finishing the taxonomy and identifying relations between concepts, we represented the obtained ontology using graphs. These graphs show different concepts and relations between them based on the defined properties. Figure 8 presents an extract of a graph showing different relationships that exist between some concepts of the ontology.

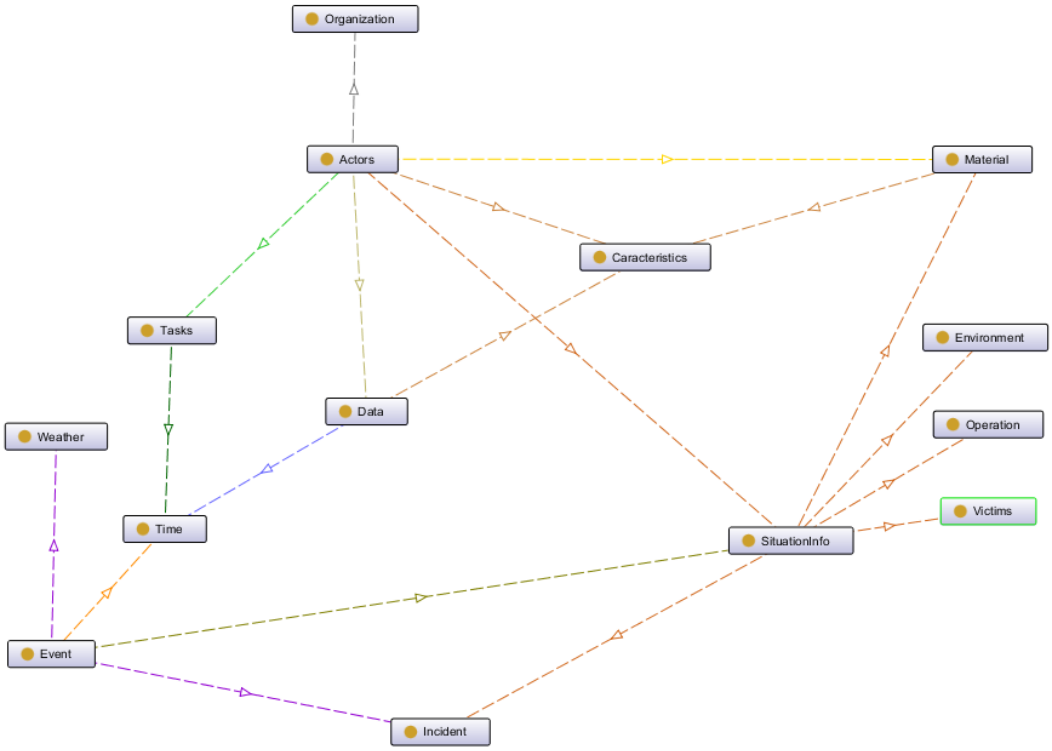

Figure 8. One graph of the implemented Ontology

In this example, we can see that an Actor is a part of an Organization. S/he has Characteristics that can be Individual such as Availability or Organizational such as Function. This actor uses Materials having characteristics too such as the state of the material. S/he transmits Data that is communicated on Time and informs on SituationInfo, which contains information on Operation, Material, Victim, Environment and Incident. An actor does also other Tasks that are scheduled on Time. On a certain Time, an event can occur and affects SituationInfo. This event can be a change in Weather or a sudden Incident.

The work done represents the methodology we adopted and different steps to construct the proposed Ontology. To do that, we identified notions. We gave then definitions and we classified these notions into a taxonomy. After that, we identified properties and relations between concepts and we reorganized our taxonomy. Finally, we implemented this ontology in a computational language OWL using Protégé 5.2 and we represented it using conceptual graphs. As a future step, we look forward to evaluate the developed ontology and submit it to an ontology catalog. The aim of building this ontology is to support situation awareness in rescue operations. It will be used not only for communication and situation's representation but also to help actors to build the relations between elements by using an inference system.

CONCLUSION

Like several dynamic and complex domains, ensuring a high level of situation awareness in rescue operations is difficult. This difficulty is caused by many factors such as multiplicity of actors, dynamicity of situations and difference in situations' perception between a person and another. All these factors and many others can affect actors' performance and decision-making. To respond to this problematic, we constructed an application ontology related to rescue operations in France. It will be used for ensuring common situation representation between actors. This representation helps to unify situations perceptions and understanding between different actors involved in rescue operations and then to enhance situation awareness. It helps also to display important elements in a situation, their evolution and the occurrence of events, which is the basis of situation awareness. To construct the ontology, we adopted a methodology consisting of three steps: Normalization, Formalization and Operationalization. We also studied domain related documentation and several domain existing ontology. After that, we implemented this ontology in OWL language using Protégé 5.2. However, our ontology is not evaluated yet since it is our first study in this aim.

As a future work, we will detail this ontology and instantiate it based on expertise collection and modeling. Thus, we will conduct more interviews with actors from different organizations involved in rescue operations. After that, we will test it in real cases, evaluate it and submit it to an ontology catalog. Finally, we will study the design and implementation of a knowledge based system that will support decision-making and situations understanding in rescue operations environments by exploiting the constructed ontology. This work will include naturally a study about the confidentiality and security of exchanged information.

ABSTRACT

This paper reports on the added value of combining different types of sensor data and geographic information for fire incident management. A survey was launched within the Belgian fire community to explore the need of added value and the use of new types of sensor data during a fire incident. This evaluation revealed that people are visually-oriented and that video footages and images are of great value to gain insights in a particular problem. However, due to the limited available time (i.e., fast decisions need to be taken) and the large amount of cameras it is not feasible to analyze all video footages sequentially. To solve this problem we propose a video summarization mechanism and a video highlight selection tool based on the automatic generated image and video tags.

Keywords: machine learning, video data, filtering, crisis management, user-evaluation

1 INTRODUCTION

During the first minutes of an intervention, the incident officer needs to take fast and appropriate decisions with very limited information. However, the scene layout, the structure of the building, the fire dimensions and position, the hazardous materials present, and the status and the position of victims, are factors that affect the initial strategy and tactics.

Currently, there are two main communication tools for fire incident management: a broadcast channel for voice communication and a second textual channel for status updating. However, from a psychological perspective it is proven that our brain is better at processing visuals than text [1]. Our brain can process an image 60 000 times faster than a piece of text. On average, when a person sees a particular image for the first time, it takes 113 milliseconds to process the information. In that sense it is advisable to focus on the development of image related tools to facilitate the incident officers instead of improving the existing auditive or textual communication tools that have problems with reliability (e.g., connection-loss in concrete buildings) and interoperability.

To generate the needed visual information we can exploit the increased performance and quality of fixed security cameras and handheld devices such as smartphones and tablets. It is important, however, that the video footage is captured in the most appropriate way for visualization to a fire incident manager. Furthermore, the sensor input of the fixed and handheld cameras can be streamed to the incident commander to have an overview of the incident scene. However, it is not possible for a person to analyze all the video streams in a sequential manner due to the cognitive disability. There is a need for a video summarization mechanism that filters out the redundant and unnecessary frames, while preserving the distinctive frames.

Besides the visual camera information there are other sensor types (e.g., temperature indications, CO levels) with valuable information for the incident commander. Visualizing too many sensors will lead to enacted sensemaking where an individual will select unconsciously some parts of the data to make their decision. Especially in critical or stress situations this can lead to overshooting or undershooting of the situation. To solve these issues the firefighting community should get aware of the opportunities of web dashboards to quickly and easily create reports and data visualizations [2]. The core idea of dynamic dashboards is to efficiently display data in such a way that it can enhance user insight into the data. An example is the fire probability calculation and visualization for residential regions by Netage. Similarly, the Moses project explored a dashboard system for seamless localization, employability and health status monitoring (e.g., heart rate, air consumption) of firefighters.

The remainder of this paper is organized as follows. Section 2 presents the specific information needs of first responders. Furthermore in Section 2 the data insights from the questionnaire are discussed more thoroughly. Section 3 goes more in detail into the video summarization process. Subsequently, Section 4 proposes the possibilities for video and frame retrieval. Next, Section 5 discusses the results of our proposed methodology and Finally Section 6 gives some conclusions and suggestions for future work.

2 FIRST RESPONDERS INFORMATION NEEDS

2.1 Visible and cognitive disability

Biologically, human beings have psychological restrictions in terms of observing and processing information. Furthermore, an individual can only process a limited amount of simultaneous stimuli. Ungerer et al. [3] stated that a person can only process a fraction of the information in a conscious way. According to his theory, each second 3 up to 5 visual and 3 auditive or tactile inputs can be processed simultaneously. Schaub et al. [4] on the other hand denoted that a human is only capable of processing 7 concurrent signals.

The head of operations and firefighters in general have to work in difficult, often unknown contexts, where there is an increased stress level. Subsequently, due to the increased level of stress there is a higher chance of reduced cognitive ability. Despite the dynamic and difficult character, decisions need to be made without detailed investigation or analysis. In general the fire scene is a complex situation due to the following factors:

- A comprehensive list of 'unknown' variables (e.g., number of people present, evacuation necessity, fire behavior, fire expansion and building contents);
- Variables that affect each other (e.g., ventilation openings will change the fire growth);
- Variables that change in time and space without being transparent or predictable.

Due to the risk of reduced cognitive ability and the psychological restrictions there is a need for a smart, adaptive visualization application. The time first-responders spend on gathering static and volatile situational information from affected people as well as from responsible persons at the emergency site can be reduced if they have access to the needed information. The following subsections will discuss the related work for fire incident visualization and the subjective criteria for data importance rating.

2.2 Related work

Nunavath et al. identified the information needs for first responders from a literature review, fire drills and interviews. Prioritizing of information items is needed for different stages of building fire emergency response operations and to ensure a maximum of 7 concurrent decision signals. The most commonly mentioned information item in the work of Nunavath et al. is the building related information, which includes important information about the building layout plans, hazardous material location, resources location, floors, and rooms. Furthermore, the other most commonly mentioned information item was fire related information such as color, location and condition of the fire which can be derived with the techniques of Beji et al. [5] and Vandecasteele et al. [6]. Subsequently, Li et al. [7] investigated the information sources used in current practice (year 2013) and those desired to be used in the future. Furthermore, Li et al. considered the information items needed by first responders and the availability of technological solutions to obtain them in the United Stated. Furthermore, Li et al. mention that there are three timings where data should be delivered: before arrival, when arriving at the emergency scene and during the attack and the mitigation. In an automatic framework these three states should also be considered and evaluated. Hamins et al. [7] created the smart-firefighting roadmap and although, the roadmap gives some directions for further research, currently only limited implementations are available. This paper proposes some technological building blocks to start with 'smart-firefighting'. Finally, emergency

responders have different roles to perform, different tasks to handle, and different modes to communicate, which lead to an insufficient view of the complete emergency situation at the emergency site. In that respect Nunavath et al. [8] presented a conceptual domain model. Their model consists of four components: event component, actor component, objective component and building component. Each component contains several information resources and all components capture the complete building fire emergency response. However, as stated before it is not feasible to process all components sequentially and filtering and summarization mechanisms will be necessary.

2.3 Subjective criteria and discussion

Within the Belgian fire community, a survey was launched to explore the necessity and the use of new types of sensor data during a fire incident. This survey can be seen as an updated version of to the work of Li et al. The questionnaire was sent to all Flemish firefighting communities and input was asked from all hierarchical levels (i.e., strategic, tactical and operational). Furthermore, we targeted a balance in the ratio of volunteer and professional firefighters that filled in the inquiry. 21 different questions were asked and the first question was: ”What kind of data should be available during an incident?”. From the survey results it was remarked that the thermal imaging device (95,9% of respondents) is the most informative device used by firefighters, followed by the explosion warning device (65,8%) and the visual camera (65,7%). In the questionnaire it was pointed out that the more information available during an incident, the higher the fire crew score their situational awareness. However, as stated earlier in this section, there is a maximum of 7 simultaneous inputs that can be used. The most important features are the location of the fire source, the amount and the position of the victims and firefighters, and the structure and lay-out of the building.

Subsequently, in the questionnaire, some questions were related to the priority of the data. The camera footages, the thermal camera footages and the surrounding temperature were pointed out as prior. It is important to remark that this should be re-evaluated within a couple of years as most of the other sensor and data values are currently not available during an intervention and the decision makers are not trained to use certain variables. Furthermore, the questionnaires indicated that they allow a maximum processing time (i.e., delay to receive the first information) for the video streaming of 1 minute.

3 VIDEO SUMMARIZATION

As indicated in the questionnaire, decision makers want to have access to visual and thermal video streams. As it is not possible to analyze the complete history of a CCTV camera and it is not possible to investigate several cameras simultaneously, there is a need for video summarization. Video summarization can be classified into two types, namely static video summarization and dynamic video summarization. Static summarization results in a set of keyframes that best conveys the overall idea of the video. In most cases, keyframes are representative frames that could identify either the beginning or end of a scene transition in a video sequence. The number of resulting keyframes can vary as per the setting. Contrary, dynamic summarization collects small chosen fragments of the original video and arranges these fragments to obtain a new version of the video (i.e., logical story units).

Depending on the use case (e.g., fire incident, hazard materials incident) and the commanders function (e.g., evaluating the evacuation, investigating the structural damage or making strategic decisions for the intervention crews) different static or dynamic fragments will be indicated as important. Furthermore, personalized interaction will be necessary to learn the visualization needs based on the incident type, the operational function and the geographical location. The main focus of the following sections is on the static summary generation as it is not feasible to analyze several logical story units sequentially in a fast manner.

A schematic overview of our proposed indexing strategy is given in Figure 1. First the different video sensors are captured. Secondly, the video summarization selects a set of representative keyframes. Thirdly, for each keyframe the scene content understanding is performed and indexed. Finally, the user can visualize and query the set of keyframes on a semantic and visual level.

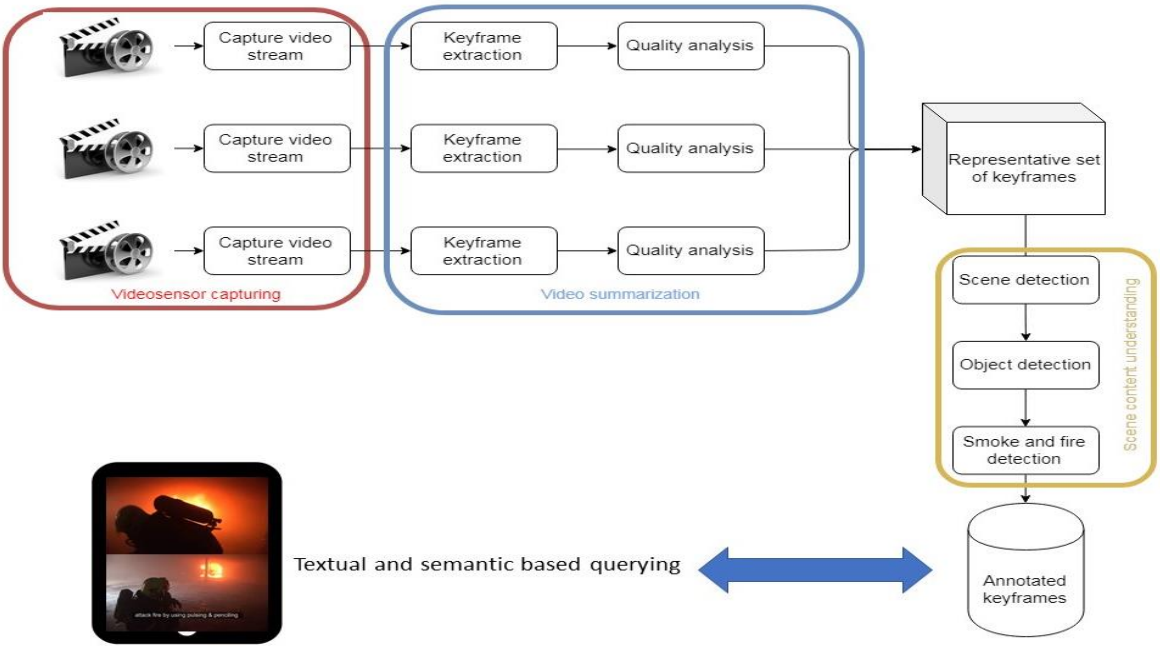

Figure 1. Schematic overview of the video capturing, summarization and content understanding process.

In order to visualize the relevant keyframes in a dashboard system and to decrease the computational cost of subsequent video processing tasks it is important to reduce the amount of video data by filtering out redundant and unnecessary frames, while preserving only those frames, distinctive and essential, to capture the entire video content. Furthermore, presenting the end-user with a limited list of representative keyframes instead of dynamic video fragments, improves their exploration, understanding and search process. Therefore the main focus of the following sections is on the static summary generation. The automated summarization of video content into representative keyframes, however, is a challenging problem due to the rapid change in lightning, viewpoint, and scene. In order to cope with these issues, we present a novel solution to extract, cluster, and filter meaningful keyframes. This summarization process consists of three major steps:

- The video summarization converts the video into a set of representative keyframes. All the keyframes represent one single video shot. These shots are detected using a grid-based histogram detection method and within each shot no-reference keyframe quality analysis is used to select the best frame within the shot as proposed by Vandecasteele et al. [9].

- The number of keyframes is reduced by clustering visually similar frames, while preserving as much as possible of the entire content.

- A limited set of representative keyframes is given to the object and scene retrieval algorithms to generate meaningful tags. This is out-of-scope of this paper, but more details can be found in the work of Vandecasteele et al. [10].

Much research has been done in the area of video summarization (i.e., keyframe retrieval). Ajmal et al. [11] give an overview of the different techniques and classification methods that are commonly discussed in literature, i.e., feature classification [12], clustering [13], shot selection [14] and trajectory analysis [15]. In the following subsection the grid-based histogram shot detection approach is proposed.

3.1 Shot detection

Compared to the state-of-the-art temporal shot segmentation algorithms [16], the proposed local histogram analysis on a 5-by-5 grid copes better with fast camera movements, zoom gestures, and similar scene discrimination (i.e., problems that arise in handheld video analysis. The proposed algorithm consists of 4 major steps:

- A conversion to gray scale frames;
- A rasterization (splitting) of each frame in a 5-by-5 grid and a calculation of the histogram for each cell in the grid;
- A correlation based temporal analysis of each histogram;
- A calculation of the amount of changed cells. If this is larger than an experimentally defined threshold the transition is seen as a shot.

The histogram based shot detection has an outstanding performance on detecting hard and gradual shots, which makes it suitable to process all kinds of video content (i.e., handheld and CCTV data streams). The only limitation is that it does not handle similar scenes very well, but this is solved in Section 3.3. In order to cope with gradual shots, like blends and fades, we also count the amount of frames that have been passed since the last detected transition. If that amount is too low and a new transition is found, we consider it to be the same transition. This way we successfully manage to detect both gradual- and abrupt scene transitions.

3.2 No-reference keyframe quality analysis

Currently, multiple image quality metrics are available [17]. However, most of them need a reference image or they are not suitable for real-time quality measurement. In our methodology, based on the detected shot boundaries, the frame with the highest quality within each shot is chosen as a representative keyframe. The quality is estimated using a weighted set of three no-reference quality metrics that are suitable for real-time images as proposed by Vandecasteele et al. [9]. The proposed no-reference exposure, contrast and sharpness metrics are evaluated on a variety of video footages.

3.3 Similarity clustering

In general, a video scene consists of many shots that are visually similar (i.e., taken in the same scene setting). On the one hand, removing these redundant and unnecessary frames improves the summarization visualization on a small screen or on a tablet. On the other hand, clustering the similar keyframes will decrease the time for tag generation i.e., an automatic annotation can be performed on all object representations within the same cluster.

The clustering process is done in three steps. First, we perform a global feature extraction with CNN based learned features as proposed by Zagoruyko et al. [18]. Subsequently, we do a feature reduction by using the principal component analysis (PCA) technique. Finally, we use k-means clustering with the L2-distance of the reduced features of the keyframe. Furthermore, it is important to remark that if the amount of clusters is too high, redundant keyframes will appear. On the other hand, if the amount of clusters is too low, outliers (i.e., very unique keyframes or single scene shots) will not be shown.

4 VIDEO AND FRAME RETRIEVAL

The set of keyframes (from different camera viewpoints and camera sources) could still be too versatile and to improve the fast exploration two additional mechanisms are proposed: (I) an automated importance scoring based on the scene content and (II) a semantic web-based querying tool as proposed by Verstockt et al. [19]. Furthermore, the tags that are generated from the scene understanding process are used as input for both mechanisms. Figure 2 gives a schematic overview of the scene content understanding framework.

4.1 Automated scene content understanding

4.1.1 Scene type detection

Over the last decade, several literature studies have already shown impressive results regarding the classification of indoor and outdoor scenes [20], and more recent studies have added the ability to predict more detailed attributes, such as the scene type, e.g., kitchen, living room, or bedroom. Zhou et al. [21] constructed a new scene-centric database named Places, containing over 7 million labeled pictures of scenes distributed over 365 classes. Currently, the state-of-the-art systems for scene classification are based on CNNs, mostly trained using a transfer learning approach on the ImageNet models [21]. For the scene classification task the current highest top-5 accuracies achieved on this Places dataset are 85,08 percent with the RESNET architecture [22].

4.1.2 Visual and thermal object localization

Despite the broad application of handheld thermal imaging cameras in firefighting, its usage is mostly limited to subjective interpretation by the person carrying the device. As remedies to overcome this limitation, object localization and classification mechanisms [23, 24] could assist the fireground understanding and help with the automated localization, characterization and spatial-temporal (spreading) analysis of the fire. An automated understanding of thermal images can transform the conventional knowledge-based firefighting into sensor-driven based firefighting. In this paper, transfer learning is applied to multi-labeling convolution neural network architectures for object localization and recognition in monocular visual, infrared images. More details are given in the work of Vandecasteele et al. [25].

4.1.3 Room configuration estimation optimization

Intuitively, individual predictions of objects and relationships can benefit from their surrounding context (i.e., the probability to predict a bed, given that he room is a sleeping room is much higher compared to a kitchen). In our work we optimized the scene classification results by exploiting the object detections. First we learned the object co-occurrence from the ObjectNet3D dataset. Some preprocessing was necessary to remove the objects that appear only once in the dataset. Furthermore the classes *'floor', 'ceiling'* and *'wall'* were removed from the object dataset as they are not descriptive for a specific room type. The object co-occurrence will assist the thermal object detection by indicating the objects that are related to the detected classes. For example if a chair is detected, there is a 60 percent chance that there will be a table in the same scene. This can then be incorporated in the fire load calculation.

4.1.4 Fire and smoke characteristics

Video based fire detection and analysis with cameras has been discussed several times in literature over the past years [26]. Different features, such as color, pixel disorder, wavelet analysis are combined with simple linear classifiers or with more advanced deep learning mechanisms [27]. However, the focus in literature was mainly on the detection, the propagation of the smoke, the height of the smoke layer or the visibility for example, were investigated less. Within our framework, the smoke and fire probability are calculated with the techniques of Frizzi et al. [27]. Finally, the visibility on each frame is calculated with the techniques of Vandecasteele et al. [6], the visibility is thereby scored between High-visibility (5) up to No-visibility (0).

4.2 Importance scoring

The content of the scene is important because it includes useful information that attracts the viewer (e.g., the decision maker). Rationally, the objects and locations that are shown for a longer period of time in the handheld video have a higher chance to be of importance. It is important to remark that further user-driven evaluations will be necessary to prove this statement. Furthermore, since there are tags pertaining to all the frames it is necessary to alter them and to preserve only the most informative words that define the main semantic components. This is done as follows. First the tags are preprocessed by tokenization and part-of-speech tagging. After the extraction, the saliency score for each subset s is calculated according to the words they contain. In combination with the similarity score (e.g., two visualized keyframes should be sufficiently dissimilar), the importance scoring is used to automatically present a couple of keyframes to the decision makers. Still, user evaluations and annotations could help improve and validate the automated video selecting. Besides the automated selecting of the keyframes, we propose a semantic querying system that allows to manually find the most related frames.

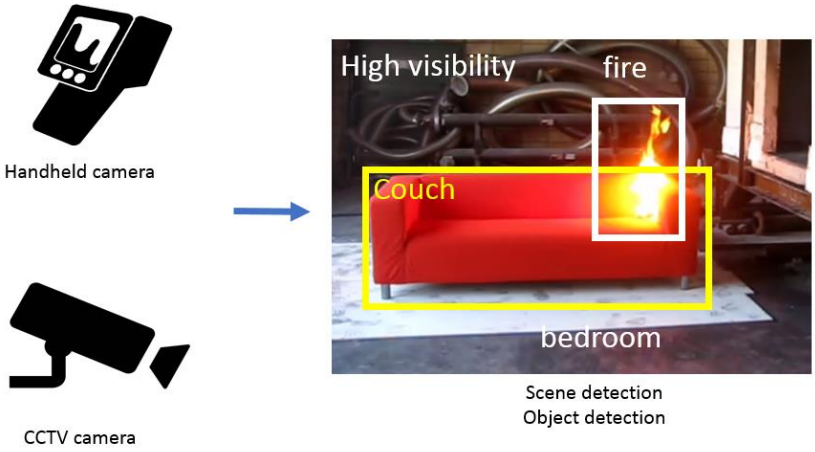

Figure 2. Automated scene content understanding from video footages (e.g., handheld and CCTV cameras).

4.3 Semantic based querying

The web-based tool that could be used to explore the enriched (i.e., the annotated) keyframes is a metadata filtering and clustering service. The querying mechanism can be activated in three different ways:

- A textual input where the user can type the tag that he wants. In case the input is not in the list of predefined tags, the tag with the closest path distance (i.e., the highest similarity) according to Wordnet [28] is selected. However, other semantic distance metrics can easily be integrated.

- A drop-down list with predefined tags (e.g., places, fire-related topics, evacuation keywords), where the user can select the necessary tags (e.g., show all the keyframes annotated with kitchen and fire).

- An interactive, hierarchical ontology visualization where the user can select and easily search for the best matching tags. Furthermore, if a tag on a higher semantic level in the hierarchy is selected, all the underlaying and related tags are selected (e.g., if the tag opening is selected, the tags door and window are likewise selected).

> *An ontology is a representation, formal naming, and definition of the categories, properties, and the relations between the concepts, data, and entities over one or more domains.*

The semantic similarity is currently calculated based on the ontology of Zhang et al. [29], but new ontologies can easily be integrated. Zhang et al. proposed a street scene ontology for qualitative understanding of outdoor scenes. This is valuable for large multi-disciplinary fire incidents as it contains building elements (e.g., floor, window, wall, column), but also construction, land and terrain elements. Some alternative ontologies that can be used are, for example, the work of Kadar et al. [30] who created a database of 100 scene categories (e.g., classroom, bathroom, bedroom, alley) derived from human vision. This ontology could be valuable in indoor firefighting scenarios. Jaoa et al. [31] created an ontology on how scene situations progress in time. The FIRE ontology was created in order to represent the set of concepts about the fire occurring in natural vegetation, its characteristics, causes and effects. Similar concepts and effects are found in indoor fire situations. Poveda et al. [32] created an ontology for designing and validating emergency plans and the sensor, users and furniture connections are highly valuable for our framework.

5 RESULTS AND DISCUSSION

Murugan et al. [33] proposed various methods for video summarization for surveillance applications still latter discussion was given on the exportability of the video footages. Within this Section a subjective evaluation is performed on our proposed mechanisms. Video footages from multidisciplinary incidents are taken as input for our evaluation. Figure 3 gives a schematic overview. First the video footages are selected (currently, this is a manual task, but the integration of online IP-cameras should be easily possible). Secondly, the keyframe extraction, similarity removal and no-reference analysis is used to select the most representative keyframes. Thirdly, the semantic tag understanding process is elaborated to automatically generate tags for each frame. Finally, the exploration and selection tools are used to get a fast overview of the current state of the incident and the actions.

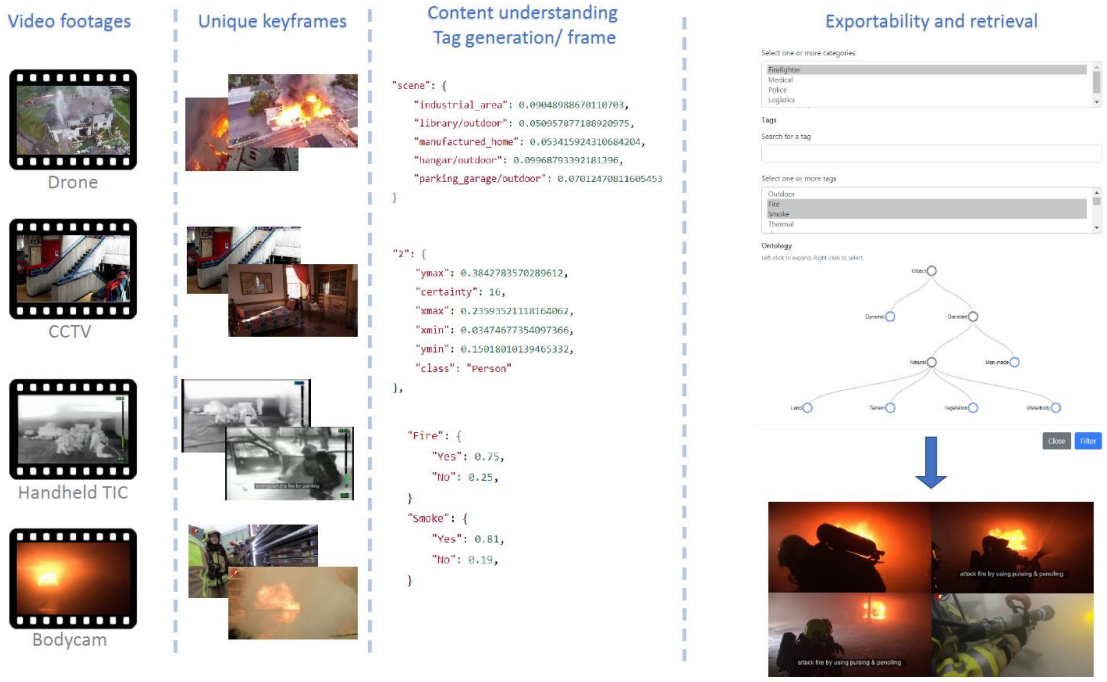

Figure 3. Schematic overview of the video footage analysis framework, first the footage linking, secondly the keyframe generation, thirdly the content understanding tool and finally the frame retrieval tool.

Some improvements for the tag generation are the classification into categories, for example an additional classifier into medical, police, fire service. Furthermore, it is valuable to add the source of the video footage as a tag (e.g., handheld camera first crew, TIC second crew, drone footage). Finally, as indicated earlier in this section, the video summarization and retrieval building blocks require further user-driven evaluations. Still the feasibility of the proposed building blocks is shown in this paper. Real-fire experiments that are recorded from different point-of-views and with different resources are highly valuable for further evaluation and improvement.

6 CONCLUSION

This paper presented the user-needs and data restrictions specific for fire incident management. The insights were gained through the analysis of a questionnaire launched in the firefighting community of Belgium. This evaluation revealed that people are visually-oriented and that video footages are great to gain insights into a problem. Still, people can only process 7 image inputs simultaneous and for that reason, the video summarization framework, consisting of shot detection, frame quality and similarity analysis was proposed. Subsequently, in order to facilitate the video search process, the video and frame retrieval mechanism was clarified and semantic tag based querying on an existing ontology map was initiated. Future work will focus on video analytics to perform person recognition, crowd analysis(e.g., detecting the amount of people and their behavior) and anomaly detection on global scale. Maybe in the future, even before a fire incident will occur the video analysis will notify suspicious behavior and faster interventions could reduce the economic and material damage. Subsequently, more user-evaluations and usability testing will be necessary to make a complete product out of our proposed framework. Therefore the next step is to organize an usability evaluation using the System Usability Scale (SUS)[34]. Finally a closed field test (limited set of users) and a open field test will give insights in the required development steps.

ABSTRACT

During unforeseen situations of crisis such as disasters and accidents we usually have to rely on local news reports for the latest updates on casualties. The information in such feeds is in unstructured text format, however, structured data is required for analysis and visualization. This paper presents a system for automatic extraction and visualization of casualty information from news articles. A prototype online system has been implemented and tested with local news feed of road accidents. The system extracts information regarding number of deaths, injuries, date, location, and vehicles involved using techniques like Named Entity Recognition, Semantic Role Labeling and Regular expressions. The entities were manually annotated and compared with the results obtained from the system. Initial results are promising with good accuracy overall. Moreover, the system maintains an online database of casualties and provides information visualization and filtering interfaces for analysis.

Keywords

Casualty, information extraction, news articles, casualty data visualization

INTRODUCTION

This paper proposes a system to extract casualty related information from news reports of any incident. The incident may be any situation of crisis, disaster, accident or attack that involves casualties - deaths and injuries. In particular, news of road accidents has been used for experimentation in this work.

For the past two decades, online news has been one of the most reliable and real-time source of information. This information when transformed into organized knowledge can have great significance. Road accidents are one of the leading cause of casualties in Nepal. A total of 95,902 crashes, 100,499 injuries and 14,512 deaths were recorded by traffic police over the period of 2001-2013 (Karkee and Lee 2001-2013). The dataset[1] maintained by the Traffic Police provides statistics of a number of accidents, fatality, serious accidents and

[1] Traffic Police Annual Accident Description, https://traffic.nepalpolice.gov.np/index.php/news/traffic-activities/425-annually- accidental-descriptions

normal accidents every fiscal year.

The existing Accident Database System maintained by the Traffic Police suffers from many deficiencies like under-reporting, inconsistencies, inadequate resources and, time-consuming data collection. Moreover, though government records regarding accidents are the most reliable source, the information is not publicly available in many countries, including Nepal (Bhandari et al. 2017). In situations of crisis, such as road accidents, immediate information is mostly reported by local news agencies only. Hence, local news feeds have been chosen for casualty information extraction in this work. Moreover, the extracted information is collected in a database and made available to the public via an online system with analysis and visualization interfaces.

Relevant entities describing the incident such as death and injury, the location of the incident, vehicle involved in the incident, types of vehicles involved, date and day of occurrence are extracted from news feeds. The extracted casualty information is presented in graphical form for analysis based on location, vehicle types and incident dates. The casualty information extraction system works based on Named Entity Recognition, Semantic Role Labeling and Regular expressions.

In the following 'Related works' section, other approaches in literature are discussed and compared. In the 'Methodology' section, the architecture of the system is presented along with proposed methods to extract casualty information. In the 'Results and Analysis' section, some experimental results are presented along with system snapshots and analysis of the results along with limitations of the system. Finally, the paper is concluded along with a discussion of ongoing and future enhancements.

RELATED WORKS

There are a number of online platforms that apply information extraction techniques in different domains e.g. the Europe Media Monitor (EMM) NewsExplorer and the Thomson Reuters Open Calais. The EMM NewsExplorer[2] automatically gathers news articles from around Europe and separates them into clusters of related articles; identifies names of people, places and organizations for each cluster; identifies name variants by applying name matching techniques to all identified names; and populates a database with the extracted information, learning more about the identified person daily. The Thomson Reuters Open Calais[3] uses Natural Language Processing and machine learning algorithms to extract entities, relations, facts, events and topic code and social tags from submitted texts which are then used for further processing.

Hamborg et al. (2018) developed an open-source, syntax-based system that retrieves an article's main event by extracting phrases that answer the journalistic 5Ws (who, what, when, where and why). Sharma et al. (2013) described 5W1H (who, what, whom, when, where, how) event semantic elements extraction using Semantic Role Labeling (SRL) along with its analysis in their work.

Reschke et al. (2014) have done event extraction using distant supervision approach to extract passenger counts, aircraft types, and other facts concerning airplane crash events. Osoba (2015) developed a system for information extraction of road accidents which extracts information about victims, hospitals and police departments using the designed set of rules that are based on identified patterns. Rules are written in the formalism of the Conceptual Annotations for Facts, Events, Terms, Individual Entities and Relations (CAFETIERE) system. CAFETIERE is an information extraction system designed by a research unit in the School of Computer Science, University of Manchester. (Black et al. 2005).

Arulanandam et al. (2014) describe extracting crime information from online newspaper article by employing Named Entity Recognition (NER) algorithms to identify locations and a Conditional Random Field (CRF) algorithm to classify whether a sentence in the article is a crime location or not. LonMaps (2014) is a work on crime and accident mapping based on news articles, LonMaps, extracts crime/accidents, places, dates and personal names from the news article. LonMaps deals with 4W (what, when, where, and who) of an incident. Places of the incident are displayed on maps and their position is obtained using geocoding. Tanev and Atkinson (2008) presented a real-time news event extraction system for violent and disaster events from online news.

There are plenty of works done on the information extraction through RSS feeds. Han et al. (2009) proposed an efficient algorithm to extract the news article contents from the news pages, that is independent of the page layout. Chy et al. (2014) developed a web crawler to extract useful text from HTML pages of news article contents to construct a full-text-RSS in their work of news classification using Naive Bayes Classifier. Qingcheng and Youmeng (2014) proposed an algorithm to extract content from web pages based on RSS index. They computed the feature of content blocks to obtain the body template with high accuracy.

[2] EMM NewsExplorer, http://emm.newsexplorer.eu/NewsExplorer/readme.html

[3] Thomson Reuters Open Calais, http://new.opencalais.com/

Few works have been done to extract the crisis information from social media posts. Burel and Alani (2018) introduced Crisis Event Extraction Service (CREES), an open-source web API that provides annotations for crisis-related documents, classifies event types (hurricane, flood, etc) and identifies information categories (casualty report, donations and volunteers, etc). The classification was backed by Convolutional Neural Networks (CNNs), which was found to outperform traditional machine learning models. CREES is one of the projects under COMRADES[4], a collective platform for community resilience and social innovation during crisis.

This paper proposes a general system that can be used to extract structured information of casualties from unstructured local news reports in any crisis situation, like disasters and accidents, using Named Entity Recognition, Semantic Role Labeling and regular expressions. Further, locations and involved vehicles are normalized and organized hierarchically. Also, the system facilitates analysis by providing information filtering and visualization interfaces.

METHODOLOGY

In the system, a polling daemon runs daily that polls news from the news sources. The fetched link is checked with the saved list of links that have already been extracted to prevent duplication. The entities from the news article are extracted and stored in a database. Then the extracted information can be filtered and visualized in various forms as needed by the user. The prototype system has been developed in the Django framework in Python and PostgreSQL database was used to store extracted entities.

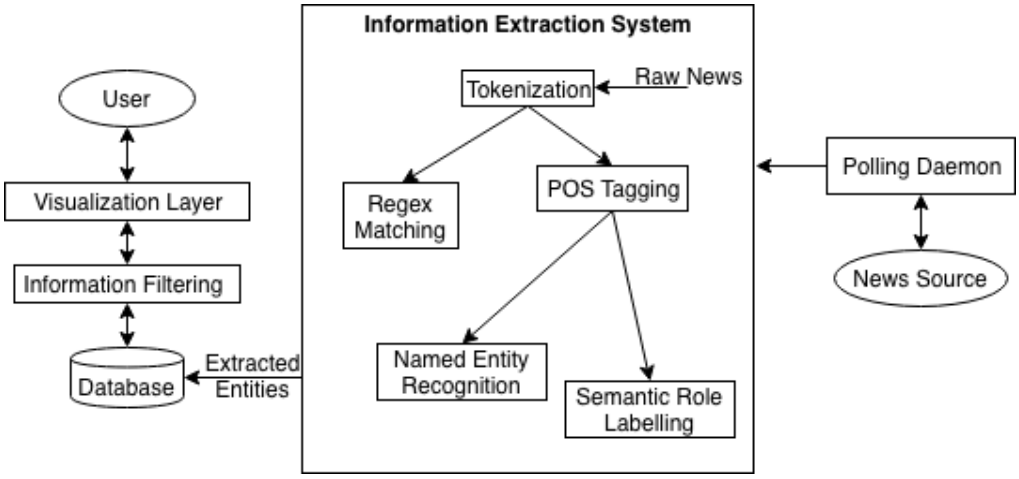

Figure 1. System Architecture.

Data Collection

The online source of news articles used in this work is ekantipur[5], a popular local news site of Nepal. RSS feed of the news articles tagged 'road accident' were fed to the system for information extraction. Since the news website does not support RSS feed, the news is converted to RSS feed using a fetcher named fetchrss[6]. The title and content of each news article from the feed were used.

Usually, news reports follow a common pattern. Every article starts with date of the news which gives the date of the incident. The body usually starts with the casualties involved in the incident specifying the number of people dead and injured along with location where the accident occurred. Vehicles involved are usually mentioned in mid sentences. The latter part usually talks about cause of the accident.

Data Preprocessing

Various methods like tokenization, Parts of Speech (POS) tagging, NER, Lemmatization, Regex matching and SRL are applied on the collected data for the extraction of relevant information.

Sentence tokenization was done using sent_tokenize module provided by Natural Language ToolKit (NLTK).

[4] COMRADES, https://comrades-project.eu/
[5] Ekantipur, http://www.ekantipur.com/
[6] Fetchrss, http://fetchrss.com/rss/5bf76e868a93f84c038b45675bf76e658a93f869028b4567.xml

The module knows what punctuation and characters mark the end of a sentence and the beginning of a new sentence (Loper and Bird, 2002). By looking at the occurrences of those punctuations and sentences the module breaks the paragraph into sentences. Word tokenization was done using word_tokenize module from nltk. It looks for spaces between words to split them.

POS tagging is important to find information regarding vehicle number. It was done using pos_tag module present in the nltk. The module consists of tagger trained in English language which assigns POS tags to the words. To assign tag to a word the POS tagger looks for attributes like if the word starts with a capital letter, has numbers, etc.

NER takes POS tagged sentences as an input to locate and classify named entities in text into pre-defined categories such as the names of persons, organizations, locations, expressions of times, quantities, monetary values, percentages, etc. It was done using NER tagger from nltk. The tagger is trained on English language and can identify named entities by examining its POS tag and the POS tag of word before it.

Lemmatization refers to the conversion of words form their inflectional form into their base form. Lemmatization was done using lemmatizer from spacy library. To convert a word into its base form the lemmatizer removes suffixes.

News articles usually contain date of news published at the beginning of the first sentence. Due to this POS tagging doesn't work as it should so before extracting day, vehicles number, vehicles involved, etc. the date is extracted and removed from the news article.

Dates are written in different formats (yy/mm/dd, dd-mm-yyy, July 1, 2017 etc). Regex matching the specific format is used to extract date. After extraction the date is removed.

Semantic role labeling, sometimes also called shallow semantic parsing, is a process in natural language processing that assigns labels to words or phrases in a sentence that indicate their semantic role in the sentence, such as that of an agent, goal, or result. It consists of the detection of the semantic arguments associated with the predicate or verb of a sentence and their classification into their specific roles. The table below represents the meaning of semantic roles for sentences along with the examples.

Table 1. Arguments in an SRL

Thematic Role	Definition	Example
AGENT	The volitional causer (subject of a sentence) of an event	*the waiter* spilled the soup.
FORCE	The entity that instigates an action, but not consciously or voluntarily.	*the wind* blows debris from the mall into our yards
THEME	The participant most directly affected by an event	only after Benjamin franklin broke *the ice.*
RESULT	The end product of an event	The city built a *regulation-size baseball diamond.*
INSTRUMENT	An instrument used in an event	he poached catfish, stunning them *with a shocking device*
SOURCE	The origin of the object of a transfer event	I flew in *from Boston.*
GOAL	The destination of an object of a transfer event	I drove to *Portland.*

An example of SRL is given below.

Input: “A person died, and four others injured when a micro bus hit them at Jorpati.”

SRL output: [‘A1’: ‘A person’, ‘V’: ‘died’, ‘A0’: ‘A microbus’, ‘V’: ‘hit’, ‘A1’: ‘them’, ‘AM-TMP’: ‘when a micro bus when a micro bus hit them at Jorpati’]

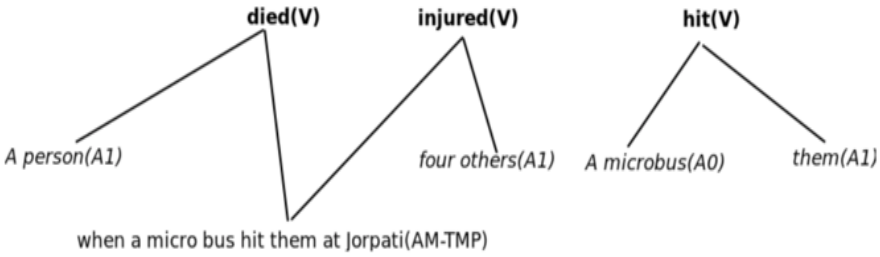

Figure 2. Semantic Parse Tree

Here 'V' refers to the verb, 'A0' refers to the agent and 'A1' refers to patient associated with the verb. AM-TMP is a temporal argument which shows when an action took place. The tag 'V', 'A0' and 'A1' appear in SRL output but they are not semantic roles.

Entities Extraction

The extraction template consists of eight entities which are described below. Entities refer to various fields that are extracted from the news article such as date, vehicle number, number of deaths/injuries, etc.

Death

The Death Field gives information regarding the people who died in the incident. To obtain such information, SRL is used with the death verbs. Death verbs are verbs like die, kill, crush and pass that are present in sentences containing information about death of people. The predicate which matches the death verb provides the required argument. Acceptor ('A0') is chosen as the answer whereas in absence of Acceptor, Accepted argument ('A1') gives death information. Death information is a phrase containing information about the number of deaths. In figure 2, A1 is associated with death verb (die) and A0 is not related with death verb hence A1 is chosen as the phrase related with death and is used for death number extraction.

Word to number conversion algorithm is used to convert the death information extracted from SRL, in previous step, into death number. The death number extraction depends on the extracted death information from the news. During conversion articles ('A', 'An' and 'The') are converted to number one.

For example: "A person died and four others ...". Here the word "A person" is converted to one and hence number of deaths equals one.

Injury

Injury Field gives information regarding the injured people in the incident. Mapping of injury template is carried out with SRL using injury verbs. Injury verbs are verbs like injure, sustain, critical, hurt, wound, harm and trauma that are present in sentences containing information about the injured people. The predicate which matches the verb provides the required argument. Acceptor ('A0') is chosen as the answer whereas in absence of Acceptor, Accepted argument ('A1') gives the injury field. In figure 2, A1 is associated with injury verb hence A1 is chosen as the phrase related with injury.

The injury field information is used to derive Injury Number using the word to number conversion algorithm as in death number conversion. Injury Number extraction depends on the extracted injury information.

Location

The location of the incident is extracted using NER. The word that is tagged as 'GPE' by NER is the extracted location. The locations of Nepal are further organized in a hierarchy. A location tree is constructed with the root node as 'Nepal', and 75 districts as its child nodes. Further, under 'Kathmandu' district node, 150+ locations are defined.

The extracted location is tallied with the location in location tree and the location that matches with the highest degree of similarity is stored. Similarity is obtained by calculating Levenshtein edit-distance between the locations. Similarity check ensures that same location with multiple spellings like 'Koteshowr', 'Koteshwor', 'Koteshor' are stored only once as defined in the location tree. In our tree, we've defined 'Koteshwor' and whenever one of the above three locations is extracted, it checks for similarity and as it passes the threshold of

70%, it is stored as 'Koteshwor' in the database. The 70% threshold was chosen by experimentation.

Vehicle Number

After POS tagging, Regular Expression is used to extract the pattern *<CD>*<CD>, the asterisk represents any character/group of character and <CD> represents a cardinal number which describes the vehicle number in the news report. Vehicle number in Nepal follow a specific pattern <word><number><word><number> and can be captured using the pattern *<CD>*<CD>.

Example: "The bus (Ba 2 Kha 4683), en route to Bardia from Kathmandu, overturned near the Hugdi bridge, said police". Here the bus number, Ba 2 Kha 4683, can be captured using pattern mentioned above.

Vehicle specifies the type of vehicle (bike, car, bus) involved in the incident. For vehicle extraction a gazetteer named 'vehicles' was constructed. The gazetteer contains only lemmatized forms of vehicles. For example, it contains 'bus' but not 'buses'. To find the vehicles, a complete news story is searched to find words whose lemmatized form match the word present in the gazetteer(vehicles) and then the vehicle is categorized into one of three categories two-wheeler, three-wheeler or four-wheeler.

Day

Almost all the news article specifies the day in which the incident occurred in the first few sentences of the news story. Since all seven days of the weekend with the suffix–day we use regex to find the day of the incident.

RESULTS AND ANALYSIS

Results

The extracted information is collected in database as structured data for analysis and visualization. A prototype system has been deployed in a webserver[7]. The site displays the extracted information from the news articles and visualizes it in various forms like graphs, charts and maps.

The main page lists the latest news articles related to road incidents and the extracted items beside the selected news article. Visualization can be done based on the number of incidents and casualties(deaths and injuries). There are filters for location, vehicle types and time range for flexible analysis of incidents.

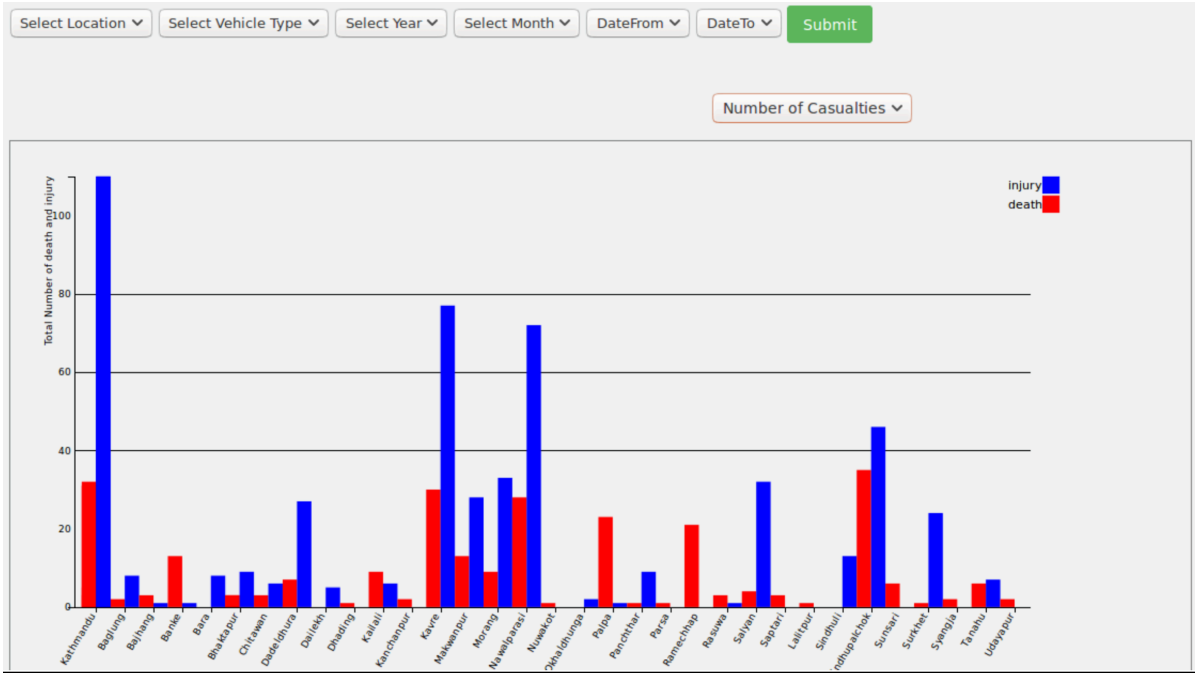

Figure 3. Graph showing district wise casualties.

[7] http://103.5.150.17

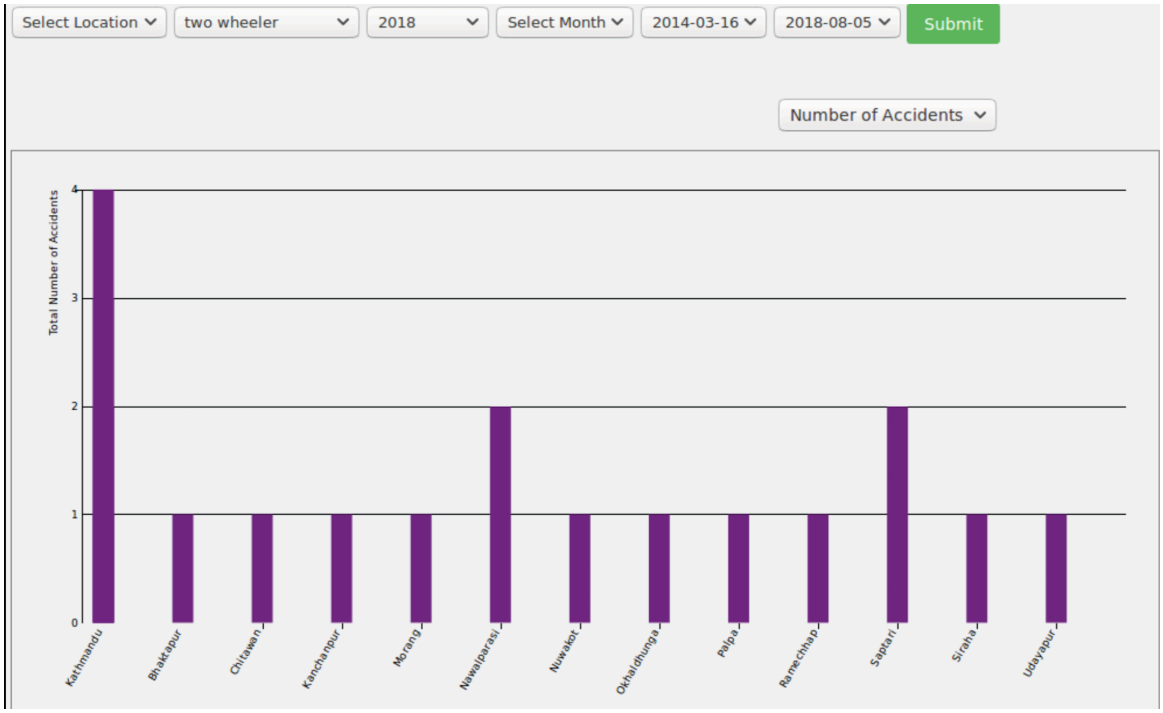

Figure 4. Graph showing district wise two-wheeler incidents in 2018.

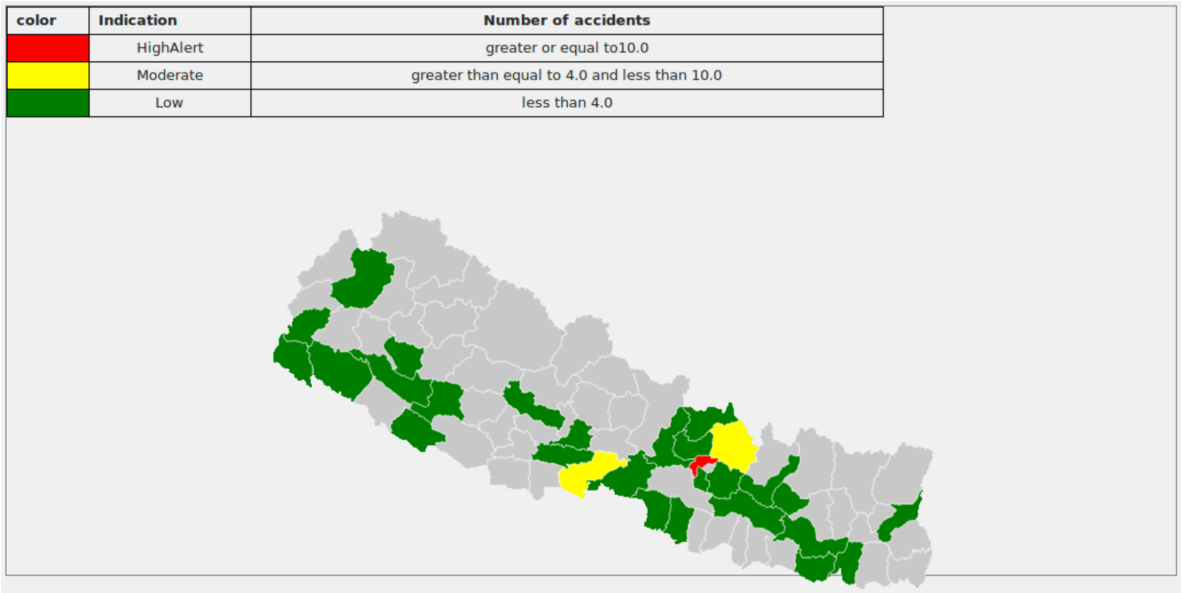
Visualization is also possible in the map of Nepal (divided into 75 districts) and map of Kathmandu. In the map of Nepal, the number of incidents is displayed for different districts with three colors: red, yellow and green representing the frequency of incidents, red being the high alert districts. Data from the server is passed in the json format which is processed using D3.js. The threshold value for the alert categories is dynamic and is adjusted according to the total number of accidents.



color	Indication	Number of accidents
	HighAlert	greater or equal to10.0
	Moderate	greater than equal to 4.0 and less than 10.0
	Low	less than 4.0

Figure 5. Map of Nepal showing district wise incidents.

Google Map's API is used to display the specific locations of incidents in the map of Kathmandu. Geocoder was used to obtain the latitude and longitude of a place that was extracted. These values are used to create heatmap using Google Maps API.

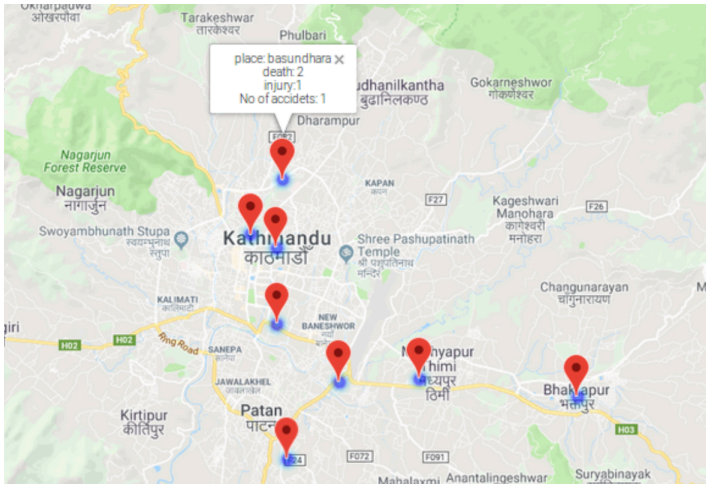


Figure 6. Map of Kathmandu pointing the places of incidents.

Evaluation

The metrics used to evaluate our extraction system is accuracy. Ten entities were used in the analysis, namely death, injury, death number, injury number, location, vehicles involved, vehicle numbers, vehicle types, date and day. The individual accuracy of each extracted entities, the accuracy of each news articles and the overall accuracy of the system is measured. These measures help to test the validity and performance of the designed system.

For an unbiased evaluation of the designed system, 50 news articles were randomly selected. The entities were manually annotated by a group of 10 engineering students and compared with the results obtained from the system to ensure the rules extract the right information. For each entity, the number of correct extractions over 50 news articles was obtained and used in the below equation to calculate the accuracy of individual entities.

$$Accuracy\ of\ entity = \frac{Number\ of\ entities\ with\ correct\ extraction}{Total\ number\ of\ entries}$$

To calculate the accuracy of individual news entries, the two sets of entities, manually annotated and system extracted were compared. The number of correctly extracted entities was obtained and used in below equation to calculate the accuracy of all 50 news entries.

$$Accuracy\ of\ article = \frac{Number\ of\ correctly\ extracted\ entities}{Total\ number\ of\ entities\ in\ an\ article}$$

Finally, the overall accuracy was calculated using the equation below.

$$Overall\ accuracy = \frac{Sum\ of\ accuracies\ of\ all\ news\ articles}{Total\ number\ of\ news\ article}$$

The accuracy of each entity over 50 news articles is as shown in the table below.

Table 2. Accuracy of the Extracted Entities

Entity	Accuracy
Death	94%
Death number	96%
Injury	84%
Injury number	94%
Date	100%
Day	96%
Location	80%
Vehicles involved	88%
Vehicle numbers	96%
Vehicle types	88%

The overall accuracy of the system was found to be 90.8% .

Analysis and Limitations

The system finds the sentences containing pre-defined death and injury verbs and assigns the subject of such sentences as death and injury. The subject of such sentences may not always be the actual deaths and injuries, leading to inaccurate extraction. Similarly, death and injury numbers extracted by the system is not always accurate as it may take other numerals in the sentence as death and injury numbers.

Extraction of date and vehicle numbers is quite accurate as they follow specific patterns while expressing. Extraction of location is least accurate (80%) because there are many locations specified in a news article like the place of incident, the destination of the vehicle, the home address of the victim, the location of the hospital, etc. and system may extract the incorrect location. Also, 75 districts and 150+ places inside Kathmandu are only defined in the location tree. If the extracted location is not in the location tree, extraction is incorrect.

Extraction of involved vehicles is not always accurate as the extracted vehicles should match from the list of pre-defined vehicle gazetteer. Some news articles do not specify the vehicle or have unconventional vehicle names like 'Toyota vehicle', due to which extraction fails. Each vehicle in vehicle gazetteer is categorized as two-wheeler, three-wheeler or four-wheeler, so vehicle type has the same accuracy as vehicles involved.

CONCLUSION AND FUTURE WORK

This paper presented a methodology for the extraction of casualty information from online news articles and demonstrated an online system for the collection, analysis and visualization of the extracted information. Named entity recognition (NER), semantic role labelling (SRL) and regular expression have been used for the extraction purpose. Vehicle and Location extraction have been standardized by using simple vehicle and location hierarchies. The overall accuracy of the system calculated over 50 news articles was found to be 90.8%. Although the system has been implemented for road accidents in Nepal, it can be used in crisis for information extraction from any news involving casualties.

There are still rooms for improvements in terms of accuracy and completeness of the system. Some ongoing and future works are listed below.

- Automatic classification of casualty related news from general RSS news feeds.
- Aggregation of news from multiple sources along with identification and consolidation of duplicate news.
- Updates on the same incident in successive news reports (for example, increase in number of casualties few days after an accident).
- Extraction of the exact cause of the incident for extensive analysis.
- Validation and correction of extracted information to maintain an accurate and up-to-date database.
- Exploration of sentence structures and verbs intention to make more sense from the news.

ACKNOWLEDGEMENT

This work has been supported by the University Grants Commission, Nepal under a Collaborative Research Grant (UGC Award No. CRG-74/75-Engg-01) for the research project "Establishment of a Disaster Telecommunications Research and Educational Facility Advancing a Scientifically Sound Disaster Telecommunication Infrastructure and Processes in Nepal".

ABSTRACT

Autonomous systems are being exceedingly used to assist humans in various crisis responses scenarios such as earthquakes and nuclear disasters. Because they operate in highly unstructured and uncertain environments, failures are an inherent part of such autonomous systems, and, techniques for making these systems robust to failures arising from computer hardware, software or communication malfunctions are already integrated into their design. However, an important aspect while designing such systems is often times overlooked: how to better coordinate and communicate across distributed, possibly diverse human teams who are working in cooperation with autonomous systems into the design of the autonomous system itself. Unfortunately, this results in limited adoption of autonomous systems in real-life crisis scenarios. In this working paper, we describe ongoing work that attempts to address this deficit by integrating research on shared mental models between humans with techniques for autonomous agent team formation in the context of search and rescue scenarios.

Keywords

Crisis management team, intelligent autonomous system, coalition formation, shared mental model.

INTRODUCTION

Timely and effective responses to disasters are an integral part of every crises management system. Over the past decade, intelligent autonomous systems (IAS) have been employed extensively in different domains to provide efficient and rapid responses to crisis. Examples include search and rescue robots for assisting humans during relief and cleanup activities following natural calamities such as earthquakes, fire and flooding (Erdelj, Krol and Natalio, 2017; Maza *et al.*, 2011; Sable *et al.*, 2018), intelligent agents that can predict damage to infrastructure or presence of hazardous material following disasters such as chemical or nuclear accidents (Sanchez-Cuevas, 2019; Sanchez 2018), and intelligent robots that can perform preventive maintenance tasks such as infrastructure inspection of bridges and buildings or underwater inspection of structures such as ship hulls (Perrot *et al.*, 2015). However, most of these IAS have focused on two areas – 1) how to build sophisticated hardware and software algorithms that can operate autonomously in unstructured environments and uncertain, unprecedented conditions with minimal human intervention, and, 2) how to adapt the IAS' behavior and decision-making so that it can interact in a socially amiable, trustworthy and reassuring manner with the human operating or interacting with it. The design objectives of these IAS have mainly focused on improving the performance efficiency of the IAS, such as the time required and energy (battery) expended to perform its assigned task, and, in some cases, the satisfaction of the human user with using the IAS. Consequently, before deployment, the IAS are tested within simulated environments while interacting with a very limited number of humans. For example, the 2015 DARPA Robotics Challenge (DeDonato *et al.*, 2017) required a humanoid robot IAS to interact only with objects in its environment such as a door handle, fire hose,

stairs, etc. Most importantly, the IAS' performance while interacting with another human or human teams was not validated as a performance criterion in the challenge.

We use this example to highlight that crisis management poses some unique challenges in the context of human-human and human-machine interaction that are usually not encountered in non-crisis or simulated-crisis tasks. Most importantly, crisis management is led by crisis management teams (CMTs) that are drawn from humans with diverse background and expertise including first responders, law enforcement, medical personnel such as doctors and nurses, legal personnel and even citizen volunteers (Yu and Khazanchi, 2015). Each of these individuals is required to work collaboratively with each other and with IAS. Unfortunately, in an unstructured and previously un-encountered scenario like a crisis, when the conventional modes of operation and interaction between human-human and human-machine are drastically altered, the performance of humans and IAS could both get severely degraded. In extreme cases, this could result in delayed or inaccurate responses, or even an inability to respond in crisis scenarios. Our research in this working paper proposes to address this deficiency by utilizing a model for human team formation drawn from coalitional game theory (Shoham and Leyton-Brown, 2009) that would enable IAS to identify and suggest ways to assimilate teams of humans based on their expertise and past performance within a team, as well as adapt the behavior of the IAS while working with an assimilated team of humans, so that the crisis management task could be handled efficiently.

RELATED WORK

Collaboration between human and agent teams has been an active research area in the field of artificial intelligence for almost two decades. Research in this area can be broadly divided into two directions – robot-based systems and multi-agent systems. Disaster robotics research (Murphy, 2014), led mainly by the robotics and engineering community, has made large advances in the past decade with robots being used in dangerous and hazardous tasks including moving concrete chunks, exploring tunnels, diffusing explosives and searching for hazardous material such as nuclear or chemical traces (Recchiuto *et al.,* 2016; Schwarz *et al.*, 2014; Haynes *et al.*, 2015; Leingartner *et al.,* 2018; Kochersberger *et al.*, 2017). However, much of this research has focused on engineering highly dexterous and robust robots that can operate either via teleoperation, or, in some cases autonomously, within adverse and unstructured environments. To the best of our knowledge, robotic disaster response systems that integrate close coordination between teams of humans and teams of robots have not been fielded or researched extensively.

Within the multi-agent systems community, a large portion of the research has focused on the problem of task allocation – how to assign tasks to agents so that the tasks can be performed effectively by the agents, such as reducing the time or effort (e.g., energy or battery) required to complete tasks and reducing the overlap or conflicts between agents while performing tasks. Much of this work has been validated within simulated agent environments closely resembling disaster scenarios (Massaguer *et al.,* 2006). In one of the earliest and seminal works in this direction (Shehory and Kraus, 1998) proposed a distributed coalition formation algorithm, where transportation-like tasks, e.g., moving blocks between locations, were allocated to teams of agents based on their capabilities. Several authors (Klein, Bradshaw, Woods, Hoffman and Feltovich, 2004; Jennings *et al.,* 2014) also laid foundation for effective cooperation between human-agent teams through a set of requirements that a human-agent collective should satisfy. These requirements included defining a mutually agreeable contract between agents and humans to perform a task jointly, being accountable to each other by revealing individual plans and intentions, being flexible to each other's requirements, having intelligent capabilities to interpret and predict each other's decisions and actions, and incentivizing each other's actions by forming coalitions, negotiating goals, managing attention and controlling costs. Future research on human-agent team formation emphasized one or more of these aspects while using a suitable computational framework to represent the interaction between agents and humans. For example, (Ramchurn *et al.,* 2015, Ramchurn *et al.,* 2016) proposed the HAC-ER (Human Agent Collective for Emergency Response) system that uses a framework called multi-agent Markov Decision Processes (MMDP) to formalize the decision making by agents to select tasks within an emergency task response scenario. A novel direction explored in this work was to include input from real-life human-in-the-loop operators to approve and selectively reassign task allocations before dispatching agents to tasks. In (Tambe, Bowring, Jung, Kaminka, Masheswaran, Marecki, *et al.*, 2005), authors observed that unifying different individual frameworks into hybrids were more effective than a single framework for performing collective tasks in disaster scenarios. For instance, integrating belief-desire-intent (BDI) and partially observable Markov Decision Processes (POMDP) frameworks enabled each framework to efficiently perform computations at different levels of information abstraction, for multi-agent task allocation and multi-agent communication in disaster scenarios. Later extensions of this concept were applied to human agent teams in security management scenarios in airports (Pita *et al.*, 2008). Recently, researchers have also focused on integrating human-agent collaboration within the context of massively multi-player online games (MMOGs) (Chan and Vonderer, 2005; Sourmeilis, Ioannou and Zaphiris, 2017). (Hafizoglu and Sen, 2018) explored the evolution of trust in human-

agent team within the context of an online trust game, while (Wicke and Luke, 2017) have modeled human-agent collaboration as a treasure hunting game where each human-agent team has to select different tasks to perform. Several interesting techniques for human agent team formation in disaster response scenarios have also been proposed in the Robocup Simulation Rescue League challenge (RSRL, 2019) where teams of simulated agents representing first responders have to coordinate with each other to perform disaster response tasks. In summary, majority of these research focus on sophisticated algorithms to enable intelligent agents to plan to perform tasks, either collectively or individually, while the human's role is limited to oversight of agents' actions along with intermediate revisions of agent allocations or roles, as necessary. In other words, agents assume the role of human avatars with embedded intelligence while humans assume the role of supervising their avatars. To the best of our knowledge, a unified system, where human teams work alongside agent teams, while sharing work and responsibilities, has not been fully researched. Our proposed work attempts to address this deficit by proposing a framework where agents form coalitions while building a representation of the shared mental model (SMM) of human coalitions or teams within them. This iterated modeling enables agents to quickly identify high-performance human teams and, in parallel, adapt the agent coalitions, so that the capabilities of human-agent teams can be matched for improving task performance. To achieve this, in our proposed solution, we utilize two formalisms rooted in game theory and graph theory called coalition formation in weighted voting game and bipartite graph matching.

SHARED MENTAL MODELS OF CRISIS MANAGEMENT TEAMS

We have previously argued that one of the essential tasks of crisis management is to develop shared mental models (SMM) among teams and members about the crisis at hand, i.e. shared understanding of the task, process, technology and the teams (Yu and Khazanchi (2015). Developing SMM is essential for developing an effective crisis management strategy. Teams can form three types of mental models - information technology mental models, taskwork mental models, and teamwork mental models (Mathieu et al., 2000; Thomas & Bostrom, 2007; Thomas & Bostrom, 2010). A team's IT mental model is the knowledge structure and beliefs held by the team about the information technology capabilities and the usage of these capabilities (Thomas & Bostrom, 2007). A team's taskwork mental model is the knowledge structure and beliefs held by the team about the task goals, steps to accomplish the tasks, and the technologies used to accomplish the tasks (Mathieu et al., 2000). The teamwork mental models refer to the knowledge structure and beliefs held by the team about the team interaction and team members' roles, skills, and knowledge (Mathieu et al., 2000). Assessment of shared *mental models' convergence is mostly focused on measuring the degree to which knowledge structures overlap or are similar among the team members*, i.e. the SMM similarity (Yu & Khazanchi, 2015; Mohammed et al., 2010).

PROPOSED FRAMEWORK: UNIFYING SHARED MENTAL MODEL WITH COALITION FORMATION

In our proposed approach, we posit that more effective human-agent teams can be formed in crisis scenarios if, for a certain task, a team of autonomous agents is paired with a team of humans who have a high possibility of interacting and collaborating efficiently with each other. This step is challenging because, although individual humans might possess desired skills or capabilities for the task, inefficient interaction between humans in a team might degrade the performance of the task (Yu & Khazanchi, 2015). We propose to address this problem using a two-step procedure, as described below.

STEP 1: HUMAN TEAM IDENTIFICATION USING WEIGHTED VOTING GAMES

Given a task to perform in a crisis scenario, the first step in our proposed human-agent team formation technique is to identify a team of individuals with diverse set of expertise suitable for a task, such that the humans in the team can efficiently collaborate with each other to perform the task. The team should also contain only the individuals essential to perform the task, as including unnecessary or superfluous individuals could hinder and delay the task's performance due to inter-team collaboration issues. To quantify the collaboration potential of a set of individuals, we can use mental model measures for *teamwork, taskwork and information technology* to represent the suitability of an individual in a team (Yu & Khazanchi, 2015). These measures of a team's SMM convergence represent different aspects of an individual *i* relevant to functioning as part of a team, as described below:

- Teamwork mental model convergence (ρ_i) represents a team members knowledge structure and beliefs about team interaction and other team members' roles, skills, and knowledge;
- Taskwork mental model convergence (τ_i) represents the knowledge structure and beliefs held by the team about the task goals, steps to accomplish the tasks, and the technologies used to accomplish the

tasks;

- Information Technology mental model convergence (θ_i) represents the knowledge structure and beliefs held by the team about the information technology capabilities and the usage of these capabilities for performing the task.

The values of these suitability parameters could be solicited as input from humans in the team and conditioned with data from their past performances of in teams. In (Yu & Khazanchi, 2015), we have described case studies of using these suitability parameters for a team of individuals performing an information technology management task These parameters are aggregated into a single suitability parameter, called the individual *i*'s *weight*, w_i, and given by:

$$w_i = \alpha_1 \rho_i + \alpha_2 \tau_i + \alpha_3 \theta_i, \qquad \text{subject to, } \alpha_1 + \alpha_2 + \alpha_3 = 1$$

α_1, α_2 and α_3 are preferences over the suitability parameters and could be specified as inputs when a task is assigned to the team. With more experience of a team, these preferences could also be learned from past performances of the team in performing different types of tasks. This weight is then used in a coalition game framework called a weighted voting game (WVG) (Shoham and Leyton Brown, 2009). A weighted voting game denoted by the tuple *(N, **W**, q)* consists of the following attributes:

- *N*: a set of individuals, also called players
- ***W***=*{*w_i*}*:, a set of real-valued weights, where w_i represents the weight or suitability parameter of the *i*-th individual in the team
- *q*: quota, a real valued number representing a minimum threshold value that the combined weights of individuals should satisfy to be able to form a team.

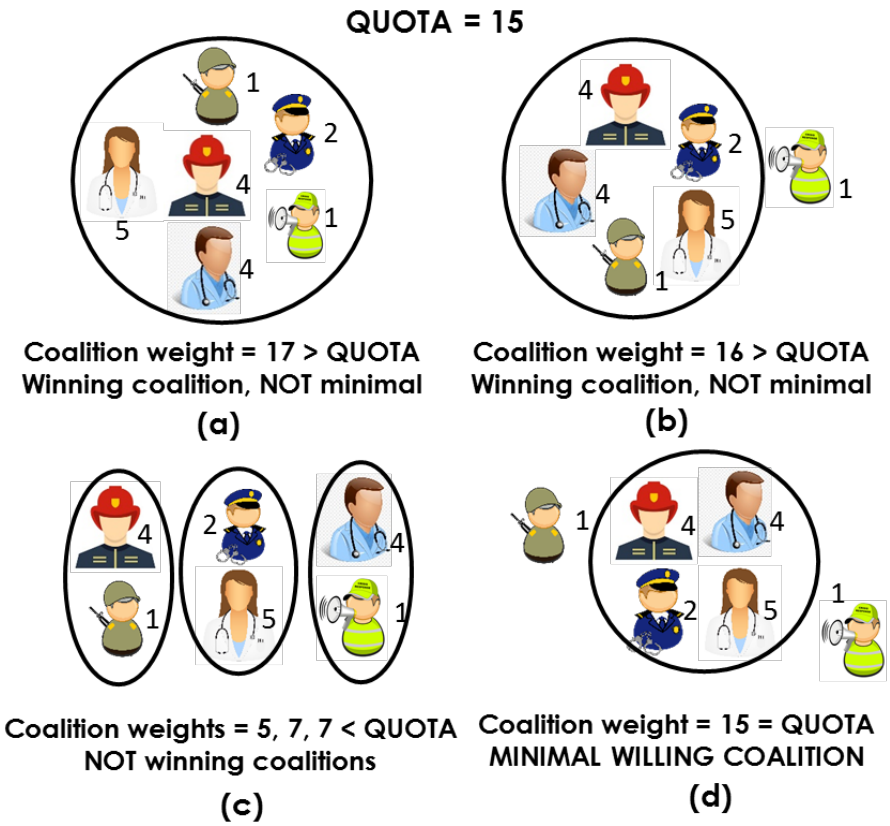

Figure 1. *A Weighted Voting Game (WVG) with quota, q = 15. (a) Grand coalition with all humans is a winning coalition as it satisfies quota, but is not minimal with 6 individuals, (b) Coalition with 5 individuals is also satisfies the quota and is a winning coalition, but is not minimal with 6 individuals, (c) None of the coalitions are winning coalitions as they do not satisfy the quota (d) A minimum winning coalition that satisfies quota and is also minimal with 4 individuals.*

To implement a voting game, all possible subsets of the players are determined. Note that for *N* players there can be 2^N possible subsets. For each subset *S*, in the 2^N possible subsets of the *N* players, the combined weight of the players in *S* is calculated as $\sum_{i \in S} w_i$. Finally, if the combined weight reaches the quota, that is, if $\sum_{i \in S} w_i \geq q$, then *S* is accepted as a winning coalition. The output of a WVG is a set of minimal winning coalitions (MWCs) – the smallest set(s) *S* out of the winning coalitions. Every WVG is guaranteed to have at least one MWC as long as $q \leq \sum_{i \in N} w_i$. An example of a weighted voting game is shown in Figure 1. Here six individuals with different weights or suitability parameter values have to form a team to perform an assigned. The objective of forming the team is to include the essential or smallest set of individuals required to perform the task. A quota value, *q=15,* is calculated for the task and given as input to the WVG. There are multiple winning coalitions in this WVG, two of which are shown in Figures 1(a) and 1(b). But there is only one MWC with four individuals, as shown in Figure 1(d). Figure 1(c) shows sets of non-winning coalitions that are not capable to perform the task as they are unable to reach the quota. Note that, in general, as the number of individuals in the scenario grows, or, as the value of quota, *q*, changes, the number of MWCs can become more than one. In other words, the minimal winning coalition is not unique and multiple teams or coalitions can be output by the weighted voting game. Consequently, the problem of calculating MWCs can quickly become non-trivial to solve as the number of players or individuals, *N,* increases.

In our earlier work (Dasgupta and Cheng, 2016), we had proposed two heuristic-based algorithms with proven performance bounds for calculating the MWC in a WVG, in the context of multi-robot team formation. These algorithms are able to calculate the MWC in polynomial and log-linear time respectively and are able to scale adequately with the number of players or individuals in the scenario. In this work, we plan to adapt those algorithms for identifying suitable human teams that are suitable for effectively performing the assigned task. Our main ongoing research questions in this direction are how to reliably elicit and combine the task suitability parameters from humans for determining the input weights of the WVG, how to address the complimentarity of individual skills or capabilities of humans while forming a team, and, how to calculate a suitable value of the WVG quota input, *q*, from the characteristics or features of a task that needs to be performed.

STEP 2: EFFICIENT HUMAN-AGENT COALITION FORMATION USING PREFERENCE-BASED GRAPH MATCHING

After suitable human teams have been identified in step 1 above, the next step towards forming human-robot collectives is to identify appropriate robots that could be paired with the human teams. In step 2 of our algorithm, we assume that different teams for different sub-tasks are formed by running the WVG algorithm multiple times, once for each sub-task. For example, in a post-earthquake scenario, a team comprising of medics and first responders could be formed to perform a sub-task of providing healthcare to injured persons, while another team comprising of medics and military personnel could be formed to clear debris and rescue persons trapped under rubble. For this, each human team formed from step 1, expresses its desired capabilities from robots in the form of preference values over the set of available robots. For example, a human team comprising of a medical doctor, a firefighter and a law enforcement officer might have a high preference for a group of three robots that can assist respectively with surgical assistance, with clearing and removing debris, and with detecting hazardous substances in the environment. This problem is non-trivial as there could be preference conflicts between human teams for the same set of robots, and, there could also be constraints between robots such as limited number of robots with certain specialized sensors or actuators being available, suitability of pairs of robots to work well with each other, etc. To address this problem, we adopt a framework from computational economics called *matching with preferences* (Pycia, 2012). The objective of the problem is to find a complete matching between two sets of agents such that every agent from one set is paired with exactly one agent from the other set and the preference values between the sets of agents is maximized. For our problem, the two sets of agents are the human teams and robots, and the result is a matching between a human team and a set of robots while maximizing the preference values given by human teams for the robots collectives. This would guarantee that the humans in the human team have the best match of skills and capabilities with the autonomy of the agents in the robot team. Overall, this would result in improved performance of the human-robot collective.

We plan to adapt a bipartite graph matching algorithm from our previous work on configuration formation by robot teams (Dutta and Dasgupta, 2017; Manne and Hiesling, 2007), to address our human-robot team matching problem. The algorithm takes as input a set of team of humans *H* and the set of robots *R* as two disjoint sets. Each human team *i* has a preference parameter p_{ij} that represents the value of a match between the autonomous assistance desired by human *i* and the capability of robot *j*. The objective of the algorithm is to find a set of matchings that maximizes the sum of preference values. Mathematically, this can be represented as $\max \sum_{i \in H, j \in 2^R} p_{ij}$ such that $| p_{ij} | = |H|$. The algorithm works by first enumerating partitions, π, of the robot set, *R*, such that $| \pi | = |H|$. For each partition $\pi_i \in \pi$, it then finds an initial matching where each human team $h \in H$ is matched to its highest preferred set of robots in π. These matchings are removed from the sets of

human teams and robots, and the process continues sequentially until all human teams are matched with sets of robots. An example of a matching between three human teams, each with an ordered set of preferences over sets of robots is shown in Figure 2. The output of the algorithm is a set of matchings between human teams and robots that has the maximal sum of preference values, which guarantees that each human team is paired with its most preferred (but not all) set of robots. This problem is an instance of the set packing problem that is a well known NP-hard problem. Within this framework, some of the research questions we are investigating include speeding up the computation of the maximal matching using recent results from coalition game theory (Hatfield, Kominers and Westcamp, 2017), integrating dependencies or externalities between the robot sets, where the formation of one set of robots affects the preferences of other sets of robots, and, considering the matching problem with dynamically varying preferences of human teams.

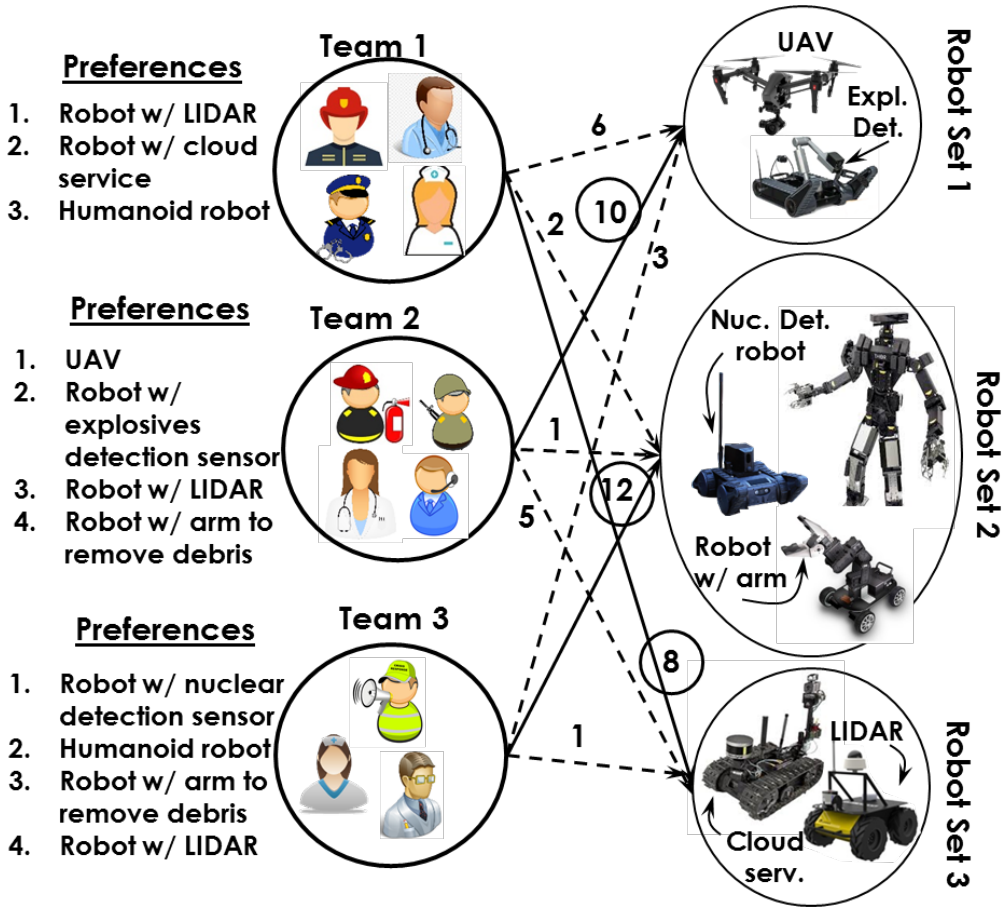

Figure 2. *Matching between three human teams (formed in step 1) with different sets of robots. The values of the different matches to each team are specified by the individuals in the team and shown as edge weights between teams and corresponding robot sets. The matching algorithm returns the maximal matching (shown as solid edges, circled edge weights) between the human team and robot sets that gives the highest combination of preference values. Non-maximal matches, shown with dashed lines, are not selected.*

ONGOING WORK AND CONCLUSIONS

Currently, we are working on formalizing the different research questions and implementing software algorithms in the two-step process for integrating shared mental model (SMM)-based human team formation with human-robot collective formation in the context of crisis management scenario. We plan to evaluate our software algorithms on the Repast multi-agent simulation environment within simulated disaster scenarios, while drawing inspiration from situations and environments featured in the Robocup Rescue Simulation League (Robocup Rescue Simulation League, 2019). In the future, we plan to integrate machine learning-based techniques into our proposed algorithms towards speeding up the computations and making them robust to errors in individuals' reporting of their capabilities and preference for robot assistance. Machine learning algorithms usually require training the model being learned with data from team formation in disaster scenarios. Real-life data for such scenarios will most likely be difficult to obtain. To address this data scarcity problem, we plan to generate virtual, game-like setups that model disaster scenarios, and engage humans to form teams to perform simulated tasks within the game setup. The data generated during these games could then be used to

train the machine learning-based models required by our algorithms. Another direction worth investigating in the future is to form teams with a specified number of humans with certain expertise, e.g., a team with at least five firefighters and two paramedics. Such constraints on team formation could be handled by richer representations of coalition games beyond weighted voting games in step 1 of our algorithm, such as marginal contribution nets (MC-nets). Awareness theory, eliciting human and agent preferences, and dependencies between formed coalitions are additional future directions that we plan to investigate.

Our proposed work investigates a novel direction by integrating human cognitive processes through shared mental models into team formation with autonomous agents. In the future, we envisage that this work will lead to many interesting problems and solutions towards making systems requiring tight coordination and close interactions between human and AI more efficient, reliable and trustworthy in crisis management scenarios.

Abstract

Up to now, the world has witnessed how inadequate communication capabilities can adversely affect disaster response efforts. There are various Emergency Responders (ERs) that potentially must work together towards a successful resolution of the disaster. However, the different terminologies and technical vocabularies that are being exchanged between the ERs may lead to a misunderstanding and lack of semantic integrity. Yet, understanding the semantics of the exchanged data is one of the major challenges. The purpose of this work is to define the complex knowledge of the ERs by proposing a common and modular ontology shared by all the stakeholders so as to come up with a common shared vocabulary in order to ensure semantic interoperability between ERs. In this paper, we present POLARISCO and we discuss how it was developed using Basic Formal Ontology as an upper-level ontology and Common Core Ontology as a mid-level ontology to define each module.

Keywords

Semantic interoperability, modular ontology, upper-level ontology, mid-level ontology, disaster response.

INTRODUCTION

When a disaster occurs, a streamlined operational response organization is crucial to handle the disaster effectively. So as to respond within seconds, an appropriate and effective response depends on a detailed plan with clearly articulated roles and responsibilities. It involves a complex network of diverse Emergency Responders (ERs) from different Emergency Response Organizations (ERO) such as firefighters, police, health care services, etc. In fact, numerous after-action reports from major disasters (11 September 2001 and 13 November 2015 terrorist attacks, Hurricane Katrina, etc.) have cited communication difficulties among EROs as a major failing and challenge. The absence of adequate communication and information sharing between the involved actors in disaster response may lead to a break down at the operational response, stakeholders will not know what is happening exactly which will consequently extend the time required to bring a full resolution of the disaster while time is an important factor that has to be considered. Respectively, communication during a disaster is primordial. Information is the most valuable commodity during disaster response. ERs necessitate an ample need for timely information sharing and data exchange to obtain a real-time operational picture of the situation. But, each ERs has its own technical vocabulary. As a result, this discrepancy of information leads to a misunderstanding, a deficiency of semantic interoperability and lack of information sharing among the different actors. This can make the operational response process slow and inefficient. In this work, we aim to define the complex knowledge of the different ERs (firefighters, police, gendarmerie, health care services, etc.) so as to come up with a common shared vocabulary in order to provide the appropriate information at the right place and in the right moment (van Borkulo et al., 2006). Once this task is fulfilled, ERs can operate together and especially can understand each other in any critical situation which is the key to a better operational response (Zlatanova et al., 2004). To do so, a modular ontology

has been developed to explore the semantics of the different ERs in the context of the project POLARISC (Plateforme OpérationnelLe d'Actualisation du Renseignement Interservices pour la Sécurité Civile) (Elmhadhbi et al., 2018). It is a French project which started in 2017. It proposes an interoperable inter-services software solution for reliable and timely information sharing for the operational management of large-scale crisis situations. The focus is about offering to all ERs a real-time operation picture of the situation in order to enable multi-stakeholders and multi-level coordination within the EROs including firefighters, police, gendarmerie, healthcare services, and public authorities. The proposed ontology POLARISCO (POLARISC Ontology) is the core of the system. It will be shared by all the stakeholders in order to enable semantically interoperable information exchange and a common understanding of what is happening on the field. Specifically, it employs Basic Formal Ontology (BFO) as an upper-level ontology and Common Core Ontology (CCO) as a mid-level ontology to present seven ontological modules. This paper is organized as follow. In section2, we overview the main ontologies related to operational disaster response. Section 3 goes into the details of the process of the development of POLARISCO then we present the proposed modules. In section 4, we discuss how POLARISCO is evaluated and is used as a shared vocabulary in a messaging service to enable semantically interoperable information exchange among ERs. Finally, conclusion and future work about our ontology use are presented.

Related work

The different interpretations of data cause semantic heterogeneity. To overcome semantic heterogeneity and to guarantee a consistent shared understanding of the meaning of information, the use of ontologies is crucial (Antunes et al., 2013). Ontologies have been identified as an effective means to implement semantic integration and achieve information interoperability. Ontologies are expressed in a logic-based language, so that accurate, consistent, and meaningful distinctions can be made among the classes, instances, properties, attributes, and relations to reveal the implicit and hidden knowledge in order to understand the meaning of the data. Thus, they offer the richest representations of machine-interpretable semantics for systems and databases**.** They serve as both knowledge representation and as mediation to enable heterogeneous systems semantic interoperability**.** With the increasing amount of data coming from different sources, there is a strong need to determine the meaning of the information to be exchanged precisely enough that a software application can interpret them (Nunavath & Prinz, 2017). So many application of ontologies addresses the problem of semantic interoperability, in which we have different users using various software tools that need to cooperate by exchanging data with unambiguous, shared meaning. In the literature, different types of ontologies and meta-models have been proposed to define the concepts related to disaster response. However, these latter are restricted to one EROs or to a specific case or purpose (Liu et al., 2013).

EMERGEL Ontology, proposed in the context of DISASTER project (Casado et al., 2015), mainly focusses on the mapping of different predefined information's artifacts, information representation and language between countries in Europe. It is composed of a core ontology (events, agents), a transversal module (time and space) and a vertical module (organization's specifications). It reuses the class event of the upper-level ontology DOLCE and other vocabularies such as FOAF (Graves et al., 2007) (peoples in an emergency situation) and the Organization ontology. However, this ontology lacks specific operational information (technical vocabulary of each ER). It can be more useful in decision making at the strategic level rather than the operational level. Moreover, Authors in (Fan & Zlatanova, 2011) looked for solving the problem of spatial data heterogeneity in emergency situations and their transmission to stakeholders by proposing an ontology. SoKNOS ontology (Babitski, 2011) includes resource planning, damages, and geo-sensor information. Regarding EDXL-RESCUER ontology (Barros, 2015), it employs EDXL (Emergency Data Exchange Language) to model the coordinating and exchanging of information with legacy systems. The focus is mainly on alerting people. Another ontology is proposed in (Chehade et al., 2018) for representing situations during rescue operations in order to support situations awareness. It aims to support French first responders in data interpretation during rescue operations. However, on one hand, the proposed ontology is not evaluated and implemented yet, on the other hand, it is dedicated only to firefighters and health care staff. In (Chan et al., 2017), authors proposed PS/EM Communication ontology (Public Safety and Emergency Management) in the context of IDA project (Institute for Defense Analyses). They were based on EDXL (Emergency Data Exchange Language) standards including resource messaging distribution element, hospital availability exchange and common alerting protocol. The ontology was constructed by adding specializations of the BFO and CCO classes. However, this ontology doesn't cover all type of communication between ERs, it is focused on alert messages.

To summarize, during our literature review, we found several ontologies developed in the context of disaster response. However, from one hand, these ontologies don't cover the knowledge of the different involved actors (firefighters, health care services, public order forces, public authorities, etc.) in the disaster response process.

From the other hand, they don't define the technical vocabulary that is used in the operational response such as action centers, functional sectors, operational roles, specific means and so on.

POLARISCO ONTOLOGY

In this work, we propose a modular ontology in order to capture the knowledge of the various stakeholders in a formalism reducible to a logic that expresses logical relationships between the different concepts, and to provide a foundation for semantic interoperability between diverse ERs. The aim is to ensure that all parties share the same extent of such derived information. That is, it aims to establish a common understanding of the shared information.

To build the proposed ontology, a methodology that guides and manages the development process is primordial. In fact, the efficiency of an ontology depends extremely on its development methodology. In (Karray et al., 2012), authors discussed the various methodologies proposed in the literature. In this work, we adopted METHONTOLOGY (Fernández-López et al., 1997) as a development methodology. According to (Corcho et al., 2003), it is the most mature approach to build an ontology. This methodology consists of five main steps of development activities: specification, conceptualization, formalization, implementation, and evaluation.

Specification

We started by identifying the purpose of defining this ontology. To do so, interviews were conducted with stakeholders and emergency experts so as to capture their needs and to analyze their experiences feedbacks. So, POLARISCO is a domain ontology built with the main goal of making the best possible definition of stakeholders' technical vocabulary. It was developed for establishing a common shared conceptualization that defines concepts and their relationships to support semantically interoperable information exchange among ERs involved in the process of operational disaster response. Afterwards, once the objectives are fixed, we used Competency questions (CQs) as a technique to define the ontology specifications. CQs consist of a set of question that the ontology must be able to answer (Grüninger and Fox, 1995). SO, POLARISCO should be able to answer the following defined CQs:
CQs1: When did the disaster [X] take place?
CQs2: Where did the disaster [X] take place?
CQs3: Who were the involved ERs in the intervention [X]?
CQs4: Who was the operational commander of the intervention [X]?
CQs5: Who was the public authority that commanded the intervention [X]?
CQs6: What were the acts of the intervention [X] of the ER [Y]?
CQs7: How many victims were resulting from the disaster [X]?
CQs8: What was the state of the victim [X]?
CQs9: What means were used in the intervention [X]?
CQs10: What are the available means?
CQs11: Where was located the action center [X] of the ER [Y]?
CQs12: Who are the sender and the receiver of the message [X]?
CQs13: What is the type of the message [X]?
CQs14: How many beds are available in the hospital [X]?

Regarding the diversity of ERs' vocabularies and process of intervention which may lead to a complexity during the knowledge conceptualization, we adopted the principles of modularization to build our ontology. Modularization is considered as a way to structure and organizing ontologies. Thus, the construction of a large ontology is based on the combination of self-contained, independent and reusable modules (D'Aquin et al., 2007). The main advantages of such a method, are manipulating smaller ontologies, reducing the complexity of ontologies development, and reusing each module independently. The idea is to develop separate ontological modules so that they could stand alone.
Then, to acquire knowledge about the field of disaster response, we conducted interviews with stakeholders of each EROs (firefighters, health care services, police, gendarmerie and public authorities) and we studied their technical resources and feedback documents to get specific and detailed knowledge about concepts, their properties, and their relationships. On the other hand, we studied many ontologies proposed in the field of disaster response to identify the needed terms including EMERGEL and RESCUER-EDXL, EDXL-RM (Resources Messaging), etc.

Conceptualization

In this phase, the domain knowledge is structured in a conceptual model. We first defined five modules to encapsulate the knowledge of the different involved stakeholders namely firefighters' module, health care services

module, police module, gendarmerie module, and public authorities' module. Then, we defined a message module to represent the needed knowledge to formalize information exchange among ERs and to improve communication capabilities. After that, we built a Glossary of Terms (GT) for each module by referring to the knowledge elucidated during the acquisition step. Terms include classes, properties, instances, and relations that exist among the different classes. As a matter of fact, we found that there are several terms in common between the stakeholders' defined modules which led us to define a core module named PCO (POLARISC Common Core). It englobes the general terms that all stakeholders share (for example disasters, transmission means, victims, etc.) in order to ensure more semantic interoperability between the modules and to facilitate their integration. Next, we selected an upper level ontology as a foundation that provide the most abstract upper level classes to define the more specific information. In (Elmhadhbi et al., 2018), several upper level ontologies have been discussed and we argued our choice of BFO as an upper-level ontology and CCO as a mid-level ontology. In fact, BFO (Arp et al., 2015) is a realist, formal and domain-neutral upper-level ontology, it is designed to represent at a very high level of generality the types of entities that exist in the world and the relations that hold between them. It is utilized as a starting point for the categorization of entities and relationships by more than 250 domain ontology including an ontology-based system used by the US army. As a starting point, BFO uses the term *entity* as a common representation of anything then there are two main division of the class entity: *Continuants* and *Occurrents* in a single framework as a top level distinction between entities. Continuants are entities that persist through time including three axes; objects (Material entity) or and spatial regions (Immaterial entities) as Independent continuant, functions and qualities as Specifically independent continuant and finally, Generically dependent continuant. Occurrents are entities that happen or develop in time such as process. BFO was then supplemented with a set of mid-level ontologies CCO (Rudnicki, 2016) which are the Information Entity Ontology, the Agent Ontology, the Quality Ontology, the Event Ontology, the Artifact Ontology, the Time Ontology, the Geospatial Ontology, the Units of Measure Ontology, the Currency Unit Ontology, and the Extended Relation Ontology.
So, in POLARISCO, classes of each module were classified according to BFO and CCO classes and properties. Figure 1 illustrates the structure of the proposed modules. The purpose behind the use of BFO and CCO is to provide a common ontological foundation for domain ontologies which describe the most general domain-independent categories of reality. It is advantageous to use a common upper layer of well-defined terms to develop the different modules since the ontology will be shared among the involved stakeholders. Indeed, the use of upper-level ontologies facilitates the alignment between several domain ontologies and enable interoperability between them. In other words, if the ontologies to be mapped are driven from a standard upper-level ontology, this will make the mapping task very easy. In addition, upper-level ontologies play the same role as libraries in software programming tasks. Once they are used, one could reuse the defined concepts and relationships and so as to inherit the inferencing capabilities furnished by them. In this way, developing a domain ontology is an easier task that requires less time than usual. Moreover, the aim is to avoid having several incompatible domain ontologies. The usage of upper-level ontologies for integrating information and sharing knowledge among heterogeneous sources has been motivated in various related works (Baumgartner and Retschitzegger, 2006) (Elmhadhbi et al., 2018).

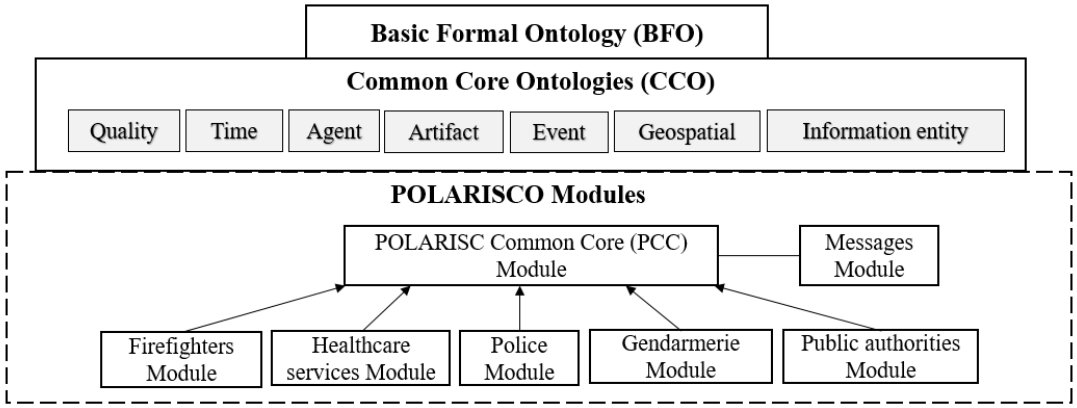

Figure 1. The different modules of POLARISCO

Formalization

After defining the modules and the related GT, in this phase, the conceptual model is transformed into a formal model by establishing relations between concepts. To connect the different concepts, we used a hybrid approach, based on a top-down alignment to the upper-level ontology BFO and the mid-level ontology CCO and a bottom-

up alignment to define classes of stakeholders' module and message module by reusing PCC module. That is to say, we approach in two ways by generalizing high-level concepts to lower levels and by abstracting the low-level data to the higher level concept. So, BFO and CCO are extended to define POLARISCO modules. In fact, CCO reuse the Relations Ontology (RO) (Smith et al., 2005) which is a collection of OWL2 relations intended to be shared among various ontologies. Moreover, another ontology called RO-Bridge has been developed by adding domains and ranges constraints to the object properties defined in RO to be used to relate BFO classes. The relations of RO-Bridge that are reused in POLARISCO are presented in table 1.

Table 1. The reused RO-Bridge relations

Relation	Domain	Range
"has_role"	Independent continuant	role
"has_quality"	Independent continuant	Quality
"supervises"	Person or organization	Person or organization
"has_participant"	Process	Person
"located_in"	Material entity	Spatial region or site
"occurs_on"	Process	Information entity
"is_part_of"	Independent continuant	Independent continuant

In the following, we represent first the various classes and their relationships of PCC module that will be reused to define each stakeholder module. Figures 2 illustrate a partial view of PCC module. Classes reused from BFO and CCO are marked with a prefix. Concerning the occurrent entities, we first defined a *disaster* as a *process*, it can be *natural* (earthquakes, floods, tsunamis, wildfire, tornadoes, etc.) or *human-made* (explosion, terrorist attacks, chemical threats, etc.). *Acts* are performed to manage disasters in an *action center* which is a sub-class of *spatial region*. ERs' acts are done as part of a real *intervention* or *training*. These two classes are integrated as a process. Concerning the continuant entity, an act is characterized by a *type* depending on the nature of the disaster. Furthermore, a *role* is accorded to each *organization member*. An organization member or an ordinary person can have the role of a *victim*. A *victim* is characterized by a *state*. In addition, *infrastructure* (hospitals and digital radio networks), *mean* (transmission mean such as radio or telephone) and *equipment* (beds) are defined as an *artifact*.

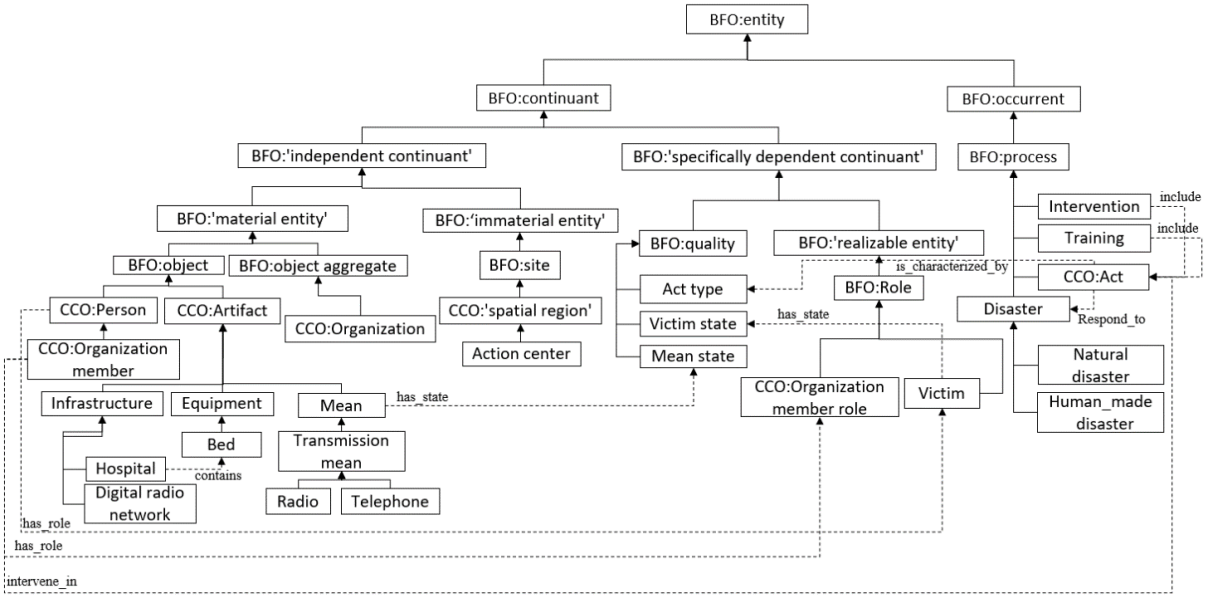

Figure 2. POLARISC Common Core (PCC) module

Concerning the stakeholders' modules, we formalized each one according to the PCC module. That is, we used PCC module as a starting point, and then we added the appropriate concepts related to each module. So, we defined the technical vocabulary of each ER (firefighters, health care services, police, gendarmerie, and public authorities) including mainly roles, commandment, and operational members, services, acts, means and their functions and availability, action centers, etc. Furthermore, we added the interventions' needs in terms of means and staff. Figure 3 shows a partial view of the stakeholders' modules.

Indeed, one of the principles to respect in building useful ontology is that any term of the ontology should be defined in a consistent manner (Arp et al., 2015). So, we defined annotation for each class (definition, the signification of the abbreviation, labels, etc.). Then, we defined relations that exist among the various modules and especially the equivalent classes. Each module has at least one relation with other modules. For example, the public authorities' module is linked to the rest of the stakeholders' modules with the relationship "supervises". That is to say, the interior minister supervises the commandment member of each ER. In fact, annotation and equivalent classes will have a key role later in the messaging service. Specifically, it will enhance communication capabilities and enable the transformation of the exchanged information from one stakeholder to another. So, each stakeholder will receive information according to his own vocabulary.

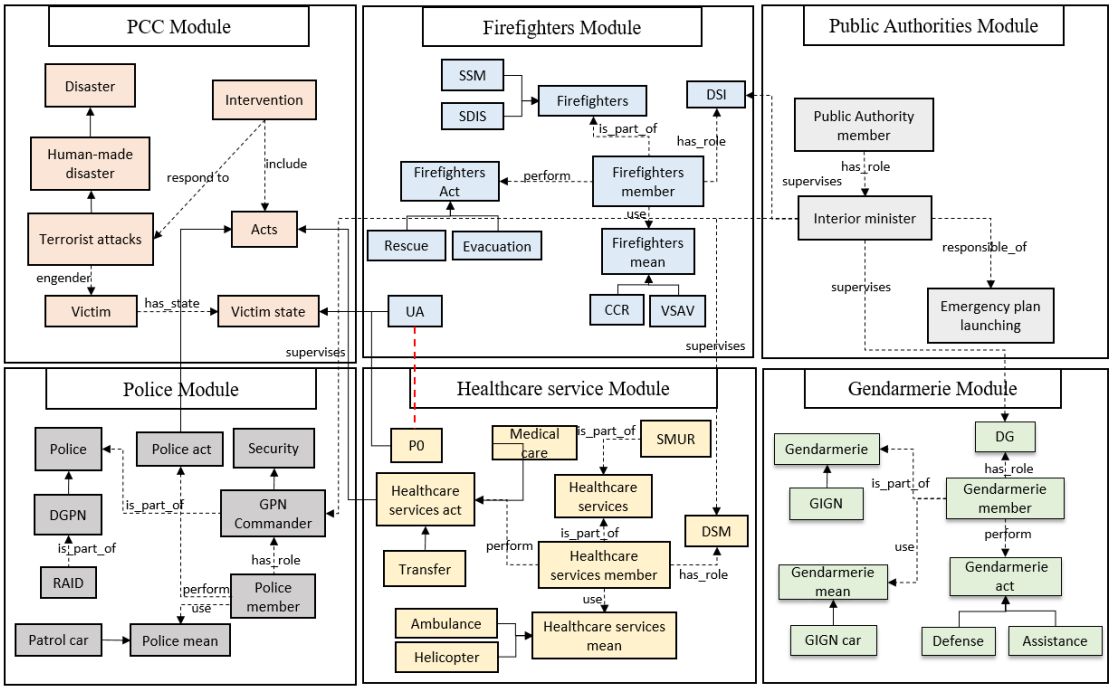

Figure 3. Partial view of stakeholders' modules

Concerning the message module, it is related to the PCC module and subsequently to the stakeholders 'modules. To defined it, we reused classes from PS/EM Communication Ontology (Chan et al., 2017). Authors were based on EDXL-RM (Emergency Data Exchange Language-Resource Messaging) standards. Figure 4 shows a partial view of the proposed module. The reused classes are marked with the prefix EDXL. We defined a *message* as an *information bearing artifact*. There are three different types of messages that could be exchanged among ERs; *informative message* (*information message*, *alert message*, *report message*, etc.), request message (*backup message*, etc.) and *response message (*a response message "is_about" a request message). In addition, a message is characterized by a state (*treated*, *untreated* or *ongoing*), a confidentiality (*public*, *private* or *limited*) and a degree of criticality of the information to be exchanged (*extreme*, *moderated* or *secondary*). Moreover, a message is identified by an *ID* and the same for *sender* and *receiver* which are defined as an *agent*.

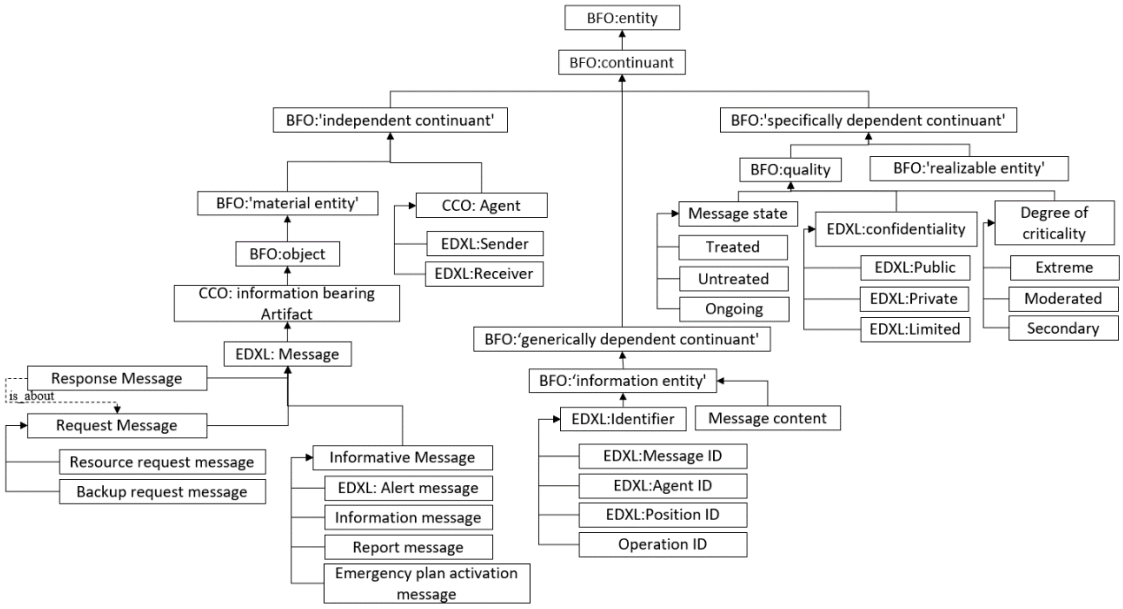

Figure 4. Message module

Implementation

The proposed formalization models are encoded in the ontology implementation language OWL and implemented using Protégé. It is an open source ontology editor and framework that propose a set of tools to construct ontologies. It facilitates the definition of classes, properties, and rules, visualization and reasoning. First, we reused BFO and CCO to build the PCC and message modules by utilizing the "owl: import" feature of OWL2. Second, we imported PCC to construct the stakeholders' modules. Then the different modules are merged together and integrated into one ontology "POLARISCO". Table 2 presents the classes and relations of the global ontology.

Table 2. Classes and relations of POLARISCO

Ontology	Number of Classes	Number of Relations
Developed ontology		
POLARISCO	447	25
Imported ontology		
BFO	27	-
CCO	195	152
Total	669	177

Evaluation

To evaluate the proposed ontology, from one hand, the consistency of POLARISCO modules was checked using the reasoner HermiT, which is an OWL2 reasoner included in Protégé. The aim is to ensure that the constructed ontology don't contain logical incoherencies or modeling issues such as contradictory relations between classes. On the other hand, to check if the ontology responds to the fixed specifications, we translate the CQs into SPARQL (Simple Protocol and RDF Query Language) language so as to query the ontology. To do so, the ontology was instantiated using feedbacks and documents of "Richter-65". It is an exercise of simulation of an earthquake in France which involves all the ERs.

One of the examples of the obtained results are presented in figure 5 to answer the following CQ: "Who are the operational commanders of the involved ERs in "Richter-65"?"

SPARQL query:

```
PREFIX rdf: <http://www.w3.org/1999/02/22-rdf-syntax-ns#>
PREFIX owl: <http://www.w3.org/2002/07/owl#>

PREFIX po: <http://www.semanticweb.org/linda/ontologies/2017/10/POLARISC1#>

SELECT    ?Rôle_de_commandememnt    (?Membre_des_pompiers as ?Membre)
WHERE {   po:Richter_65    po:commanded_by    ?Membre_des_pompiers.
          ?Membre_des_pompiers    po:has_role    ?Rôle_de_commandememnt.
          }
```

Rôle_de_commandememnt	Membre
COS	Jacquin
DSM	Durand
Directeur_GPN	MORVAN
DG	Lizurey

Figure 5. SPARQL query and result of the CQ

To summarize, we proposed POLARISCO, a modular ontology that define ERs knowledge and the needed information to ensure a semantically interoperable information exchange among stakeholders. It concerns firefighters, health care services, police gendarmerie and also public authorities. The modular conceptualization of the ontology enables its reuse as separate modules. One strength point of the development of the ontology is the fact that the process of collecting information, testing and evaluating the ontology was made referring to stakeholders. In addition, the designed ontology is validated by the emergency experts. POLARISCO will be used in English or French, we are working on labelling each class of the ontology in the two languages. The global modular ontology described in this paper is available in OWL format on GitHub: https://github.com/LindaElmhadhbi/POLARISC-Ontology.

CONCLUSION AND FUTURE WORK

In operational disaster response, there are various ERs from different EROs that potentially must work together towards a successful resolution of the disaster. However, communication is still ineffective since each ER uses his own technical vocabulary without realizing that they can be referring to different concepts. As a result, a different interpretation of data may happen that handicap the response process and cause slower decision making. To resolve semantic heterogeneity among ERs, there is an ample need to define the complex knowledge of the different stakeholders. Therefore, the purpose of this work is to come up with a common shared vocabulary in order to ensure semantically interoperability between ERs. So, we proposed POLARISCO, a modular ontology that enables semantically interoperable communication among stakeholders a comprehensive operational picture of the field. As future works, the proposed ontology can be extended to be used in the field of smart cities once it is aligned with existing standards and well-known models for smart city data. In addition, the ontology will be tested by means of a concrete use case to show how a communication act can be improved across different ERs and practitioner's feedbacks will be presented.

ACKNOWLEDGMENTS

This research was conducted as part of the POLARISC (Plateforme OpérationnelLe d'Actualisation du Renseignement Interservices pour la Sécurité Civile) project. It was funded by the regional operational program FEDER/FSE « Midi-Pyrénées et Garonne 2014-2020 » as part of the call for projects "Easynov2016".

ABSTRACT

Taxonomies are integral to systems engineering, as they structure our knowledge of a field and so provide the foundation for technological development. We contribute such taxonomies for the field of Community Interaction and Engagement in Crisis and Disaster Management, which represents the interface between members of the public who commit to relief efforts and established organisations that have a pre-defined role in crisis management. These actors are unified in their purpose to help those in need, but also set apart by their organisational structures and modes of operation. We classify the actors of Community Interaction and Engagement, as well as the interactions between them. Our contribution outlines areas where the application of Information and Communication Technology can offer benefits to Community Interaction and Engagement.

Keywords

information and communication technology, sociotechnical systems, crisis and disaster management.

INTRODUCTION

Citizens' behaviour in the event of a disaster or crisis has been subject to academic interest for decades. The earliest research on this matter dates back to the Halifax harbour munition explosion disaster (Prince, 1920). Later, the research conducted at the Disaster Research Center of the Ohio State University investigated the sociological and organisational aspects of the involvement of citizens in *Crisis and Disaster Management* (CDM). Especially the works of Dynes and Quarantelli and their classification of organisation types are still often referred to. Since the turn of the century, the introduction of global and ubiquitous *Information and Communication Technology* (ICT) provides affordable means of rapid coordination, resulting in new forms of cooperation. The emergence of volunteer groups, which independently organise and operate through online social media and digital communication services (Liao et al., 2016; Starbird and Palen, 2013; Twigg and Mosel, 2017), attests to the influence of ICT on CDM. Citizens can now react to an incident with great reach and speed (Palen and Liu, 2007).

For this paper, we denote as *Community Interaction and Engagement* (CIE) the confluence of such committed members of civil society and the established entities of disaster relief: emergency organisations, public authorities and civil defence. Citizens and communities have been overlooked as important actors in CDM, as the field was long considered subject to the sole command and control of governmental bodies or military forces (Dynes, 1994). Although communities of civil society and their efforts in crisis and disaster relief have long been part of the research discussed at ISCRAM, comprehensive taxonomy of their interactions with other actors has not been attempted. Addressing this gap in the existing body of literature, we propose two taxonomies, of actors and their interactions, to outline CIE.

As primary contribution, our description of Community Interaction and Engagement provides a basis for determining which interactions can be supported through ICT, and facilitates a profound design of technological systems to achieve as much.

ORIGINS

We draw on insights from our own research efforts as well as related literature. Two research projects were especially influential on this paper:

1) 'Resilience Enhancement by Advanced Communication for Team Austria' (RE-ACTA[1]), concluded in 2015, aimed to bring the structure and best practices of a successful national volunteer programme to new media. Outcomes suggested that the lateral information exchange among volunteers and their individual initiative should be considered when designing for CIE (Auferbauer et al., 2016; Auferbauer and Tellioğlu, 2017).
2) 'New media technologies in crisis and disaster management for enhancing the resilience of communities' (MEDIATOR), initiated in 2015, investigates the interaction between self-organising volunteers and the established organisations for crisis and disaster management in the context of the European migration crisis (2015). MEDIATOR focuses on interactions between formal and informal actors, as described from their respective viewpoints.

Both research projects follow(ed) an empirical approach that derives ICT for CIE through induction, based on the analysis of qualitative data from interviews and field observation. Representatives of formal organisations were involved in both projects, while unaffiliated and pre-registered volunteers participated in one project each. From RE-ACTA, we inferred a need to differentiate in more detail the various forms of volunteer engagement; a classification into 'emergency organisations' and 'volunteers' did not appear to sufficiently cover the actors of relief efforts. Data from MEDIATOR confirmed this by revealing well-organised and structured groups of volunteers that were active on a long-term basis outside the formal response system and beyond ephemeral actions of spontaneous groups. Ultimately, both projects prompted us to attempt a comprehensive taxonomy of interactions between the emergency response system and civil society as a foundation for the application of ICT in CDM.

RELATED WORK

A typology of factors that influence multi-agency coordination has previously been proposed to the ISCRAM community by Curnin and Owen (2013). Their typology describes attributes of successful communication for coordination; whereas our present work aims to map out the purpose and participants of interactions. We consider the two synergistic, as the work of Curnin and Owen can be applied to each of the interactions we detail herein. Further, communication structure, channels and content during incident response have been described in a detailed, scenario based manner (Eide et al., 2013); primarily considering information exchange within the formal emergency response system, but lending some concrete examples for parts of the abstract taxonomy presented herein. Liu et al. (2013) provide a comprehensive review of existing ontologies and their applicability for CDM; within their conceptualisation of subject areas, our present work would likely concern 'processes', for which the authors report no ontologies similar to the one proposed herein.

TAXONOMY OF ACTORS

In this work, we distinguish between actors based on their socialisation in the field of CDM, meaning their internalisation and incorporation of norms, values and social behaviours related to CDM. In Table 1, actors of CIE are shown in two categories, each ordered by increasing level of socialisation.

Together with established organisations, volunteers play an important role in relief efforts. However, the definition of 'volunteer' varies between organisations, context of activity and cultural background (Whittaker et al., 2015). As *unaffiliated volunteer* we define a person who is participating in relief efforts, but is not part of an organisational structure that has a predefined role or obligation in CDM planning. The unaffiliated volunteer acts outside of the formal crisis management system and has thus been referred to as 'informal volunteer' (Whittaker et al., 2015). The *pre-registered volunteer*, on the other hand, has signed up with a volunteer programme or platform (possibly managed by a formal organisation, see below) and has, as such, become part of an organisational structure (Neubauer et al., 2013). However, they have not entered a long-term membership association with a formal organisation for crisis management or disaster relief. *Affiliated supporters*, on the other hand, hold membership status with a formal CDM organisation, thus being subject to different obligations (e.g. mandatory training or adhering to the chain of command). They may be volunteers, receiving little to no monetary compensation for their contribution, or employed by the organisation they are members of, contributing as part of their gainful employment. Lastly, *affiliated decision-makers* are differentiated from

[1] http://www.kiras.at/en/financed-proposals/detail/d/re-acta/

affiliated supporters by being afforded enough authority through embodied cultural capital to make tactical or strategic decisions within the organisational structure. While these roles may be filled by volunteers, the term 'volunteer' traditionally has included primarily those that we have classified here as affiliated. However, unaffiliated volunteers and their consideration in crisis and disaster relief have increasingly gained attention (Barsky et al., 2007; Harris et al., 2017; Neubauer et al., 2013; Twigg and Mosel, 2017; Whittaker et al., 2015). They may be regarded as disturbance, as valuable resources or as critical factor for recovery, depending on the observer's viewpoint (Rogstadius and Teixeira, 2013).

Individual actors	
Unaffiliated volunteers	Persons intending to participate spontaneously in relief efforts without prior affiliation to formal emergency organisations.
Pre-registered volunteers	Persons who have signed up for a programme or initiative and conduct their activity within its organisational boundaries.
Affiliated supporters	Persons who have membership status in a formal CDM organisation, who conduct their activity along its organisational structure.
Affiliated decision-makers	Persons who have membership status in a formal organisation, who are afforded decision making in its organisational structure.
Composite actors	
Emergent groups	Formed through the self-organisation efforts of persons as reaction to a crisis or disaster event.
Supporting organisations	Established organisations that participate in relief efforts, but do not engage in such activity as part of their regular operations.
Formal CDM organisations	Established organisations whose regular objectives include crisis and disaster management activities.

Table 1 Taxonomy of Actors in Community Interaction and Engagement (Summarised)

Individual actors, as they are outlined above, can form compound entities with a complex organisational structure. Most prominent among these are the established *formal CDM organisations*, whose regular functions include responsibilities in disaster relief. Emergency organisations, humanitarian aid agencies, civil defence and public authorities all have a pre-defined role in CDM; legally and socially, though their involvement and role varies based on cultural context. Their capacity and contributions are included in *a priori* planning. They rely on organisational structures, hierarchies and formalised procedures that have existed before the onset of a crisis, comprising the formalised side of CDM.

When unaffiliated volunteers coordinate to address perceived issues, emergence of organisational structure can follow, in the sense of institutions (Berger and Luckmann, 1967). *Emergent groups* form their own identity as a collective and build organisational structures to varying degrees of complexity. They are institutions *in status nascendi* and become more than a simple gathering of unaffiliated volunteers. Emergent groups may be organised with little vertical hierarchy, later developing more formal hierarchies and division of labour. We define emergent groups as a collective of individuals that has formed an organisational structure after the onset of a crisis or disaster, with the purpose of meeting challenges posed by the causal event. As with unaffiliated volunteers, emergent groups operate outside of formalised CDM system and often find no consideration in the planning of response efforts. For an in-depth discussion on the topic of emergent groups, we refer the reader to Drabek and McEntire (2003) as well as Twigg and Mosel (2017).

There are communities within the public whose structures have existed before the onset of the event, but were not established for CDM. These *supporting organisations* take on tasks that fall beyond their usual scope of activity to support relief efforts and keep their internal structures intact while doing so. Whittaker, McLennan and Handmer (2015), as an example for this type of organisation, note Four Wheel Drive clubs organising caravans, transportation and clearing debris in a bushfire event. Our classification closely follows the typology of organisations formulated by Dynes and Quarantelli (1976): formal organisations, supporting organisations and emergent groups correspond to Types I, III and IV, respectively[2]. Transcendence of this typology has been suggested (Drabek and McEntire, 2003; Schmidt et al., 2018), but lies outside the scope of this work.

[2] We have not explicitly included Type II as actor; we consider this to be constituted implicitly through formal organisations managing pre-registered volunteers and expanding in this manner to provide surge capacity.

TAXONOMY OF INTERACTIONS

In the context of CIE, we only consider such interactions as happen between an actor within the organisational system – c.f. (Luhmann, 1995) – of a CDM Organisation and one without. Further, we include those interactions that occur among individual volunteers, emerging organisations and supporting organisations. This excludes the interactions between actors within the organisational system of one or more formal CDM organisations. The taxonomy of interactions thus defined is summarised in Table 2 and described in detail below.

	Category	Functions
A.	Contribution	*Co-creating, Crowdsourcing, Crowdtasking*
B.	Dissemination	*Warning, Preparation & Education*
C.	Experience	*Telling Stories, Sharing Knowledge, Feedback*
D.	Coordination	*Awareness, Orchestration, Intermediation*
E.	Personalisation	*Reception, Personal Mobility, Acknowledgement*

Table 2 Taxonomy of Community Interactions

A. Contribution

Under 'Contribution', we classify interactions to elicit action or information from other actors.

Co-creation

In the context of commerce, (autonomous) co-creation was defined as process where 'individuals or consumer communities produce marketable value in voluntary activities conducted independently of any established organisation, although they may be using platforms provided by such organisations' (Zwass, 2010). The resulting marketable value may be placed in commons, universally shared and accessible to all. The information flow in co-creation is that of all-to-all, whereby every participant eventually has access to the information provided by any other participant. Geiger et al. (2011) classify these interactions as '[i]ntegrative sourcing without remuneration'. When we consider 'marketable value' as being information relevant to crisis management, Zwass' definition represents an approach that is popular in the CDM context. Online social networks, Micro-Blogging platforms and messengers have been successfully used to gather and share relevant situational information (Alexander, 2014; Palen et al., 2009; Vieweg et al., 2010). Support for this activity has previously been considered a worthwhile goal for community infrastructure designed specifically for CDM (Wu et al., 2008). Similarly, many platforms for Volunteer Geographic Information (VGI) are based on co-creation (Haworth, 2016; Meier, 2012). The actors involved in co-creation are primarily unaffiliated volunteers, as both producers and consumers. Formal organisations may also benefit from becoming consumers of such information, if they have the capacity to do so (Alexander, 2014; Haworth, 2016; Simon et al., 2015; Tapia et al., 2011).

Crowdsourcing

This term encompasses a wide variety of approaches, whereby one sourcing actor elicits contributions from a 'crowd' of actors (Geiger et al., 2011). In differentiation to co-creation, the sourcing and contributing actors do not necessarily share peer status in this interaction. Not every actor in the system necessarily has the authority to source for contributions. Similar to co-creation, Wu et al. have also found this type of interaction to be a goal in the design of their Community Response Grid (Wu et al., 2008), though they restrict the applicability of this interaction to incidents that are critical neither in time nor severity. Tapia *et al.* have previously discussed crowdsourcing in the context of citizen science and how this approach can benefit CDM through event detection (Tapia et al., 2014). An example of crowdsourcing in CDM is provided by GDACSmobile, where the submission of relevant information is elicited by enabling a mission space for contribution by any member of the crowd. The manner of contribution is at the discretion of the participant, i.e., which information they submit is decided by their notion of what is important. Information submitted by untrusted volunteers is vetted by a central agency before being re-released to all users (Link et al. 2013, 2015). For an in-depth discussion on sourcing in the CDM context, we refer the reader to Liu's comprehensive crowdsourcing framework (Liu, 2014).

Crowdtasking

To elicit contribution through crowdtasking (Neubauer et al., 2013), a central entity sends a request for specific

information to a selected group of participants, qualified through their skill, experience, or physical location. Crowdtasking is a one-to-many interaction that does not necessarily make contributions available to the crowd. In contrast to crowdsourcing, this interaction usually employs micro-tasking to request specific action and does not allow the submission of information on the crowd's initiative[3]. The crowdtasking concept lends itself to a form of interaction oriented towards the Command and Control paradigm, such as between formal organisations and pre-registered or affiliated volunteers (Auferbauer et al., 2016; Auferbauer and Tellioğlu, 2017). The interplay of the examples we have given for crowdsourcing and crowdtasking in the CDM context has been previously discussed (Middelhoff et al., 2016).

B. Dissemination

The dissemination of information that is relevant to health and safety of citizens in a crisis or disaster represents an exchange between formal organisations and the public as well as unaffiliated and pre-registered volunteers. Whereas in many types of crises and disasters the active involvement of helpers delivers substantial benefits while hardly imposing any limitations on their engagement, there are clearly situations in which their participation should be carefully tailored to the situation on the ground due to concerns for their safety and wellbeing in the context of a dynamically developing situational picture. Technical means of one-to-many (i.e., multicast) or one-to-all (i.e., broadcast) communications are required to inform, warn or alert the potentially affected persons about the prospective or imminent dangers. The quality of such communication is an important factor in building community resilience (Cohen et al., 2017).

Alarming

It is imperative to reach all the potentially affected persons while minimising disturbances to all unaffected persons who should not be bothered with unsolicited information (Collins et al., 2009). Traditionally, societies around the world have been relying on public radio and TV broadcasting and on siren networks in order to warn or alert their citizen about potential public safety-relevant dangers, whereas in recent years SMS, cell broadcast and mobile apps have been added to the portfolio of potential information channels (Gojmerac et al., 2016; Preinerstorfer et al., 2017). These technological advances allow crisis managers to make citizens aware of potential danger in a fine-grained, context-aware manner, alarming only those persons that would potentially be affected, while still increasing the coverage and reach of the dissemination of critical information. Citizens in large urban areas, for example, may be more reliably reached through their phones than via sirens, due to noise pollution and demographic factors (Gojmerac et al., 2016).

Preparation and Education

In the same manner as new ICT allows for a tailored dissemination of critical information in the response and recovery phase of a disaster, so does it also afford crisis managers new ways to prepare and educate citizens in between crises and disasters. The dissemination of information regarding environmental hazards to the local population has been argued to contribute to reducing the vulnerability of both individuals and society, due to an association between a person's risk perception and their disaster preparedness (Helsloot and Ruitenberg, 2004; Miceli et al., 2008). Social networks, multimedia content and web sites provide opportunities to engage citizens, e.g., in public health efforts (Merchant et al., 2011). A wide variety of smartphone applications are already targeted at providing educational material to citizens (Bachmann et al., 2015). Contemporary ICT could be used to further tailor and personalise the disseminated information to the needs and context of the recipient, as well as monitor their perceived and actual level of preparation.

C. Experience

The exchange of personal experience among actors is a category of interaction that serves multiple distinct purposes, depending on recipient and intent of communication.

Sharing Knowledge

The content transmitted during knowledge sharing includes best practices and lessons learned regarding the

[3] We consider this sufficient differentiation between crowdsourcing and crowdtasking. However, the two are undeniably related: crowdtasking has been classified based on Liu's crowdsourcing framework (Liu 2014) by Auferbauer *et al.* (Auferbauer et al. 2016) and further fits the type of crowdsourcing process that Geiger *et al.* defined as 'selective sourcing without crowd assessment' (Geiger et al. 2011).

originating actor's past activity in their respective roles and fosters the collaborative learning of practically relevant knowledge, pertaining to disaster management processes themselves. The information flow in this activity is considered many-to-many; shared knowledge is accessible to all participants of the information system. Supporting this function for emergent groups and unaffiliated volunteers may require different approaches than knowledge management in formal organisations. Due to the high volatility of emergent groups, Majchrzak et al. (2007) suggest that a Transactive Memory System for such entities likely consists of links between tasks that are required and the skills needed to perform these tasks, rather the currently supported links between person and expertise. As the formation of a knowledge base and sharing mechanisms is a normal social process during institutionalisation, it will be necessary to determine the viability of ICT support during the different phases of formation.

Telling Stories

Storytelling is an emotional way of sharing knowledge and creating interpersonal social reality. People connect to common narratives by talking about episodes through the filter of their socialisation. The psychosocial component to cope with distress is important, considering that volunteers are prone to higher mental health impact after volunteering in disasters (Thormar et al., 2010). The content of information exchange shifts, from purely practical subject matter, to experiences that have been stressful for the participant or accounts of their current situation. Participants in our interviews during MEDIATOR have stated that such exchange gives them the feeling of not being alone in their efforts, that their activity is not futile. One participant told us how regular exchange regarding their group's activity has become 'a form of self-help'. Representatives of formal organisations in our group discussions have shown awareness of the importance of this function. They report having established dedicated (digital) points of contact where volunteers can submit accounts of their experiences, and that this feature has found heavy use. Telling stories can either be done via many-to-many interactions, e.g., via a public forum (digital or physical), or in the form of many-to-one submissions of accounts to one actor. Said actor may then selectively disseminate stories they receive to the public.

Feedback

Giving feedback is a one-to-one information exchange, where an individual volunteer submits an account of their experience to a formal organisation. This is intended to either provide emotional relief (regarding an experience that occupies the mind of the volunteer), or to improve the work of the formal organisation (as perceived by the sender). It is differentiated from knowledge sharing and telling stories by being targeted at one specific actor and the subject matter being not necessarily applicable or relevant to actors not involved in the exchange.

D. Coordination

Coordination has been defined as 'the act of managing interdependencies between activities performed to achieve a goal' (Malone and Crowston, 1990) and interpreted as the arrangement of tasks for cooperation through organisation of activity that prevents loss of communication and efforts (Fuks et al., 2008). Solutions for coordination aim to facilitate that actions are planned and conducted in such a way that they utilise the synergies between them and avoid redundant activities in the pursuit of a common purpose.

Awareness

It has been accepted for more than two decades that awareness of participants' activities is critical to cooperation, as far as computational support is concerned (Dourish and Bellotti, 1992). In the context of CDM, that means awareness regarding relief activities of other helpers, capabilities of actors (such as time to deploy, number of personnel and available equipment) and their know-how as well as their organisational structure (so far as it is relevant to coordination). This function becomes especially important when considering interactions between emergent groups and formal organisations: due to the volatile nature of emerging structures, it is difficult for other actors to keep track of their formation and establish contact with the right liaison. During group discussions in project MEDIATOR, formal organisations have reported difficulties when trying to establish communication with emergent organisations, because they were not aware of qualified[4] points of contact. Further, we found that formal organisations would appreciate more awareness regarding the presence and activity of individual, unaffiliated and pre-registered volunteers, to prevent them from overworking

[4] Qualified, in this case, does not necessarily mean that the liaison is in charge or speaks for all the group, but they need to have enough internal standing to act on information. This is particularly true for groups with less vertical hierarchies.

themselves and burning out; volunteers were reported to do shifts that sometimes span multiple days. Considering this, we feel that ICT could contribute through e.g. the concept of awareness by shared feedback: the ability to passively monitor other's action, through continuous and automated status updates, allows the tailoring of one's own contribution and elicits response (Dourish and Bellotti, 1992).

Orchestration

Actors that 'understand' each other, in vocabulary and manner of organisation, can use the same communication channels to work towards a common goal and coordinate *ad hoc*. Orchestration has been investigated as happening between unaffiliated volunteers, resulting in emergent groups. Starbird and Palen (2013), for example, have reported on the work of the initiative 'Humanity Road', consisting of digital volunteers, which was orchestrated to support relief efforts by information processing. This initial orchestration has resulted in an organisational structure with formalised activity and processes. Another example of orchestration has been noted by Kaufhold and Reuter (2016) when they discussed the role of a 'moderator', filled by unaffiliated volunteers, who used social media to mediate supply and demand and to organise other volunteers. They further remark that coordination with formal organisations, in contrast, did not work through social media, which suggests a need for intermediation (see below). For a more in-depth investigation into orchestration, we refer to the publication of Liao et al. (2016).

We would remark that the endeavour of providing a specialised ICT solution for orchestration in CDM likely yields a questionable ratio of benefit to effort when unaffiliated volunteers are involved. In our current research on project MEDIATOR, we found that volunteers can well organise mature organisational structures for orchestration of work within large groups, without the help of specialised ICT solutions. Contemporary online social networks and messengers are sufficient for this purpose and indeed are preferred due to their familiarity. Such observation is in line with works that have reported on volunteer's creative appropriation of technology (Starbird and Palen, 2013; Voida et al., 2015) and social media being well suited for the purpose of volunteer collaboration in disaster response (Waldman and Kaminska, 2015).

Intermediation

Intermediation focuses on bridging the gaps between actors that do not share common communication channels, vocabulary or organisational structure - i.e., cases where interoperability is low. It is not so much the task of coordinating actors in their cooperation towards a certain goal. Rather, intermediation aims at establishing a common ground that makes coordination and cooperation viable in the first place. Such intermediation can contribute specifically to the relation and interaction between unaffiliated volunteers, emergent groups, supporting organisations and formal organisations - actors who follow different organisational structures and are likely diverse regarding their regular activity outside of crisis or disaster situations. Research on a platform to match reports of displaced and found pets in the aftermath of a disaster (Barrenechea et al., 2015) is one example of intermediation through ICT. By providing an appropriate data structure and pulling data from social media into the platform, information is made more accessible to formal organisations (shelters) and exchange is facilitated.

In intermediation, social media channels alone appear to be of limited applicability. While they work well as tools for volunteers to orchestrate efforts with their peers, formal organisations have as of yet not institutionalised them for two-way communication (Alexander, 2014; Simon et al., 2015; Tapia and Moore, 2014). An approach to intermediation that is not primarily technological in nature is postulated by Zettl et al. (2017), who discuss the role of emergent organisations as intermediaries between spontaneous volunteers and emergency organisation.

E. Personalisation

The transitory and self-motivated involvement of citizens (Hustinx and Lammertyn, 2003) requires affordance of greater mobility, regarding the manner of participation.

Reception

Receiving (convergent) helpers is an interaction between formal organisations and unaffiliated volunteers. Due to the problems posed by convergence of people and goods (auf der Heide, 2003; Whittaker et al., 2015), unaffiliated volunteers may come to be seen as a complication, rather than a potential asset (Rogstadius and Teixeira, 2013; Skar et al., 2016). To mitigate this, solutions are required that support formal organisations in the reception of unaffiliated volunteers, while at the same time providing these helpers with information and

guidance. Arriving volunteers will be looking for information on the local situation and where to best apply their efforts. Formal organisations need to register arriving unaffiliated volunteers, to file their skills, capabilities and contact data, as well as to fulfil possible legal obligations. The On-Site Operations Coordination Centre by the United Nations Office for the Coordination of Humanitarian Affairs or the Volunteer Reception Center of the US Federal Emergency Management Agency address the reception of incoming helpers (relief organisations and volunteers, respectively). There have been no investigations into the viability of a digitalisation of this interaction, though the development of such a virtual reception centre could prove helpful (Waldman and Kaminska, 2015).

Personal Mobility

Considering the transitory activity of unaffiliated and pre-registered volunteers, we see an opportunity for ICT to contribute by providing digital identification of helpers' skills, know-how and experience. This function offers a transfer of information from individual, pre-registered or affiliated volunteers towards multiple formal organisations with the goal of quickly signing up for relief activities via an established volunteer identity. Using the concept of cultural capital according to Bourdieu (1986), this means a symbolical representation of embodied cultural capital (of experience and know-how in CDM), potentially transferring it to an institutionalised state.

From an organisational perspective, this means the establishment of a meta-organisation that issues verification of volunteer data. From a technological perspective, such an infrastructure will require a data format and storage option for volunteer data and experience that offers high usability to the volunteer on one hand and meets the standards of formal CDM organisations on the other. We are currently not aware of any such format being widely accepted in CDM. A digital persona of the volunteer could be established at the initial registration (during reception, see above) and stored locally on volunteers' smart devices. From that point, it would be available to returning volunteers as rapid form of 'checking in,' acting as identification and verification. However, the establishment of a persistent digital identity immanently brings with it issues regarding privacy and social impact, potentially leading to discriminative treatment of volunteers based on their past activities.

Acknowledgement

Acknowledging volunteers for their activity stands to reason as being a motivating factor in their engagement – c.f. (Liao et al., 2016). This may be achieved through acknowledgement and showing appreciation (Kriplean et al., 2008), highlighting the importance of a task for common goals (Zhu et al., 2012) or the impact it has on relief efforts (Voida et al., 2015). Our findings from group discussions with formal organisations show that they would appreciate a way to say, 'thank you' to volunteers, while interviews with members of volunteer groups suggest they draw motivation from acknowledgement by peers and formal organisations. Technological support for this interaction has not been extensively addressed. Providing a persistent digital persona for volunteers (see above) could enable such feedback and credit for the contributions of pre-registered and affiliated volunteers.

DISCUSSION

Methodological Considerations in Taxonomy

As Nickerson et al. (2013) have pointed out, the development of taxonomies for information systems has mainly followed an *ad hoc* approach, relying on the researchers' intuition for classification. We must count our present work among them. The taxonomy proposed herein, the dimensions and characteristics it uses for differentiation, have grown over the course of several research projects, instead of being established through a formalised methodology. Further, our classification of actors and interactions could be likened to a typology, based on sociological assumptions regarding volunteers and societal factors, rather than a taxonomy (Smith, 2002). However, Nickerson and colleagues also argue that 'a taxonomy is useful if others use it' and when it allows for observations that were not possible before. Our present work is intended to serve as basis for discussion and guidance – if it serves this purpose, which we are convinced it will, then it offers utility. Nevertheless, we aim for a formal taxonomy development approach in future work on this taxonomy.

On the Classification of Actors

In our taxonomy of actors, we have used as differentiating factor their socialisation in the field of CDM, internalised in the form of long-lasting dispositions. This differentiation is not discrete. Rather, it is a continuum along the axis of the internalisation of the norms, values and social behaviours in CDM. This represents the

degree to which a person's perception, thought and deed are shaped and changed through identification with the field. Such classification draws inspiration from what Bourdieu has termed '*habitus*' – the key between individual behaviour and the social structure of a field, formed through learning processes specific to the field (Kieserling, 2008). Also from Bourdieu (1983) comes the concept of cultural capital, which, in its embodied form ('*Inkorporiertes Kulturkapital*'), becomes part of a person and thus habitus. When we say that socialisation in CDM is used as the distinguishing attribute, we refer to the actor's embodied cultural capital in this field: their attained and incorporated knowledge regarding such things as, e.g., nomenclature, organisational structure, forms of cooperation or processes being followed.

Conversely, the differentiation between affiliated supporters and affiliated decision-makers could arguable be made based on *institutionalised cultural capital* instead, such as, e.g., titles, rank or certifications, which can be used societally to determine the cultural competencies of a person. Such symbols are canonical and confer a different kind of cultural capital than the embodied form, i.e. 'the capital of the auto-didact, which may be called into question at any time' (Bourdieu, 1986). The circumstance that these symbols likely hold more value in a hierarchical context (such as most formal CDM organisations) than they would in emergent groups, where social capital potentially plays a larger role, suggests segmentation of the field (Anheier et al., 1995). A more thorough examination of actors in CIE through the lens of Bourdieu's theories appears an intriguing prospect for future work.

Lack of Multi-Dimensional Representation

Any eventual taxonomy of CIE that aims to model a substantial part of interactions will necessarily be of multi-dimensional character; for classifying both actors and interactions. We expect distinctions to be added on multiple levels to the one-dimensional classifications in this paper. Given that the present work follows from research that is empirically disposed, space and time would be obvious candidates in the light of transcendental idealism. A spatial dimension may be introduced by differentiating between 'on-site' and 'virtual' actors (also: 'online' or 'digital'); such as in the case of volunteers (Kaufhold and Reuter, 2016; Schmidt et al., 2018; Starbird and Palen, 2013). Introduction of a temporal dimension may be based on the phases of the disaster management cycle; to differentiate in more detail the interactions we have presented. Further, our classification of interactions is based on the primary intent under which actors use ICT for interaction. It does not consider latent social functions of interactions; such as building trust (Hughes and Tapia, 2015), persuading actors (Vineyard et al., 2012) or building new structures (Liao et al., 2016).

Global Applicability

From a constructivist point of view, we consider it important to note the cultural preconceptions that influence this work. Related literature we have considered is primarily published in Anglo-American and Western European venues and written in English, which is relevant both due to the cultural context from which data was drawn and when considering that the language being used itself exerts an influence. Cultural differences will, without doubt, affect the applicability of our taxonomies and any eventual technological framework based on them.

CONCLUSION

There currently exists no comprehensive, systematic description, classification or taxonomy of Community Interaction and Engagement (or any otherwise named domain with a comparable definition). Because taxonomies are integral to systems engineering and provide the foundation for technological advances by structuring our knowledge of a field, we address this gap to facilitate future development of ICT. As the primary contribution of this work, we have provided two taxonomies for the context of CIE: one that classifies its actors and a second that classifies the interactions between them. They shall provide the reader with an improved understanding and overview of the different types of interaction in CIE and offer an outline for potential contributions through ICT.

ABSTRACT

Emergency response organisations struggle with resource constraints and thereby faces challenges in providing high-quality public services. Utilising voluntary first responders is one way to address these challenges. There are different types of volunteers who can help at an emergency site, e.g. citizen volunteers or voluntary professionals from other occupations. To successfully engage with and utilise these resources, adequate information and communication technology (ICT) is necessary. In this meta-study, combining and further exploring two previous studies, the aim is to identify, analyse and evaluate suitable functions for smartphone applications that can be used to dispatch and support volunteers. The results show that the functions can be divided into essential ones that are necessary for the response to work at all, and others that might contribute to a more effective response. The study also shows that the same functions can be used for different volunteer groups.

Keywords

Voluntary emergency response, ICT, smartphone application, end users, co-production.

INTRODUCTION

In many countries, high public demand and decreased budgets make it difficult to maintain proper service levels for emergency response. In rural areas, professional first responders are supposed to serve geographically large jurisdictions, while in urban areas few responders often serve large populations. When distances become longer, and available rescue personnel are scarce, nearby volunteers might be dispatched to emergencies to provide assistance before professional responders arrive, potentially saving lives and mitigating damage. Previous research has highlighted the need for more studies concerning onsite volunteers (Schmidt et al., 2018) and pre-planned and long-term collaborations with professional emergency response (Diaz et al., 2016; Johansson et al., 2018).

Two emerging types of pre-planned and onsite volunteers as first responders are citizen volunteers and semi-professional volunteers, who respond to local accidents or medical incidents in collaboration with the professional emergency services (police, fire, emergency medical services). Citizen volunteers can be neighbours helping each other in their village or residential area. Thus, they have no formal organisational affiliation (Jaeger et al., 2007; Linders, 2012; Venema et al., 2010; Whittaker et al., 2015). Voluntary semi-professionals on the other hand are employed, or paid, by some level of government (typically local, e.g. municipal) to take on additional tasks in emergency response (SOU, 2018). Thus, they have their regular full-time employment and add on the new responsibility as a first responder (Sund and Jaldell, 2018; Venema et al., 2010). Semi-professionals can be seen as a kind of volunteers, just like citizen volunteers. Even though they perform their new tasks as part of their employment, in most cases it is not mandatory to accept the new duties and it is always up to themselves if they want to respond to an emergency or not. These two emerging types of

volunteering can be viewed as co-production of public services (Alford, 2014; Ostrom, 2016). Volunteering have also been referred to as "do-it-yourself government" as an emerging culture within public services (Linders, 2012; Venema et al., 2010). Although co-production seldom focuses on the information and communication technology (ICT) artefact, current public-sector trends all have modern ICT as an enabler. However, the existing infrastructure for emergency dispatch (e.g. radio) is often not convenient or available to voluntary first responders (due to e.g. organisational hindrances and legal obstacles) (Ramsell et al., 2017). Therefore, new ICT solutions become necessary in order to coordinate their emergency response work with professional first responders.

Many initiatives utilising the new resources have opted to use smartphone-based solutions (e.g. Gomez and Murray Turof, 2007; Ringh et al., 2011). However, studies have shown that developing and using these includes a number of unsolved challenges, e.g. identifying suitable functions based on end-user needs (Havlik et al., 2016; Roberts et al., 2014; Schönböck et al., 2016). This perceived knowledge gap is addressed in this study. In addition, earlier studies (Mojir et al., 2018; Ramsell et al., 2017) indicate that basic needs for such resources, such as training and equipment, are often similar for different voluntary groups, but research to establish whether this is also true for the specific ICT artefact is needed.

Study Aim

The aim of this study is to:

- Identify and evaluate suitable functions of an ICT artefact in the form of a smartphone application, based on end-user involvement (the volunteers).
- Explore whether the same ICT functions, can be used for different volunteer groups.

The study is a meta-analysis, built on two previous case studies analysing and identifying both general needs and ICT needs of two different volunteer groups: citizen volunteers and semi-professional volunteers. Both take place in the context of Swedish emergency response. However, since many basic tasks in first response are similar at an international scale, the results are also discussed in a wider emergency response context. For instance, the existing research on specific platforms and applications for volunteers in disaster management (e.g. de Lanerolle et al., 2010; Schmidt et al., 2018) may benefit from this study's contributions.

THEORETICHAL CONTEXT: CO-PRODUCTION AND USING VOLUNTEERS AS FIRST RESPONDERS

Voluntary engagement that is informal yet conducted in collaboration with professional response is described using different terms in the literature. For instance, Whittaker et al. (2015) highlight "spontaneous organisation volunteers", Diaz et al. (2016) use the concept of "citizens as agents", and St. Denis and Hughes (2018) report on an online application used with "trusted volunteers" of emergent community groups. Thus, to define the two voluntary groups in this study – citizen volunteers and semi-professional volunteers – we use a broad definition: "volunteerism refers to the activities of people who work outside of formal emergency and disaster management arrangements to help others who are at risk or are affected by emergencies and disasters" (Whittaker et al., 2015:361).

At a societal level, it is possible to see a shift in public service delivery, and emergency response specifically, where communities, citizens and other professions are increasingly involved in first response. Here, the exchange of resources, non-hierarchical patterns and social relations are some of the keywords among different types of actors united in the common endeavour of providing more effective and flexible public services (Agranoff and McGuire, 2010; Börzel, 1998). These kinds of collaborations are usually described by network concepts such as collective action (e.g. Carlsson, 2000), collaborative networks (e.g. Agranoff, 2006) and network governance (e.g. Loukis, 2016). A common denominator is the necessity of ICT in the networks, whereby ICT "helps connect various actors to the network, build relationships between them, […] and manage[s] and sustain[s] the networks themselves" (Janowski et al., 2012:52).

Building on the network context, the concept of ***co-production*** can be used to more specifically describe different actors' involvement in public-service delivery, e.g. volunteers. With digitalisation, the possibilities to co-produce have increased (Linders, 2012). For instance, nowadays almost everybody has a smartphone that can be used for advanced information exchange and coordination. According to the definition, co-production is "the process through which inputs used to produce a good or service are contributed by individuals who are not 'in' the same organization" (Ostrom 1996: 1073). Alford (2014) mentions one example of co-production in which a Fire and Emergency Services organisation expanded the role of residents to include performing different preventive tasks aimed at protecting "life, property and the environment" (Alford, 2014:302).

In this study, ***ICT-facilitated co-production*** is used as a concept to describe volunteers' involvement in emergency response. Specifically, two different types of voluntary co-production initiatives are in focus. ***Semi-professional volunteers*** refers to persons who, as part of their professional work, volunteer to act as first responders. ***Citizen volunteers*** refers to citizens taking over certain tasks from the authorities for themselves and their co-citizens, creating a "do-it-yourself government" (Brandsen et al., 2018; Diaz et al., 2016; Linders, 2012). While volunteer engagement has been studied using various network perspectives from different research disciplines – including co-production – the perspectives have in common that they seldom focus on the ICT artefacts, but rather on politics, policies, values, economic and welfare aspects. (Agranoff, 2006; Carlsson, 2000; Janowski et al., 2012; Loukis, 2016). Regardless, the technology is a prerequisite for the phenomenon in the first place; if the ICT does not work adequately, volunteers cannot be dispatched to act as first responders.

Earlier research emphasizing the ICT artefact for volunteers in emergency and disaster response often focus directly on the technical solution and general evaluations of the solution, while the process by which it is reached is seldom explored in detail (e.g. Ferguson et al., 2016; Ringh et al., 2011). We have not managed to find earlier research where the users' perception is central, what their actual needs and requirements are. In some studies it is possible to receive information about identified functions even though this is not the core focus of the studies (see Table 1.). Thus, here we believe that our study can make a significant contribution. In order to enrich previous research, it focuses on the ICT artefact in a co-production context, and how it should be realised in order to be useful for various types of volunteers.

METHODS

This study is a meta-analysis of two earlier case studies of volunteer engagement in emergency response (Mojir et al., 2018; Ramsell et al., 2017). The former took a broader perspective, encompassing the overall collaborations, including training, equipment, legal issues and also specific needs for ICT, but without a thorough analysis or evaluation of the functions of an ICT solution. Therefore, we now focus on the functions identified and implemented in a prototype smartphone application, and explore it in relation to the two voluntary groups, i.e. the semi-professionals and the citizen volunteers.

Study Context in the Separate Cases

The two previous studies here can be described as exploratory, referring to case studies that explore emerging phenomena (Flyvbjerg, 2006).

Case 1 was the development of the concept of ***semi-professional*** first responders in the municipality of Norrköping (a medium-sized municipality in south-east Sweden). The project ran from 2015 to 2017. The purpose of the project was to identify, analyse and evaluate potential first responders who could support the professional first responders, e.g. by extinguishing small fires or performing first aid. An additional purpose of the project was to identify their needs for training, equipment and ICT support. There was no existing organisation or infrastructure at project start. Therefore, a prototype smartphone application for semi-professional first responders was developed. Four different professional groups were analysed: security guards, home-care personnel, municipal facility service personnel and day personnel at the fire and rescue services (FRS). Finally, day personnel at the FRS were selected as voluntary first responders in the project. The day personnel are not part of the operative response organisation, but work with such aspects as logistics and the procurement of materials, information management, education and inspections.

Case 2 was an emerging collaboration, initialised by the FRS in the rural province of Medelpad which was first studied 2014-2015 and then 2017, where ***citizen volunteers*** were provided with training to enable them to perform first response to accidents and selected emergency medical cases in their own villages, such as fires, traffic accidents, drownings and cardiac arrest. Some volunteers were, or had been, working within the medical or rescue domain, while others had no previous experience. Many of the volunteers were retired, and others worked on farms or in sawmills. The selection criterion to start a voluntary group in a village was that the expected response time for the FRS should be at least 25 minutes. When there was an incident in one of the villages, all volunteers in the village were alerted by an SMS (short message service) on their private mobile phones through the Swedish PSAP (in Sweden this is SOS Alarm, which is responsible for answering the national emergency number 112, and also for dispatching some emergency response resources and coordinating different emergency response organisations). To find a more sophisticated ICT solution for the volunteers, with additional functions, the same prototype smartphone application as in Case 1 was adapted to the citizen volunteers' specific needs.

Data Collection

In both cases, a variety of methods were used to collect data, including semi-structured interviews, focus group interviews and future workshops. Throughout the data collection, end users have been the source of information and have participated actively. More detailed information concerning the data collection in each case is reported in Mojir et al. (2018) and Ramsell et al. (2017).

Prototype Development – a Smartphone Application

Based on the data collection for each case, specific ICT functions for the end users were identified for each voluntary group. To test how these functions could be implemented, and to analyse and evaluate them, a ***prototype smartphone application*** was developed. The reason why we developed a prototype instead of using an already existing application, e.g. Mobile Life Saver, MLS (Ringh et al. 2011) or a commercial application such as Safeland (safeland.se) was to gain a better experimental control for the study. A compilation of identified functions was conducted, and a selection was implemented in the prototype, based on which: a) were considered most important by the volunteers and b) were possible to implement and test.

The prototype are for smartphones running on the Android operating system. The primary function of the application is to be able to receive an alert. When this happens, the application notifies the user with a signal, and a notification on the lock screen and in the notification list. When the user has opened the application, brief information about the incident is presented, and the user can accept (green button) or decline (red button) to go (See Figure 1).

Figure 1. A new alert in the smartphone application

A first prototype was developed in Case 1, but partly based on results and learning outcomes from Case 2, where some user needs had already been collected. After using and testing the application in Case 1, the application was used in Case 2 with some additional functionality based on an additional data collection in the later phase of the study.

Tests of the functions and Evaluation

Four tests were conducted in which the smartphone application was tested by the volunteers/end users. Thereafter, the tested functions were evaluated and discussed by the users, who reflected on which functions seemed satisfying, which could be improved, and possible solutions. Since this study is a meta-analysis, the tests are not identical or designed to be comparable across the two cases, but they all have the overall aim of determining whether the functions fit the end users' needs.

Test 1 was performed over a time-span of two months. Nine potential ***semi-professional*** first responders in Case 1 were equipped with a smartphone with the application installed. Alerts were sent to the participants, who were supposed to indicate, whether they would have been able to accept the assignment, had it been a real case (they were not supposed to go to the incident site). During the test period, an online qualitative questionnaire was available where the participants could give feedback about the test and the application, and suggest new functionality.

Test 2 was performed with two of the ***semi-professional*** first responders from Case 1, who were dispatched to a simulated traffic accident with two injured victims. The responders were placed in their own cars and received the alert on the smartphone application. They went to the accident site and performed first aid until the arrival of the emergency medical services and the FRS. The test was observed and filmed, and was also evaluated in an After-Action-Review (AAR; Myers, 2009) with all participants (semi-professionals, FRS, ambulance services), where the application and its functionality were discussed.

Test 3 was performed with five ***citizen volunteers*** from Case 2 during two days. Before the test, the participants had to download and install the application onto their own Android-based smartphones. During the test, a set of alerts was sent to the participants, who could accept or decline according to their own preference. The aim was for them to become familiar with the application and its functions. About a week after the test, a group interview was held in which the application and its functions were evaluated.

Test 4 was also held with ***citizen volunteers*** from Case 2 and partly as a consequence of the low number of

participants in Test 3, as the requirements of having your own smartphone and being able to install an application were too high for many potential participants. Thus, this test was performed as a workshop with one moderator (researcher and first author of this paper) and with prepared smartphones that the participants could borrow. This resulted in 12 participants who, during the test, received alerts and tested and evaluated the application and its functions.

Meta-analysis

From the collected data, a comparative meta-analysis was conducted. First, we collected all functions which were identified in both cases. Secondly, we went through the functions once again to get a more detailed understanding and to compare them; e.g. if similar or the same functions were identified in both cases, and what differences there were. After this, we grouped the functions in a) all identified functions, b) functions identified in both cases and c) functions only identified in one of the cases. In group a) we also added the volunteers' perception of each function. Then, with help from the grouping, we summed up the analysis of the functions, i.e. which functions the users perceived were most important and if these were the same or not for both volunteer groups. Finally, to generalise the results and put them into context (i.e. co-production), we compared the identified functions with studies from the literature.

RESULTS

The results include the identified functions, as well as user feedback from the tests and evaluations.

Identified ICT Functions

From the two cases, 12 functions were identified by both of the two groups (see Table 2). One additional function, information to the employer (No. 6), was identified by the semi-professionals, but was not applicable to the citizen volunteers (because they have no employer in their role as first responders). In Table 1, the 13 identified functions are ordered according to how they would occur during a mission; with the non-mission-specific check in/check out function (No. 1) at the top, followed by the alert signal (No. 2), and ending with a function for leaving and receiving feedback (No. 13), which occurs after a finished mission. While some of the functions are self-explanatory, additional information is provided for the others below.

The ability to check in and check out (No. 1) is requested by responders who will sometimes not be able to accept a mission for some time (hours, days or weeks), but still want to remain a responder. The ability to see who else accepts an assignment (No. 5) was highly desired by citizen volunteers, while some of semi-professional volunteers stated that it should not matter who else responds; if you get the mission, you should go either way.

Information to the employer that the responder has deviated from normal duties (No. 6) was only relevant for semi-professional volunteers; even though it is possible that a citizen volunteer will leave their ordinary job to go on a first response alert, the responsibility for the regular work tasks left undone would remain with the volunteer. Comparing this to semi-professional volunteers, the responsibility would transfer to the employer, since semi-professionals are doing first response as a task within their current employment contract. By notifying the employer, it is possible to arrange substitutes, or just reschedule the abandoned task for later.

The ability to communicate that a volunteer should abort a mission (No. 8) was originally suggested by professional response personnel in discussion with volunteers, who also thought that this function would be useful. For instance, if volunteers have been dispatched to an incident, and new information indicates that the situation is dangerous (e.g. gunfire or toxic substances), there should exist some quick way of reaching the volunteers to tell them to stop and wait. Another abort signal, but from the volunteer responder side (No. 9), was also deemed useful. It should be possible for a voluntary responder to indicate that the mission will be aborted, if he/she cannot reach the incident site; e.g., due to car problems.

In terms of a checklist for the responders (No. 11), various ways of having the application support the work on site were discussed; for example, having specific written (or audio) instructions for different types of incidents, or connecting it to other existing applications (e.g. first-aid guides).

While it is technically easy to implement communication with professional responders or emergency call operators (No. 12), it is more complicated to determine who should be contacted. One obvious choice is just to add a button that enables a call to the national emergency number 112. Since the PSAP in Sweden is responsible for coordinating different emergency response resources, this makes sense. However, when calling 112, if the closest alarm centre is busy, the call is transferred to another centre, where the operators might not know about the new resources, and time might be lost if the volunteers have to explain their role in the response.

Feedback (No. 13) can be used for different purposes; firstly, when the voluntary responders want to share their experiences in order to facilitate learning and development. Secondly, it can also be used to initiate a dialogue, or request help with dealing with potentially traumatic experiences related to an emergency response.

Table 2. Identified functions by voluntary first responders

No.	Identified functions	by semi-prof. volunteers	by citizen volunteers
1	**Check in/check out**: The possibility to opt out of the role of responder for a limited time	x	x
2	**Loud and unique signal:** It has to be possible to hear an alert at all times, and it should not be mistaken for any other notification	x	x
3	**Information**: A brief description of the incident	x	x
4	**Acknowledgement**: The possibility to accept or decline a mission	x	x
5	**Other voluntary responders**: It is possible to see who else has accepted the mission	x	x
6	**Information to employer**: Automatic information to the employer that the responder has deviated from normal duties	x	Not applicable
7	**Navigation**: A map with the incident site marked, navigational instructions, voice navigation	x	x
8	**Abort**: Information if the mission needs to be aborted, due to a dangerous incident site, or if the responder is no longer needed	x	x
9	**Abort status**: The possibility to indicate that the mission has been aborted	x	x
10	**Arrival status**: The possibility to indicate arrival at the incident site	x	x
11	**Checklist**: Information supporting practical response, e.g. how to act in specific accidents	x	x
12	**Communication possibility**: A quick way to contact professional responders or emergency call operators	x	x
13	**Feedback**: The possibility to fill out a mission report	x	x

Test and Evaluation of Identified Functions

Nine of the identified functions were implemented in the prototype, and tested by the voluntary groups. Specifically, six functions were tested by both groups (see Table 3), and in addition, due to relevance and/or test limitations, two more functions were tested by citizen volunteers and one other function by semi-professional volunteers. For semi-professionals, the feedback function (No. 9) was only partly tested (in Test 1), where the only possible feedback was that the users could indicate why they had missed an alert. For the citizen volunteer tests, the volunteers could respond to a larger set of questions (in Tests 3 and 4).

Table 3. Functions implemented and tested in the smartphone application

No.	Function	Tested by semi-prof. volunteers	Tested by citizen volunteers
1	Check in/check out	x	*
2	Loud and unique signal	x	x
3	Information	x	x
4	Acknowledgement	x	x
5	Other voluntary responders	**	x
6	Navigation	x	x
7	Arrival status	x	x
8	Checklist	**	x
9	Feedback	Partly	x

**Not tested due to test limitations, **Not tested due to not being a priority for semi-professionals.*

Overall, the smartphone prototype functions satisfied the previously identified user needs – the responders received their alerts, acknowledged them, and followed the navigation system to the test incident site (physically or virtually, depending on the test).

The check in/check out function (No. 1) was only tested by the semi-professionals, who thought it was a good function to have since the application is running in the background, and it may not be sufficient just to turn it off. Both semi-professional volunteers and citizen volunteers commented that they missed alerts because they did not notice the signal or the vibration when their phone was in silent mode (No. 2). One semi-professional thought the vibration was too weak. Some citizen volunteers claimed that it was not loud enough and sounded like a regular notification. They emphasised that you need to be able to hear it even in noisy environments and when you do not have the phone right next to you; for example, by means of a blinking light, a stronger vibration and an even louder sound alert. In the AAR in Test 2, the semi-professionals stated that the amount of information about the incident (No. 3) was sufficient. Apart from complaints about the design of the application (confusing symbols and small text), no issues were reported for the acknowledgement function (No. 4). The ability to see who else accepts an assignment (No. 5) was greatly appreciated by citizen volunteers (in both Test 3 and Test 4).

In the application, if the user accepts the alert, an offer of navigational assistance is made; if accepted, Google Maps enabling navigation is launched (No. 6). The navigation aid is the same as in the existing solution for citizen volunteers (through a link in the SMS to Google Maps). Still, the citizen volunteers said that it was easier to access the map from the SMS, and that it should be possible to access the map in the application before the mission is accepted, as soon as the responders receive the incident information. The main reason for this is probably that their current system alerts everybody on the SMS list, and not only those who are actually close to the incident, as in the prototype application. There was also criticism of the navigation aid from the semi-professionals after Test 2, when one of the responders was doubtful whether he would have arrived at the right place if he had followed the instructions. Also, the possibility to indicate arrival at the incident site (No. 7) was forgotten by some volunteers – they did not remember to press the button.

The citizen volunteer responders stated that the checklist (No. 8) should be specific to each type of incident, and contain a limited amount of text. On the other hand, some citizen voluntary responders, as well as other semi-professional responders, said that they did not want to use any type of smartphone application at the emergency site, but needed to focus on the emergency work. Instead, they claimed that the checklist could be used as a preparatory tool, to remember what to do before an incident and during the travel to the incident site (if there was more than one responder travelling together).

Regarding the feedback function (No. 9), the citizen voluntary responders said that there were too many questions, and that the answers to some of them could easily be automated, e.g. arrival time. Also, they did not like the use of the word "debriefing" in the question: "Do you want debriefing?", and felt that this indicated that the responder might have psychological problems. It would be better to ask if they had identified any lessons that they would like to share or to have a routine to meet up for a cup of coffee after a response.

One of the citizen volunteer groups had already enhanced the SMS-based solution with additional smartphone applications; for example, by providing a loud and unique signal with flashing lights as well as GPS tracking and a position presentation for all responders. During Test 3, the citizen volunteers who were used to the enhanced SMS solution expressed negative opinions about the tested application and believed that it was difficult to use and not intuitive. The other citizen voluntary group in Test 4 (who had not developed additional

functionality) also said that the application was not user-friendly and that the button symbols were confusing, but at the same time they stated that the application, with its additional functionality, was a great improvement upon their current SMS solution. The semi-professionals were generally pleased and did not believe that they would have made much use of additional functionality in the application, but instead highlighted the value of training and education.

To sum up, the tests with citizen volunteers indicated that the two most important functions were the alert signal (No. 2) and the possibility to see who else is responding (No. 5). While an explicit ranking of the functions was never performed in the tests with semi-professionals, the ability to see who else responds was not highlighted as one of the more important functions. However, a loud and unique signal was also highlighted as crucial by the semi-professionals.

Evaluation: Identification of Additional Needs and Functions

The tests gave rise to new suggestions about needs and functions, which were discussed during the evaluation. The citizen volunteers also wanted to ***receive information about when professional responders will arrive*** (a similar function to No. 5 – to see who else has accepted an assignment). While the semi-professional responders agreed that it may be nice to know this, they did not rank it as vital information. One argument was that the incident in Test 2 took place in a city, where professional emergency services typically have a short response time. This may be compared to the citizen volunteers, who respond in a rural area involving long distances.

Another new need was to be able to ***see which equipment the responders are bringing***. Equipment that volunteers could be asked to bring to the incident site include automated external defibrillators (AEDs) and fire extinguishers. There were various ideas about how this need can be implemented as a function:

- Simple general information about what might be useful to bring to the specific type of incident.
- A status button, where the responder can indicate that he/she is bringing the equipment. This is particularly relevant for citizen volunteers, because some villages only have one AED; if somebody picks it up and indicates this, it might prevent others from losing time by going to get it as well instead of heading straight to the incident site.
- Assignment of equipment to responders, where the system decides which responder should bring each piece of necessary equipment, and informs responders of this through the application.

One of the semi-professional responders forgot to report his arrival in Test 2, giving rise to the suggestion that the application should be able to ***detect when a responder has arrived***, and log this automatically. Moreover, the ability to ***send coordinates from the incident site*** was suggested by both voluntary groups. This would be useful in cases where the exact location of the incident site is uncertain or approximate. Being the first on site, the voluntary responders could then easily send the correct coordinates to the professional responders so that they reduce their response time. To be able to ***send pictures and video from the incident site*** was discussed by both voluntary groups (in Test 2 and Test 3). The professional emergency personnel who supported the tests said that information from the incident site might be very useful, especially the number of victims.

From the tests with citizen volunteers, it became evident that the development of the application must take into account the ***technical maturity*** of the intended users. Many potential participants did not have an Android smartphone or could not download and install the application, which was a prerequisite to participate in Test 3. Of the ones who did participate, some had received help from friends or family to get ready.

The Same Solution for Different Volunteer Groups

The results indicate that the functionality offered by the tested smartphone application was sufficient for both volunteer groups, so the same solution can be used for different types of volunteers. While the majority of the identified functions were relevant to both groups, some differences emerged. The perceived relative importance of some functions differed, just like opinions about the design – not intuitive enough. It should be noted, though, that this partly might be due to the context; for example, citizen volunteers in Case 2 already had an existing, working solution (SMS) to compare the application with, or due to differences in test design, as Tests 1 and 2 were not performed in the same way as Tests 3 and 4. Thus, the study indicates that the basic ICT needs of different groups of voluntary first responders are similar and can mostly be implemented using the same functions. While some specific functions might differ, the same solution can easily be adapted to satisfy these, by adding, removing or revising some functions.

DISCUSSION: ICT AS AN ENABLER IN NEW FORMS OF GOVERNING AND CO-PRODUCTION

ICT opens up new forms of governing and improved resilience in public-service delivery, not least in emergency response. Volunteers can be engaged and collaborate with public bodies to improve services for others and themselves through co-production (Linders, 2012; Pestoff et al., 2012). However, in order to realise this co-production, suitable technological solutions are necessary. Although the ICT artefact and its surrounding collaborative infrastructure are closely interconnected, it can be fruitful to separate them and study the ICT artefact solely in order to enhance our understanding – especially if the context of the ICT artefact have already been explored (Alter, 2002).

Here, the involvement of end users is essential (Bjögvinsson et al., 2012). Still, there are few, if any, studies on co-production focusing on the ICT artefact with end-user involvement. In the information systems (IS) research field, on the other hand, there are some studies relating to user participation in emerging public-sector community initiatives (Bjögvinsson et al., 2012; Robertson and Simonsen, 2012). In the specific area of volunteers, emergency response and resilience, there exist studies on ICT solutions, but it is still difficult to find any in which suggested ICT functions and solutions are solidly anchored in user needs (e.g. Ringh et al., 2011; Schönböck et al., 2016). This study contributes explicitly in this respect, since it focuses on suitable functions of applications who are directly based on user involvement, user needs and user experience. As for emergency response, an ICT artefact that is well suited to volunteer first responders' opens up new possibilities for voluntary co-production whereby the resources of professional emergency services can be saved and used more effectively, and at the same time a quicker response is enabled. From a wider public-sector perspective, the study opens up space for an interesting merger of co-production and ICT perspectives, in line with studies claiming the benefits of a cross-fertilisation of policy science and information systems research fields in general (Janowski et al, 2012).

Identifying ICT Functions with End-User Involvement

Capturing the specific ICT functions can be difficult and time consuming. The number of identified functions became extensive. Initially, 13 functions were identified and after testing approximately half of them, an additional four functions were identified. Through the involvement of the volunteers – the end users – these functions could be divided into two groups: functions that are absolutely necessary and functions that might be nice but are possible to manage without. For example, in Case 2, the volunteer initiative had been running successfully for over two years when the tests were performed. This indicates that the basic SMS-based solution was actually sufficient for the intended purpose, implying the necessary functions to be only the ability to receive an alert and getting brief information about the incident, including the location. However, additional functionality might lead to a quicker and more effective response. For example, the volunteers may notice the alert more easily and quickly with a louder and unique signal. Another example is the ability to see who else is responding, which could make the volunteers more comfortable about responding themselves. This may make them more willing to continue to devote their time and also enhance the collaboration with professional emergency services. This again points to the benefits of connecting co-production and ICT artefacts based on end-user involvement. It may be cost-intensive and time-consuming at the beginning but will be worth it enabling a long-lasting way of governing the response.

Applicability of the Results: International Perspectives and Disaster Response

Given that many basic first-response tasks are similar globally (e.g. first aid, fire extinguishing), many of this study's results should be transferable to settings in other countries, for instance, importance of an intuitive interface is probably general. It is likely that volunteers will not use the application very often since they are only complementing the professional emergency services. Thus, the number of alerts that a voluntary responder can expect to receive are few; in the studied cases, often less than one per month. Therefore, the responders will not have the opportunity to learn to handle the application through frequent usage. Instead, it has to be sufficiently intuitive, or test alerts have to be sent regularly, for the volunteers to have the chance to learn to use the functions. Intuitive interfaces are also argued for in previous related studies (Lanerolle et al, 2010; Havlik et al., 2016). Similar functions are also highlighted, for instance use of acknowledgements, bringing equipment, possibility to share information (between volunteers and between volunteers and professionals) and possibility to get feedback (Auferbauer and Ganhör, 2015; Schmidt et al, 2018; Schönböck et al, 2016).

In a disaster response context, at least three possible user groups can be discerned: the ones who are already volunteers for everyday emergencies, and volunteers specific to a current disaster, either through some established non-profit organisation, or spontaneous volunteers (Havlik et al., 2016; Ringh et al., 2011; Whittaker et al., 2015). While disaster response volunteers connected to such organisations as the Red Cross might have the time and ability to become acquainted with an ICT solution like a smartphone application beforehand,

spontaneous volunteers will typically have no such experience. Thus, for this user group, the user friendliness of the application is even more crucial than when it is used for frequent, smaller emergencies (Falasca and Zobel, 2012).

CONCLUSIONS AND FUTURE WORK

This study set out to identify suitable functions in a smartphone application for volunteers in emergency response. The study's contributions thus relate mainly to the functions of the application, connected to the two voluntary groups in the meta-analysis. The study concludes that:

- Several functions were identified by both voluntary groups. Elementary functions comprised the ability to receive an alert on a mobile phone and receive sufficient information to be able to find the incident site. More specifically, this included functions as easy noticeable and unique alert signal, and an intuitive navigational aid to access and follow.
- However, there were also multiple functions identified that might contribute to the more effective utilisation of volunteers, reduce the first response times, and make the volunteers more comfortable in their role as first responders, making them willing to continue to devote their time, and enhancing the collaboration with professional emergency response organisations. Examples of functions for a more effective response and collaboration were a function indicating which equipment to bring, ability to send coordinates and pictures/videos from the incident site to professional resources, and – particularly for citizen volunteers – to receive information about when other responding resources will arrive.
- Different volunteer groups can use the same basic functions, but opinions about the design and realisation of the functions might differ depending on user background and context.
- Generally, it is a necessity for the application to be intuitive and easy to use, since most of the volunteers will be infrequent users and have varied technological literacy – if the users have a low technological maturity they may need education and support when installing and using the application.

Several functions were identified for the volunteers' ICT solution (the smartphone application) and, during the evaluation, new needs were also identified – which need to be further analysed and tested through exercises in order to arrive at implementable functions. Future work should address this, together with the professional response organisations and the Swedish PSAP.

At a more general level, the results of this study may be a useful input to research on the development of support for volunteers in emergency and disaster management. In this study, we also tried to open up space for the merging of ICT and various network perspectives, specifically co-production. While we only provide a starting point in this respect, the trait can be pursued in future research investigating the linkage of the respective perspectives further, from the macro-societal level, to theory development, to practical information systems development and inter-disciplinary design teams, not least concerning new emergency response volunteer initiatives.

ABSTRACT [150]
Health response plays a major role during disasters and information management plays a crucial role in situational awareness to adapt to evolving needs. Health organizations exchange information often through narrative-based documents called situation reports. Although situation reports are widely shared, they are an increasingly challenging information source from which to infer knowledge for situational awareness. This paper analyzed health information from traditional health reports using mixed methods during the aftermath of the 2010 Haiti Earthquake and provides insights into the patterns of what's being said, how it's being said, and trends over time. Opportunities lie ahead to analyze narrative documents at scale by combining human knowledge from qualitative coding with machine intelligence. In addition, developing unifying health domain ontologies representing diverse humanitarian health concepts will advance computational techniques to improve the efficiency and accuracy of retrieving knowledge for improved situational awareness and potential decision making during humanitarian health response.

Information management, health information, knowledge bases, curation

INTRODUCTION

Information Management and Humanitarian Health Response

Information management during disasters and humanitarian response plays a crucial role in maintaining situational awareness, adapting to post disaster evolving needs, and coordinating with local, national, and international responding agencies. (Crowley and Chan, 2011; OCHA, 2002; Waugaman and Fast, 2016)

WiPe– Community Engagement & Healthcare Systems
Proceedings of the 16th ISCRAM Conference – València, Spain May 2019
Zeno Franco, José J. González and José H. Canós, eds..

Recognized by many agencies as playing a central role to the response system, information management remains a challenge across many sectors including health. (Crowley and Chan, 2011; Goyet et al., 2011; Van de Walle and Comes, 2015; Waugaman and Fast, 2016)

Rapid collection and dissemination of key information including infrastructure assessments, morbidity, and mortality statistics are key factors which influence effective decision making during a humanitarian health response. However, environmental, political, and cultural contributing factors influence how information is collected and shared among responding organizations and humanitarian actors. (Morton and Levy, 2011; Van de Walle and Comes, 2015) In particular, the fragmented nature of a disaster response, underdeveloped models of information management, and limited information sharing have been cited as contributing factors to a hampered response. (Altay and Labonte, 2014; World Health Organization, 2009; Waugaman and Fast, 2016)

The 2010 Haiti Earthquake marked a turning point for technology and information exchange but also highlighted major challenges in information sharing among new actors, including persistent cultural behavior barriers of information and data sharing. (Crowley and Chan, 2011; US Department of State, 2010) The World Health Organization's (WHO) post-earthquake report recognized that "information and coordination management was a challenge that was not met adequately." (Goyet et al., 2011) The 2014 West Africa Ebola response marked another series of information management (IM) challenges, where the complexity and unchartered nature of the Ebola response highlighted systemic shortcomings in IM. (Comes et al., 2015; Engel et al., 2007; McDonald, 2016; Waugaman and Fast, 2016) Early paper-based data collection, colliding information systems, and static information reports from responders in affected countries were all cited challenges in this unprecedented humanitarian health crisis.

In the diverse environment of information generation, sharing, and coordination, the United Nations Office of Coordinating Humanitarian Affairs (OCHA) plays a central role in coordination and information management in disasters and humanitarian crises where they are activated. Their mission is to "coordinate(s) humanitarian action to ensure crisis-affected people receive the assistance and protection they need", with information management as one of its major efforts to achieve these goals. It is "responsible for consolidating and publishing information across the spectrum of humanitarian response." (OCHA, 2019) Information management principles that stem from overarching humanitarian principles help guide standardized tools and products for which regional and country offices aim to provide focused, timely, and relevant information during the response. (OCHA, 2002; OCHA, 2018)

Health response plays a major role during disasters and humanitarian crises, from minimizing mortality due to infectious diseases (e.g., malaria, diarrhea, ebola) and mitigating morbidity by providing essential health services (e.g., maternal child health, chronic diseases, mental health). Health organizations exchange information often through various channels such as emails, in-person meetings, documents, and at times web-based platforms. The WHO acts as the lead agency for the health cluster in collaboration with OCHA to facilitate the sharing of health information during crises when the OCHA acts as a coordinating body. The WHO also oversees activated health clusters around the world and, according to the 2018 response framework, aims to "Ensure[ing] the best possible information, analysis and understanding, and facilitating coordination." (WHO, 2008) At the end of 2018, 27 countries around the world have clusters which are working to coordinate health response activities with host nations and NGOs to deliver health programming. (WHO, 2008)

Situation Reports

Situation reports, or "sitreps", are documents that are shared among humanitarian actors that aim to provide an overview of a response. (Finn et al., 2018; Finn and Oreglia, 2016; Van De Walle and Muhren, 2009) These documents have been used for well over a decade, and they are as numerous as they are diverse. These narrative

documents are created by NGOs, government agencies, and UN organizations, to name a few. (King, 2005) While there is no single standardized situation report, these documents provide an overview of the disaster/humanitarian crisis. (Zhang et al., 2002) Health situation reports frequently provide available mortality statistics, an overview of diseases of epidemic potential, public health efforts, medical supply chain logistics, and an overview of which health organizations are working where and with what specific focus (i.e., 3W). Depending upon the crisis or disaster, health sitreps are generally updated daily, weekly, biweekly or monthly. Documents, often in PDF or word doc formats, are short narrative documents that may also include maps, tables and graphs and are shared either publicly or privately depending upon the organization or group. (Finn and Oreglia, 2016) They are intended to update responding actors and aim to influence coordination and decision-making. While situations reports are commonly created, shared and perceived as useful by some responders, they have been cited as difficult to analyze in the ever increasing environment of information and data overload. (Finn and Oreglia, 2016; Zhang et al., 2002) Despite criticism by some actors that "sitreps are a thing of the past" the situation reports continue to be created by many stakeholders despite ongoing challenges and criticisms. (Finn et al., 2009a)

Previous studies have investigated the production and labor investments in primarily UN agency situation reports through qualitative interviews. (Finn and Oreglia, 2016) Perceptions of IM challenges have also been studied using interpretive case study methodologies with four individuals involved in the 2010 Haiti earthquake response. (Van de Walle and Dugdale, 2012) Grey literature publications also provide an early view of content analysis of situation reports focusing on coding "meta data" of information types (e.g., date of production, disaster type, information structure) (Finn et al., 2009b) To date, there has been fewer published studies that perform an in depth analysis of the narrative content in situation reports as it relates to a specific sector of response. (Dhillon and Annunziata, 2012), A document review of PAHO and health cluster documents determined the epidemiological completeness of these documents, but did not assess other health sector content such as coordination, essential health services, and medical logistics.

This paper describes an analysis of health situation reports and similar documents called health bulletins distributed during the early phase of response from one of the largest recent humanitarian crises in the past decade. While previous peer-reviewed and non peer-reviewed literature has explored the practice and perceived usefulness of situation reports, this study explores the trends of health information within the content of these narrative documents. It also focuses on the health content as part of the IM paradigm, and not only how health information is presented in these public documents over time but to what degree they align with known humanitarian health response themes and terms. Lastly, it aims to complement published literature that frequently focuses on general IM and coordination.

The 2010 Haiti Earthquake

In January 2010, a 7.0 magnitude earthquake struck 13 miles west of Port-au-Prince. With estimates of 220,000 dead, more than 300,000 injured, and billions of USD in damages, Haiti caught the attention of the world in a single day. (Goyet et al., 2011; Zhuang et al., 2012) Thousands of health agencies arrived less than three weeks after the earthquake. The influx of international aid resulted in unprecedented coordination challenges. Though the actors worked to meet immediate needs, the number of unprepared stakeholders overwhelmed coordination efforts. The fragmented nature of the response, disorganized models of information management, and other factors have led some observers to describe the information and coordination efforts in Haiti as "a challenge that was not met adequately". (Altay and Labonte, 2014; Goyet et al., 2011) The World Health Organization (WHO) and Pan American Health Organization (PAHO) led the Global Health Cluster. WHO/PAHO helped to coordinate non-governmental organizations (NGOs) alongside Haiti's Ministry of Health and Population, to manage medical supply chain logistics, and hold daily coordination meetings. The Health Cluster and PAHO

were also designated to produce publicly available bulletins detailing information that reflected operational and coordination field activities along with guidelines. These reports provide a unique opportunity to qualitatively and quantitatively analyze trends in health information.

METHODS

Mixed methods of qualitative and quantitative content analyses were used in the study. Forty-nine publicly available situational reports were collected from the WHO (n=23) and PAHO (n=26) from January 13th to April 15th, 2010. The study was reviewed by the Northwestern University Institutional Review Board and was consider exempt. A qualitative codebook was created using an integrated approach employing both inductive and deductive methods to develop and modify codes as described by Bradley. (Bradley et al., 2007) A list of themes was created using humanitarian health guidelines widely accepted within the global health sector, including *The Sphere Handbook: Humanitarian Charter and Minimum Standards in Humanitarian Response* and Médecins Sans Frontières' *Refugee Health: An Approach to Emergency Situations*. The resultant *a priori* codebook was then revised using an iterative inductive (grounded theory) method as the reports were reviewed. (Glaser and Strauss, 1967; Strauss and Corbin, 1990)

Prior to applying the code structure to the data corpus, four articles were randomly selected using an online random number generator. Two coders separately reviewed the selected articles and finalized the codebook by accommodating new themes, clarifying ambiguous definitions of codes, and eliminating redundant codes. The final terms were organized into 12 [major codes] (e.g., injuries, health infrastructure, medical logistics, and essential health services) and 61 'minor codes' (e.g., mental health, mobile clinics, rehabilitation services, shelter). A third coder was trained until a sufficient intercoder reliability ratio was achieved using the Kurasaki approach. (Kurasaki, 2000) The Kurasaki method enables coding of free flowing content or text that may have overlapping themes. Each coder reviewed and applied the codes to five randomly selected articles separately. The unit of analysis for codes were idea units also called meaning units, most frequently in the form of sentences. The intercoder reliability ratio was found to be 0.71, using the method described by Kurasaki. (Kurasaki, 2000) This method measures the agreement across the three coders for each theme by calculating a ratio of agreements to disagreements. Overall agreement is calculated by averaging agreements across all themes. Codes were applied to the data corpus using computer software QSR NVivo for Macintosh (QSR International Pty Ltd, Doncaster, Victoria, Australia) by assigning thematic codes and sub-codes to sections of text.

The three coders met to discuss individual major codes, minor sub-codes, and cross-references. Themes and qualitative trends were discussed and recorded including examples of content that reflected the findings. Descriptive analytics of major and minor codes were then performed using Tableau 9.0 software (Seattle, Washington, USA).

RESULTS

Overview

7,398 codes were applied to 26 PAHO health reports and 23 health cluster bulletins from January 13th to April 15th, 2010. Almost half of the codes occurred in the PAHO reports (45.3%), with a majority of the codes occurring in the health cluster reports (54.7%). All major codes from the qualitative codebook were included and 3,606 codes were minor codes. Only 2 minor codes 'health facility-closed' and 'protection' were not identified in the data corpus during the study period. The top three minor codes were stakeholder subgroups (i.e., 'Haitian government', 'NGOs', and the 'Health Cluster'). 'Water and sanitation' and 'shelter', closely related sectors of response, were frequently cited. The most frequent health infrastructure minor code was

'permanent hospital'.

Two themes were qualitatively analyzed, [access] and 'Haitian government', and are discussed later in this manuscript. Codes related to [access] occurred primarily during the first few weeks of the response. The minor code 'Haitian government' occurred 260 times during the study period as part of the [stakeholder] major code which was the most frequently coded term in the study (n=2556).

General Prevalence of Health Topics

	n	Percentage (%)
Access	66	0.89%
Death	20	0.27%
Injuries	28	0.38%
Affected	57	0.77%
Health Risks	476	6.43%
Health Insfrastructure	1,099	14.86%
Health Priorities	23	0.31%
Essential Health Services	1,019	13.77%
Medical Logistics	534	7.22%
Health Workforce	271	3.66%
Stakeholders	2,556	34.55%
Cross Sectoral Activitites	1,249	16.88%

Table 1 Percentage of Major Health Codes

Figure 1 Prevalence of Major Health Codes

The four most common major codes were [stakeholders], [cross sectoral activities], [health infrastructure] and [essential health services]. (Table 1) Major codes peaked during the first month of the study period reflecting both the intense reported needs and growth of health response activities. (Figure 1)

Essential health Services

Essential health services are considered a core pillar of humanitarian health response. (Sphere Association, 2018; UNHCR, 2011; WHO, 2008) There were 1,019 essential health services codes throughout the study period. 11 subtypes of essential health services were analyzed (i.e., minor codes) which provided a more detailed content analysis over time. Minor codes included 'urban search and rescue', 'maternal child health', and 'rehabilitation services', to name a few. References to urban search and rescue occurred during the first 2 weeks of the response, while trauma care peaked during the

second week and primary care and post-operative care codes increased during the third week. Based upon the minor code pattern analysis, at the end of the study period, approximately two months after the earthquake, immunization, surveillance activities, and mental health predominated as essential health services.

Medical Logistics

Healthcare logistics including provision of materials, medications, and human resources are all major contributing factors to health response during a disaster. These functions are considered a key to the planning and management of the WHO. (WHO, 2008) Despite the sector's recognition of the important role of logistics, bottlenecks are often an ongoing challenge. (Jacob et al., 2008) During the 2010 Haiti response, the ability to procure and distribute medical supplies was believed to be a critical factor in the efficiency of the health response. (Inter-agency Standing Committee, 2018)

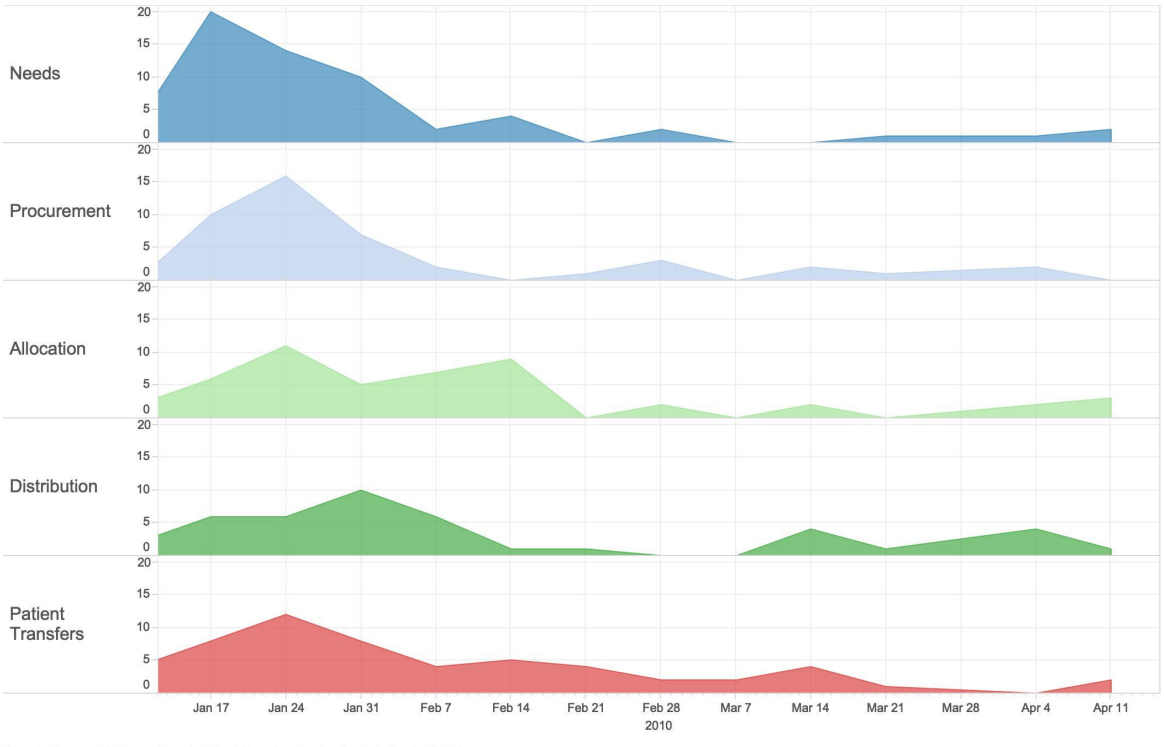

Figure 2 Temporal Patterns of Medical Logistics Minor Codes (Jan. 10 - Apr. 15, 2010)

There were 250 minor codes (i.e., 'needs', 'procurement', 'allocation', and 'distribution') providing a more in-depth analysis of medical logistics. Figure 2 depicts the patterns of these minor codes during the study period, indicating early findings that the narrative of logistics needs occurred prior to the subsequent content, reflecting procurement, allocations, and distributions over time.

Health Infrastructure

Understanding the status of health facilities was a major part of the humanitarian response in the aftermath of the Haiti earthquake. Over 60% of the hospitals in affected areas were damaged, and the Ministry of Health's

main building was also destroyed. (Jacob et al., 2008) Damage to permanent hospitals and the constantly changing status of field hospitals and mobile clinics posed a major challenge in coordination. As temporary health facilities became operational, health responders continued to struggle to understand which facilities were open and what services they were able to provide to patients.

There were 1,099 codes related to health infrastructure for which 348 codes could be further specified to minor codes such as 'permanent hospital', 'mobile clinic', or 'primary care clinic'. During the second week of the response, all minor codes peaked, similar to other codes, likely reflecting increased communications and reporting to health coordinating agencies as well as an overall increased awareness of health needs by a multitude of health responders. Codes reflecting field hospitals predominated during the first month of the response, while mobile health clinics increased during week two with sustained references for the following weeks. Permanent hospital was the minor code reported with the most frequency through the study period.

Qualitative Analysis

The qualitative analyses in social science and health sciences enables a more in-depth content analysis of topics enumerated by quantitative analysis of coded content (e.g., number of major and minor codes over time). These social science techniques bring forth human interpretation and knowledge of the public health medical and disaster domains for which simple enumeration and processing techniques cannot achieve.

Access

Access to affected populations in large scale natural disasters and complex humanitarian crises is a priority. (Bigot et al., 1997; Brennan and Nandy, 2001) Content analysis of the major code [access] appears earlier in the study period, occurring primarily in the first few weeks of the response with a peak period in week one. Qualitative analysis of this theme describes limited road and air access as a major operational challenge that contributed to overcrowding and further damage to healthcare infrastructure.

"The airport is intermittently open and closed. In addition, supplies arriving into the country are piling on the tarmac"

"Logistical challenges still remain at the airport in Port-au-Prince, where many supplies are offloaded with the expectation that they will be transported to relief agencies"

"Roads in Port-au-Prince are extremely difficult to navigate due to rubble and large amounts of people. Roads from the border with the Dominican Republic to the Port-au-Prince appear to be open"

"The airport is open for humanitarian flights only. There are reports of planes not being able to land or having to be diverted to other countries due to congestion on the only functional airstrip."

Over time, status updates (i.e., open and closed roads) are described with the likely intention of providing situational awareness for responding agencies.

"the road is being repaired between Jacmel and Port-au-Prince"

"The southern pier at the port in Port-au-Prince is functioning for humanitarian cargo only, but not at full capacity"

"the priority objective is to deliver health care services should a department become isolated from

other communes due to road flooding"

Stakeholders: The Haitian Government

The role of the Haitian government in the broad response has been discussed widely. (Grünewald et al., 2010; University of Haiti, 2011) Severe damage to Port-au-Prince left many major government agencies and staff directly affected. Situational awareness of the host nation's response in the early days was reported as limited and sparse.

Quantitative analysis of 'Haitian government' content from PAHO and health cluster reports show a similar trend to the overall trend of general codes, increasing in the first weeks after the response. (Figure 4) 'Haitian government' compared to other stakeholders is mentioned consistently throughout the study period. However, 'Haitian government' is mentioned only 7 times during the first week compared to PAHO (n=25), NGOs (n=34), and the UN (n=29).

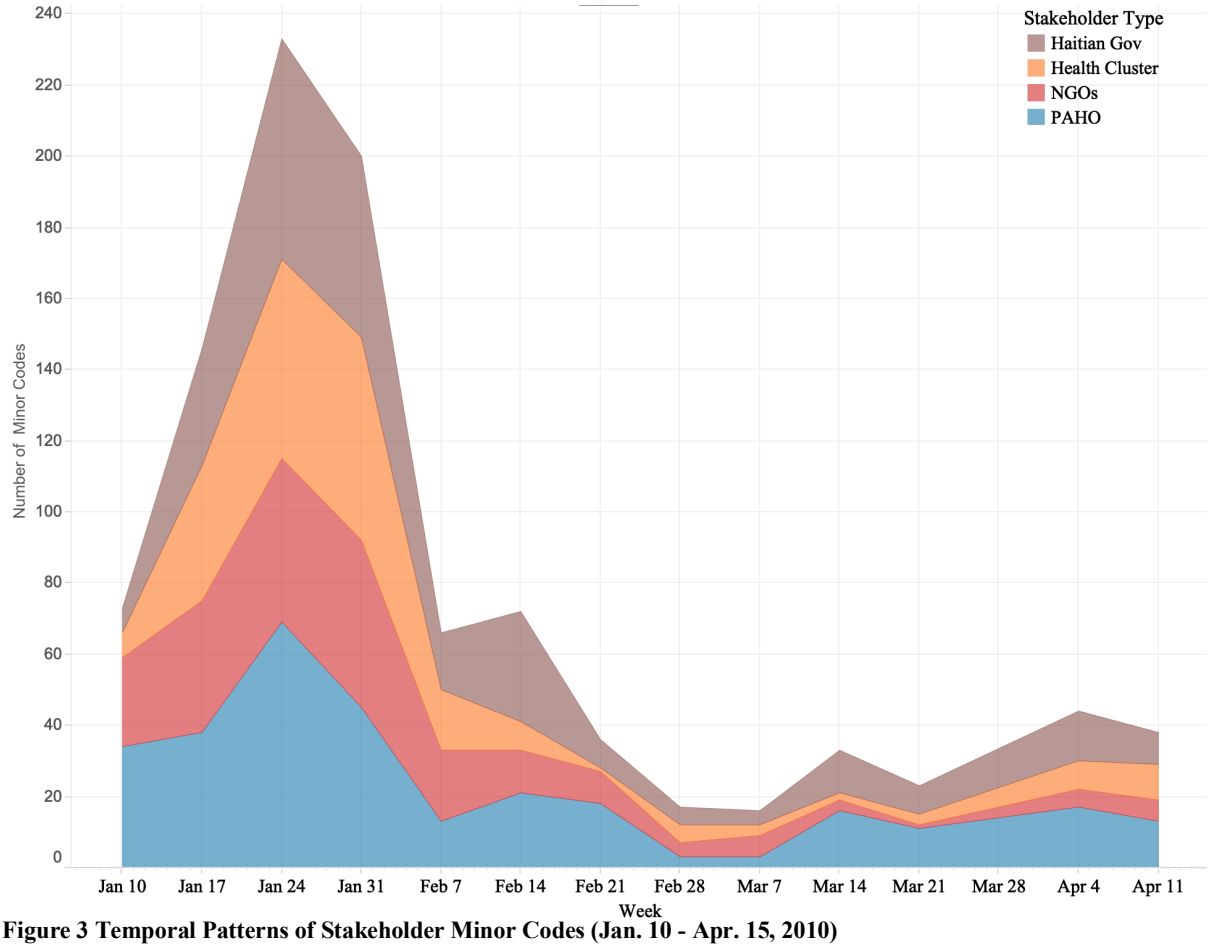

Figure 3 Temporal Patterns of Stakeholder Minor Codes (Jan. 10 - Apr. 15, 2010)

Qualitative analysis of the stakeholder minor code 'Haitian government' highlights the type of coordination efforts between UN actors, non-governmental organizations and other stakeholders. It also shares information on other response activities related to health programming (i.e., water services) and acts as an information channel to disseminate broader government strategic planning and collaboration during the post disaster phase into recovery.

"In order to enhance coordination between health actors, information on the location and services offered by organizations will be presented to Haiti's Prime Minister today, Friday"

"The Minister of Culture and Communication announced that the Government of Haiti is planning to issue a regular bulletin detailing ongoing humanitarian activities"

"The Clinton Foundation, in collaboration with the Ministry of Health, is contacting all organizations listed on the 'who, what, where' sheet who have medical staff in the country to find out exactly how many and which institutions are working"

"The Ministry of Health's strategy for the coming weeks shifts from focusing on emergency surgical cases to primary health care, health centers and hospitals. All health partners in Haiti support this strategy"

"WHO is collaborating with the Direction Nationale pour I'Eau Potable et I'Assainissement (DINEPA) on water quality"

"The Ministry of Health established a mental health group that will create a work plan for psychological support"

CONCLUSION

This study analyzed trends in health information from traditional health reports using mixed methods. Situation reports from the health cluster and PAHO were collected and qualitative codes applied to the corpus of information from January 13th to April 15th, 2010. Using a qualitative codebook, 7,398 codes resulted during the study period. [Stakeholders], [cross-sectoral activities], [health infrastructure], and [essential health services] were the most prevalent codes reflecting the sector priorities during the response. Temporal pattern analysis of enumerated codes showed a general increase in reporting of health content in the first few weeks of the response, with limited information about the Haitian government response in the first week. Specific codes such as [access] peak early, and persist over time but are less prevalent as the response continues compared to other health topics such as [health infrastructure] and [medical logistics]. The presented results and analyses help define the categories of relevant health information to create new and refined existing machine learning methods, which could extract health information from unstructured data at scale for disaster information management.

Lesson Learned

While temporal pattern analyses over time enumerate the health sector's current operational priorities and challenges, qualitative analysis provides further insights and specificity to the priorities, services, and coordination among stakeholders. Qualitative analysis of one major code [access] and one minor code 'Haitian government' provide more in-depth insights into specific access restrictions, road status updates, and coordination efforts with the host nation as well as the government's strategic planning going forward. IASC's six month report noted that the government "felt that despite the colossal achievement in re-establishing themselves hours after the earthquake, they were neither supported nor sufficiently recognized by the international community". (IASC, 2018) The relative absence of 'Haitian government' in situation reports during the first week, compared to 'PAHO'. 'NGOs', and 'UN' supports this conclusion. Additional situation report analysis from other actors (i.e., NGOs, local actors, government sitreps) may provide further insight.

Few studies have analyzed situation reports from a health focused perspective, investigating content type and trends over time. The health sector plays a significant role in large scale natural disasters and humanitarian crises, producing both internal and public situation reports. This study provides not only early findings of health

information trends over time, using the 2010 Haiti Earthquake as an example, but also employs two complementary methods of analysis, qualitative coding and descriptive statistics. This mixed method approach allows for temporal pattern analysis as well as more in-depth analysis of the narratives found in situation reports.

Situation reports continue to be an almost ubiquitous information source in humanitarian response, generated, produced, and shared broadly. The narrative format of sitreps coupled with the sector's daily, weekly, and bimonthly sharing practices through digital means creates an overwhelming information overload for those who seek situational awareness through these documents. This contributes to the broader challenges humanitarians face with information overload. The narrative format of situation reports further complicates one's ability to acquire knowledge for decision-making at the current scale of production and sharing. As disasters and humanitarian crises increase in both scale and frequency, the volume of narrative content that exists in the form of sitreps can be overwhelming for both understanding the nature of crises as they unfold in near-real time and retrospectively reflecting on lessons learned to transform the way forward.

Although perceived by many to be "useless", others throughout the sector continue to require sitrep generation and many more seek them out during crises. Regardless of the various positions on the value add of sitreps, or the published literature that reflects evidence on the perceived value of these documents, this study aims to further the understanding of "what is being said" in these health sector documents through a mixed methods research approach with a specificity and focus on health. Utilizing a qualitative coding framework from humanitarian operational handbooks to analyze trends during the crisis response, this study begins to reveal what factors influence health and humanitarian decision making during early phase response.

Future opportunities

This research provides early insights into the patterns of "what is being said", "how it's being said", and information and communication trends over time. Opportunities lie ahead to harness insights from these potential health narrative documents at scale, by expanding the scope of information to multiple disasters and other relevant sources of health information. The presented results and the codebooks allow the definitions of relevant health information categories for which machine intelligence could be built upon to extract health information at scale. Using advanced computational methods will provide a crucial and complementary approach with which to scale. In particular, we envision three key areas of future research investigations in the short term.

First, the exploitation of relevant, complementary data sources from the relevant response sectors such as situational reports from the logistics, shelter, water, and sanitation sectors would complement and enrich the overall knowledge acquisition process of health IM systems. Often, the knowledge required by health response operations is dependent on other sectors, thus systems that capture, analyze, and integrate information from related sectors will provide more targeted and comprehensive situational awareness for action-oriented decision-making. One of the largest humanitarian information repositories in the world, humanitarianresponse.info, represents a small fraction of overall situation reports that can be structured and analyzed for health information across both natural disasters and complex emergencies. Nonetheless, there are 10,987 publicly available situation reports and humanitarian bulletins in h for which to analyze and build a knowledge base not yet achieved to date for health in humanitarian response.

Second, we need to develop unifying health domain ontologies to represent the diverse concepts of humanitarian health information management unambiguously and seamlessly for both humans and machines/automated systems, with a focus on humanitarian actors. While human intelligence has contributed in developing a variety of coding schemes and lexicons for qualitative-quantitative analyses, such resources, unfortunately, remain

siloed and primarily non-interoperable for the tasks of information management. In addition further exploratory studies are needed to investigate and build more lexicons and taxonomies (i.e., schemes of classifying health terms) that associate health with key related sectors such as logistics and shelter in humanitarian response. For example, 66 logistics cluster situation reports and similar narrative documents, and 67 shelter cluster reports from the 2010 Haiti response are publicly available. Such ontologies will help transform the unstructured situation report data from various sources into uniform structured information that can easily be harnessed by advanced computing methods integrated across different systems for interoperability.

Lastly, there is a need to validate existing computational methods and design novel approaches to extract health information at scale from the large variety of existing data sources. While it is challenging to utilize these computational methods in real time given the complexity of relevant health information, state of the art methods of pattern recognition, natural language processing, and machine learning provide a good starting point for structuring the narrative. By using unstructured health information across various narrative information environments, including non-traditional sources such as social media, there is opportunity to extract health information and initiate timely analytics. Also, to further analyze large scale narrative information sources, such as situation reports, across various crises, we need to combine the power of human knowledge embedded in traditional qualitative coding with the automated systems. Automated systems, specifically machine intelligence, have the ability to extract relevant health information for a specific event at scale. More studies are needed for analyzing multiple disasters and humanitarian crises (e.g., Nepal Earthquake, Kerala Floods, West Africa and DRC Ebola responses) to further understand common health priorities as well as unique public health and medical needs for designing such universal qualitative codes, which can eventually be integrated into automated systems with machines that identify patterns for information categorization and knowledge management for health.

ABSTRACT

This paper presents a study where nine Swedish citizens were interviewed about their concerns and expectations, from a customer perspective, in relation to a 10 day disruption in the payment system. The purpose of the study was to understand the customer's perspective in order to provide input to the development of a simulation environment. This simulation environment aims at allowing different stakeholders to experience how a disruption in the payment system affects the local community and thereby create understanding of how resilience is built and affected. The research questions were: What do customers expect to get access to? When? What are customers prepared for? How does this differ among different customer groups? The results indicate some understanding of how such a crisis affects the local community and what the informants expects to happen. The respondents represented a diversity of socio-economic backgrounds from rural and urban parts of the municipality.

Keywords

Community resilience, customer perspective, payment system, crisis management

INTRODUCTION

Disruptions in the payment system in societies where cash is no longer king may lead to dire consequences with unexpected cascading effects. In a society where many business owners have chosen to avoid cash payments, relying on credit cards or internet payment solutions (for example, Swish, Apple pay, Google pay, Paypal etc.) a disruption in the payment system lasting over several days will have unpredictable consequences. For example risks with interconnectedness of supply-chains, breakdown in the transport system due to lack of fuel for cars and trucks, social unrest and hoarding, failures in human handling of complex socio-technical system (Chopra & Sodhi, 2004; Reason, 1990; van Laere et al., 2017; Wears, Cook, & Perry, 2006).

The study is a part of the project Creating Collaborative Resilience Awareness, Analysis and Action for the Finance, Food and Fuel Systems in INteractive Games (CCRAAAFFFTING), commissioned by MSB (the Swedish Civil Contingencies Agency). Earlier papers from the CCRAAAFFFTING project have focused on different aspects of disruptions in the payment system and how to build a simulation environment for this (van Laere et al., 2017; Johansson, van Laere, & Berggren, 2018; 2017; Berggren, van Laere, & Johansson, 2018; Johansson et al., 2018; van Laere et al., 2018). This paper takes on the customer perspective. The study reported in this paper is based on a bachelor thesis (Lundberg, 2018). Within the CCRAAAFFFTING project, gaming-simulation is used to simulate this interconnected infrastructure in the payment system. Simulation generally aims at designing a model of a system in a complex problem area in order to perform various experiments (Grune-Yanoff & Weirich, 2010). The simulation approach used in CCRAAAFFFTING is described in detail in Johansson, Laere, and Berggren (2018). In short, the simulation comprise a number of grocery stores (ranging from local convenience stores to mega-stores), petrol stations, banks and the flows of goods, fuel, and payments (both cash and by other transfers) that occur between these. Gaming-simulation is used to gain deeper insight in the behaviour of the participants by evaluating various operating strategies against each other in one or multiple scenarios (Laere et al., 2006). It also creates a deeper learning opportunity since the participants are active

participants in the simulation and are not just passive observers.
