Resilience is used to describe how a system critical to society, such as industry, infrastructure, finance or ecology, can absorb changes or disturbances and still persist (Holling, 1973; Foster, 1993). Community resilience is defined as a "process linking a set of networked adaptive capacities to a positive trajectory of functioning and adaptation in constituent populations after a disturbance" (Norris et al., 2008, p. 131). A community is defined as "an entity that has geographic boundaries and shared fate. Communities are composed of built, natural, social, and economic environments that influence one another in complex ways" (Norris et al., 2008, p.128). Community resilience is about the community´s ability to identify, summon, and address social problems and to use resources held by the community such as knowledge, skills, and systems to handle a disturbance. The customers are part of a community and can thus contribute to community resilience. A disturbance can be seen as a crisis, which might develop into a disaster. No matter if a disaster is natural or human-induced (Shaluf, Ahmadun, & Mat Said, 2003), it might affect the citizens access to cash. Parker (1992) suggested a definition of disaster as "an unusual natural or man-made event, including an event caused by failure of technological systems, which temporarily overwhelms the response capacity of human communities, groups of individuals or natural environments and which causes massive damage, economic loss, disruption, injury, and/or loss of life". Despite the effort to understand risks and develop routines for preventing and easing the effects of serious disruptions in the payment system in Sweden, there is still a lack of insight into how numerous actors in society (e.g. citizens, food stores, petrol stations, voluntary organizations, and so on) will act in case of a temporary or complete breakdown of the payment system (Johansson et al., 2018). Several key actors in the payment system have articulated that they will take a larger responsibility than their formal responsibility (MSB, 2009). How then, would the general public react to a prolonged disturbance in the payment system? More specifically:

How is the customer prepared for disruption in the payment system?

What does the customer expect to get/have access to?

When does the customer expect to get/have access?

How does this differ among different customer groups?

The answers to these questions will be used to inform the continued development of the simulation platform and scenarios for the CCRAAAFFFTING project. This will allow for a gaming-simulation, as the knowledge source is rooted in empirical findings. In addition, participants will feel more at ease relying on the stated behaviors of real customers.

METHOD

This was carried out as an interview study with different customer groups.

Participants

Nine persons volunteered to participate (5 women and 4 men). Their age varied between 23 to 76 years. The participants represented several different customer groups. All participants lived in a mid-sized Swedish municipality (> 100 000 inhabitants). They all were the primary provider of food for the household they belonged to (or shared the responsibility equally with another person). Two were students at the local university, one person was retired, and seven persons were employed. Six participants lived in or next to a larger city, one in a smaller town, and two were living in the countryside. Hence, the respondents represented a wide diversity of socio economic backgrounds and came from different parts of the municipality

All participants were informed about the study and gave informed consent to participating. No reimbursement was given. The study complies to ethical research regulations (Vetenskapsrådet, 2002) and the GDPR (the General Data Protection Regulation effective in EU). No ethical approval was necessary for this study according to Swedish law.

Material

A semi-structured interview approach was used (Howitt, 2013). Pre-identified questions were used, which were supplemented with questions that evolved during the interview. The pre-identified questions were identified through walk-throughs of identified payment disruption scenarios and piloted with persons who took the roles as customers when responding. The proper interviews were recorded and later transcribed. All interviews were held in Swedish.

Analysis

After the material had been transcribed, it was analyzed using thematic analysis. Thematic analysis is a method for identifying, analyzing, and reporting patterns in data (Braun & Clarke, 2006). Howitt (2013) states that thematic analysis is studying what is being said, rather than how it is said. Themes are found through an inductive approach, or using a bottom-up perspective, where the quality of statements in relation to the research questions is important (Braun & Clarke, 2006).

RESULTS

Four main themes were identified. These had ten sub-themes connected to them. The main themes and sub-themes can be seen in Table 1 (below).

Table 1. Themes and sub-themes identified using thematic analysis.

Main theme	Sub-theme	Comment
At home (A)		This theme is about the preparedness of the customers
	Having cash is random (A.1)	
	To manage 72 hours without shopping (A.2)	
When the crisis is present (B)		This theme focus on types of products the customers would look for and desired information
	Durable products (B.1)	
	The importance of information (B.2)	
When the debit cards does not work (C)		This theme focus on concerns regarding not being able to use bank cards
	Worry about cash machines running out of money (C.1)	
	Anticipations when cash runs out (C.2)	
	Alternative solutions to the problem (C.3)	
Who is responsible (D)		This theme is about expectations on how society and the community will react
	The responsibility of the stores (D.1)	
	The responsibility of the banks (D.2)	
	The responsibility of the government and the state (D.3)	

The first main theme *At home* (A) is about the preparedness of the customers. It includes the subthemes *Having cash is random* (A.1) and *To manage 72 hours without shopping* (A.2). *Having cash is random* (A.1) is about that many persons do not have any cash at home or in their wallet. The majority of the informants usually did not carry any cash, and if they had cash it was mostly from when other people had paid them cash. One informant explained that cash was from older relatives who had paid for something with cash or that the kids had cash to better understand how money works. *To manage 72 hours without shopping* (A.2) concerns if the informants would manage without shopping for 72 hours. All informants claimed that they would. However, people living inside the cities, close to grocery stores, said that that was about the limit of their food stored at home. Persons living further away from the grocery stores or outside the cities said that they would be able to cope for a longer time without shopping. They had a stock of food and fuel, and would be able to cope for up to

a week.

The second main theme *When the crisis is present* (B) focus on types of products the customers would look for and what information is desired. The first subtheme *Durable products* (B.1) emerged as a response to the question "If you know there was going to be a disruption in the payment system, what would you buy?". All informants said that they would buy durable basic products; eggs, canned food, milk powder etc. Only people living outside the cities would buy fuel. This subtheme points at that the customers are looking for durable products that are easy to stockpile so that they won't have to shop as often as they usually do. This demonstrates that a resilient behavior emerges as the crisis has already happened. *The importance of information* (B.2), the second subtheme, is about what information the informants think they need. A majority of the informants considered that information should be available through newspapers, internet, and television, while also on billboards outside shops. What information is needed differs, but they think that information about how to go about paying without bank cards is central.

When the debit or credit cards does not work (C) the third main theme focus on concerns regarding not being able to use bank cards. Three subthemes were identified: *Worry about cash machines running out of money* (C.1), *Anticipations when cash runs out* (C.2), and *Alternative solutions to the problem* (C.3). Under the subtheme *Worry about cash machines running out of money* (C.1) some informants would anticipate that cash machines would run out of cash and that the amount of cash in the Swedish society was not enough in relation to expected need. This could lead to higher rate of criminality and a "we against them" feeling. At the same time some informants did not think that there would be any problems with access to cash from cash machines. From the next subtheme *Anticipations when cash runs out* (C.2), in direct opposition to the previous subtheme, some informants thought that collaboration and support among the public would increase. People might car pool, use public transportation, or stay with friends (closer to work) to save fuel. One informant thought that trading possessions might be a way of getting around not being able to shop. *Alternative solutions to the problem* (C.3) was a subtheme where the informants stated different alternative solutions that they saw possible; use credit, invoice, ration cards, Swish (a Swedish digital system for exchanging money between users), or manual reading of bank cards.

The final main theme *Who is responsible* (D) is about expectations on how society and the community will react. Here, three subthemes become apparent. The subtheme *The responsibility of the stores* (D.1) involved that most informants considered that the stores had the major responsibility for resolving the situation. That is, some informants thought that the stores were to settle the issue with the payment system, while others considered that the store's responsibility was to set up a temporary solution for payment. Some informants expected the stores to close down during the payment disruption. Another subtheme was *The responsibility of the banks* (D.2). Here, the informants thought that the banks had a large part in handling the disruption, both in terms of resolving the actual cause of the disruption as well as expecting that the banks support society in providing cash and making offices and cash machines available through extended opening hours. *The responsibility of the government and the state* (D.3) concerned how the government and governmental agencies needed to step in and take control of a situation so that everyday life of individuals could continue.

DISCUSSION

This study aimed at answering the following questions:

- How is the customer prepared for a disruption in the payment system?
- What does the customer expect to get/have access to?
- When does the customer expect to get/have access?
- How does this differ among different customer groups?

This section will first present the answers to the research questions and then provide a general discussion.

How is the customer prepared for a disruption in the payment system?

Most informants were not prepared if the debit or credit cards stopped working. Few had any cash readily available, while some had food stocked lasting for up to more than a week. Most informants said that they could last 72 hours without shopping (a time frame that citizens are expected to cope without the government providing food in the event of a crisis; MSB, 2015).

What does the customer expect to get/have access to?

Expectations point in different directions; some informants hoped that the banks and stores could resolve the problem, others thought that cash would not be available as the cash machines would run out of cash. All informants anticipated information needs on the development and escalation of the crisis. The information should be accessible through usual information channels, be clear and concise, should focus on facts about the situation and how to act as citizens in order to not increase the crisis escalation. The informants foresaw that durable food products would be in demand, as it is easier to store and keep. However, informants in the cities expected that food would be accessible and available through shops as they did not have large stocks of food at home (more than 72 hours of food).

When does the customer expect to get/have access?

The 72-hours recommendation from authorities seemed to be a rule of thumb for informants' expectations. Hence, a longer crisis would burden community resilience to larger degree. Most informants would not manage a 10-day crisis without support from the authorities.

How does this differ among different customer groups?

Citizens living inside cities have expectations and preparedness that indicate a less resilient behavior, as they are less prepared with stored food and consumables with short turnover in their homes. They are used to visit the shop frequently next to their home to purchase products that they need. One reason might be since living in city centers, every square meter is more expensive. Hence, to keep costs down, less money is spent on storage space where durable food can be stored. Further, the fact that stores are available, usually within walking distance, decreases the need to stockpile food and other consumables. People in the cities are more dependable on food, while people outside the cities seem to have more need for fuel in order to be able to move around.

General discussion

The interviews suggest that people living in the countryside are more resilient than those who live in the city, in a situation where the payment systems stop working. People need more information about payment systems to be more resilient and to reduce concerns and social unease regarding what might happen. A disruption in the payment could lead to distrust in the payment system including the authorities and businesses responsible, even if it is just an expected responsibility. Welch et al., (2005) state that "trust makes market behavior possible by allowing people to exchange money, a scarce re-source, without great levels of risk or uncertainty being incurred" (p. 466). Declining trust in government leads to reduced support for government action (Chanley, Rudolph, & Rahn, 2000). The validity and authority of a democratic system becomes hollow when citizens withdraw support for government and become less willing to comply with governmental decisions. Brehm and Rahn (1997) showed a correlation between social trust and civic participation. Hence, a disruption in the payment could lead to distrust in the payment system causing lower levels of trust in the government and in lower levels of civic participation. This would decrease community resilience, the community´s ability to identify, summon, and address social problems and to use resources held by the community such as knowledge, skills, and systems to handle a disturbance. Such a decrease in community resilience could become a downward spiral into social disorder. From the sociological literature we assume "that stable social relationships cannot exist for long in the absence of social order. However, it is equally apparent that trust is a requirement for both social order and social relationships" (Welch et al., 2005, p. 467). This dependence on trust in social relations on the individual level have shown to affect and be transferred to group and community level (Welch et al., 2005).

Future work

Including citizens with different backgrounds would provide alternative experiences. For example, interviewing citizens/refugees who have fled from warzones could bring a different perspective on what is essential in times of crisis.

CONCLUSION

The themes identified in this interview study provides input to the larger CCRAAAFFFTING project in that they offer empirical findings as input to the gaming-simulation so that the realism is as truthful as possible, and that the injects and their effects in the simulation environment are authentic and reasonable. The current simulation utilizes an agent-based model, implemented in the AnyLogic™ platform. Customer agents shopping needs are modeled based on available statistics and assumptions. These agent-models can be altered to better reflect customer expectations during the disruption event. The findings from this study also suggest that the

community resilience and social trust can have a grand effect on the escalation and cascade effects initiated by a disruption in the payment system.

ABSTRACT

Several attempts have been made at creating mobile solutions for patients with mental disorders. A preemptive approach would definitely outdo a reactive one. This project seeks to ensure better crisis detection, by assigning patients (veterans) to caregivers (mentors). This is called the mentor-mentee approach. Enhanced with the use of mobile technology, veterans can stay connected in their daily lives to mentors, who have gone through the same traumatic experiences and have overcome them. A mobile application for communication between veterans and their mentors has been developed, which helps mentors get constant feedback from their mentees about their state of well-being. However, being able to make good deductions from the data given as feedback is of great importance. Under-representing or over-representing the data could be dangerously misleading. This paper

presents the design process in this project and the key things to note when designing a data visualization for timely crisis detection and decision-making.

Keywords

crisis, mental health, visualization, veterans, clinical decision.

INTRODUCTION

The process of moving from the days of active military service into living within the community of civilians could be very challenging for members of the military. It has been found out to be a major change in the life of veterans, since it affects almost every aspect of their lives (Elnitsky *et al.*, 2017). Their lifestyle, attitude, responsibilities have to change or be suitable for these areas of their lives, to avoid chaos, crisis or unpalatable situations. This shows how important re-integration is, as this can negatively impact various aspects of the veteran's life, such as the mental state of the veteran, leading to psychological issues and distress.
It has therefore been seen and recognized that there is the strong need to prepare veterans for reintegration as much, if not more, as they are prepared for deployment to war (Rizia, 2016).

Simple solutions sometimes are not adequate enough to solve crisis situations, due to the interconnected and interwoven nature of these crisis situations. There are certain similarities between dissimilar events such as natural disasters and mental health crises suffered by individuals. These similarities include: vulnerabilities created beforehand, warning signs that appear early enough, before the occurrence of the crisis or disaster, and a crisis event occurring beyond the critical point; for which efforts and resources must be employed in order to remedy any harm done and to bring things back to normalcy. Predicting true crisis events, using human or computational techniques have been quite difficult and not getting accurate predictions can lead to serious problems (Franco *et al.*, 2016).

Dryhootch (DH), a veteran-led community organization in Milwaukee has successfully implemented a veteran peer-mentor support program for helping veterans reintegrate into the society, which has been shown to be effective (Rizia *et al.*, 2014). A technological approach has also been put in place and is still currently being worked upon. The approach makes use of an online support system for the DH veterans, which has already been built and is in use. Also, a mobile technology-mediated peer-mentor support system called the Quick Reaction Force (QRF) application, which was carefully designed considering quite a number of factors, has been built and is now being deployed for use (Rizia *et al.,* 2015). Since detecting possible crisis events before they occur is of utmost importance here, the task of being able to visually present, in the best possible way, any data collected from veterans to their peer mentors must be solved. A solution to the stated problem would allow for better predictions and detections of possible crises. Presented here is a design solution for the representation of data, on the state of well-being of veterans, giving a visually-aided clinical decision support system.

The Use of Mobile Technology in Behavioral Medicine

Mobile technology use in healthcare has seen significant growth and has been proven to be a very good choice in the development of healthcare solutions. Free *et al.*(2013) conducted a review to assess the effectiveness of mobile technology solutions provided to healthcare consumers. Healthcare providers need to effectively encourage their patients to make healthy lifestyle choices, which can help combat their diseases. Traditional face-to-face consultations are limited, but mobile technologies such as mobile phones help to achieve the desired effectiveness in the delivery of health messages for behavioural situations.

It was demonstrated that mobile interventions through text-messaging increased adherence to the therapy administered, albeit applied to a niche of smokers (Free *et al.*, 2013) and adolescents with chronic health conditions (Badawy *et al.,* 2017). Also, Santosh *et al*. (2009) conducted a similar review, geared towards evaluating the role of cell phones and text messaging interventions in improving health outcomes and processes of care for health conditions such as diabetes. Their findings concluded that enhancing standard care with reminders, disease monitoring and management, and education through cell phone, voice, and short message service could help improve health outcomes and care processes.

Informatics Approaches to Clinical Decision Support

Clinical decision support systems (CDSSs) help caregivers make appropriate clinical decisions. CDSSs have been adopted by both professional and paraprofessional caregivers. A review was done on how well CDSSs affect physicians' performance. The use of CDSSs, by medical professional caregivers, to recommend proper medicine doses, diagnose chest pain or send notifications for immunizations were examined and the findings showed that given the use of CDSSs, physician performance can be improved (Johnston *et al.*, 1994). CDSSs have been proposed as the solution to overcoming the significant barriers, which exist and are hindering the effective and efficient application of genetics at the point of care. Incorporating CDSSs is seen as a practicable solution to help clinicians manage the complexities of genetics at the point of care (Welch and Kawamoto, 2013). In different countries, paraprofessionals like skilled nurses use clinical decision support software for tele-health (Russell *et al.*, 2017).

Various studies show that visualization tools positively impact clinical decision support and increase practitioners' performance. Visualization tools assist in clinical decisions in infection management (Garcia-Caballero *et al.*, 2015). In another study related to child health improvement, with the use of an electronic medical record platform, utilizing 170 unique variables representing unique clinical observations, in 300 medical logic modules, the use of visualization tools allowed for more effective interaction of different teams (Liu *et al.*, 2015). Mane *et al.* (2011) mentioned how the use of visual analytics can play a significant role in making clinical evaluations and understanding the effectiveness and risk of different therapeutic options for different subpopulations of patients. It is believed in Mohr *et al.* (2013) that data visualization approaches are necessary for making effective clinical decisions via mobile technologies in mental health, rather than the use of mobile technologies without data visualization. It is believed that data visualization approaches are necessary for making effective clinical decisions via mobile technologies in mental health. In this paper, we address this issue with respect to veterans' mental health and paraprofessional decision-making for early crisis detection.

Essentializing Early Warning and Crisis Information for Paraprofessional Caregivers

Assessments of change, dynamics, and cause-and-effect are at the heart of thinking and explanation. To understand is to know what cause provokes what effect, by what means and at what rate. Representation of such knowledge is also vital. A carefully thought-up design strategy must be in place to ensure the proper arrangement in space and time of images, words and numbers. Tufte (1997, p.9) suggests that clarity and excellence in thinking is a parallel to clarity and excellence in the display of data.

In any data representation and visualization endeavour, the principles that inform the design for the representation of the data involved are very important. Questions such as, "What principles should inform the designs for showing the data?", "Where do the principles come from?", "How can the integrity of quantitative descriptions be maintained?" and "What are the standards for evaluating visual evidence, used for making decisions?", need to be asked (Tufte, 1997). Caroll e*t al.* (2014) conducted a systematic review focused on the landscape of infectious disease visualization tools for public health professionals. This would clearly impact the decision to be made based by them, given the varying choices of data visualization tools. Their objectives included identifying public health user needs and preferences for infectious disease information visualization tools. The first visualization used in the study was a dot map to represent each incidence; the second visualization used a choropleth map to represent data on an individual level. The map showed the incidence rate per 100,000 persons and this further showed differences. Graded colours were used to indicate the values of some aggregate measure in specified areas, that is, telling the disease incidence rate based on the colour intensity. A darker colour was an indication of a higher rate of incidence. Also, individual or aggregate level data could be used to derive a spatial risk gradient. The possibility of using an individual or aggregate level data to statistically derive a spatial risk gradient was also demonstrated (Carroll *et al.*, 2014). These three visualization techniques made use of the same data, but different approaches to visualizing the data, at hand. The third showed the information in a much more condensed and useful manner, with a risk gradient depicted, making it much more helpful, as compared to the second, which showed the concentration of the incidences only and the first which merely showed each individual occurrence, without a good decision support framework.

Prior Work

This work builds upon and is an enhancement to an existing work. The team has an ongoing work, namely the Quick Reaction Force (QRF) mobile application, which has been centered around the design and implementation of a mobile solution, which harnesses a peer-mentor model for monitoring, communicating and mentoring younger veterans by older ones (Rizia *et al.,* 2015). Over time, there have always been attempts to build an improved solution to the existing mobile application and this explains one such improvement made. All efforts or work described here have received Institutional Review Board (IRB) approval for human subjects research.

Veteran Community Engagement for Research

This work is driven from a Community Based Participatory Research (CBPR) perspective, Dryhootch leaders and faculty from the Milwaukee Veteran Affairs (VA) Medical Center and the Medical College of Wisconsin. We have partnered with Dryhootch of America, a non-profit veteran-led, veteran-serving community organization headquartered in Milwaukee, Wisconsin for about 5 years to develop a smartphone app to support veteran-to-veteran mental health intervention. Descriptions of this community-academic partnership, the Dryhootch Partnership for Veteran Health, its formation, and lessons learnt are detailed elsewhere (Franco, Logan et al. 2016). One common area of interest within the partnership was improving outreach to younger veterans returning from Operation Enduring Freedom (Afghanistan) and Operation Iraqi Freedom (often referred to as "OEF/OIF veterans") using technology. OEF/OIF veterans have different expectations about connecting with systems of care often preferring technology-mediated contact as compared to veterans from prior US military service eras (Franco *et al.*, 2018).

METHOD

The QRF system is one that requires that veterans' data, collected in form of feedback, be appropriately represented, due to the reason that an early detection of crisis warning signals is paramount to the success of the peer mentorship program. This can only be achieved if the information is presented to the mentors in the appropriate way. With the right data representation, a mentor can easily detect, with the visual cues, what the state of the veteran is and can notice early any signs that may indicate a potential crisis.

This work makes use of a collaborative design approach, by engaging the stakeholders in the design of a key part of the mentor view of the mobile application, which involves giving a mentor the necessary information needed to make a decision on the state of his mentee. Throughout the design of the application, there were inputs from the veterans as to what would be good to have, with the more important and essential ones taking top priority. For this aspect, however, a broader coverage of veteran mentors were involved in deciding the appropriate parameters to be used. This obviously made the design path clearer and strengthened the acceptability of the application to its users. From the veteran view of the application, the veterans are presented weekly surveys, which they fill. The survey consists of five questions, which are centered around their current state of physical and mental health and can be taken at any time in a day. Some of the questions asked are:

a. Have you engaged in any risky behavior (as you define it) this week?
b. Has your health changed this week?

All questions have only three options: Yes (a score of 3), Maybe (a score of 2) and No (a score of 1). This was made simple due to the veterans' preference that options be simpler than a typical 5-point research study scale. With these, the scores are assigned based on the responses for each question and an aggregate of these is the final score of the veteran.

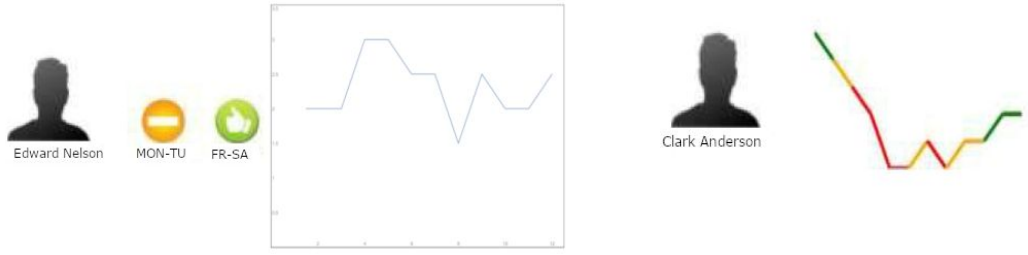
For instance, if the responses to the questions included 3 "Yes" responses, 1 "No" and 1 "Maybe", the total score for the veteran would be 12 out of 15. Every time that the veteran takes the survey, this score is calculated. In essence, if a veteran had better responses throughout the survey, he garnered a score of 15; if worse responses were given, he got a score of 5 and if mixed responses, he got a cumulative score based on the response scores. If the veteran missed the survey, a score of zero was given to represent that the survey was missed.
These scores are reported to their mentors, by virtue of a graph representation. Since the scores are indicative of whether the veteran is performing well and is in a good state, there is the need to adequately show the state of a veteran over a period of time. The chosen period to be displayed to the mentor was the last seven (7) days from

the current day. That is, for every day, over the last seven days, the state of the veteran is shown, with visual aesthetics that can adequately portray the needed information to the mentor.
There were a number of different approaches tried, in a bid to get a visualization that best explains the state of the veteran. In all of these approaches, certain things were observed, learned, and adjusted upon for a better visualization. These approaches are discussed here and the key points to note from each trial approach and its outcomes are stated, as well. After utilizing different approaches, the approach that was finally adopted and taken was one that involved the input of the mentor veterans. With reference to the earlier design specification, Rizia (2016, p.54) states the tasks that need to be performed by a mentor, once the dashboard showing his assigned veterans is displayed. The tasks include:

a. Detecting early warning signs of crisis.
b. Determining if there is an immediate need to reach out to particular veterans who are in an acute mental health situation.
c. Make a decision about how to best use limited resources.

The initial design approach, prior to this, involved creating three different levels of mock screens for the mentee panel User Interface (UI). This was moved from a UI with maximum information availability (one having a trend indicator icon and a monochromatic graphical display) towards a UI that was fully essentialized (one without a trend indicator icon and a coloured graphical display) with minimal elements. The UI levels were defined by the researchers and the UI in the latest application version was taken as a reference and improved upon. For three of the UI levels, only the UI representation changed. All other information such as survey scores and veteran information were the same (Rizia, 2016).

The icons were a thumb-down, a thumb-up or a neutral sign. A thumb-up indicated an improvement from the past response, a thumb-down indicated a declination from the past response and a neutral sign represented no change or very little change. A graph was also displayed for each veteran and the graph values were the scores of the veteran, based on the responses to the weekly surveys, filled over the past twelve weeks in a prior completed survey (Rizia, 2016).



(a) **(b)**

Figure 1. (a) Mock Screen for Maximum Information UI; (b) Fully Essentialized Mentee Panel UI

This approach made use of community-based feedback, by seeking responses from the veterans, specifically about which UI level best appealed to them. The conclusion was to implement a fully essentialized UI.

Also, prior to the implementation of a mobile application, a twelve-week survey was conducted, which involved recruiting veterans for a study over the stated period. The aim of the study was to assess the effectiveness and impact of a 12-week veteran peer mentorship program on the wellbeing of the veterans. This was done by assessing the veterans' PCL-5 scores at the entry into the program, mid-point and at the discharge from the program. The veterans were asked the questions stated above on a weekly basis and their responses were analyzed afterwards. The next figure shows the result of statistical analyses carried out to determine the Post Traumatic Stress Disorder Checklist (PCL-5) score of each veteran, who participated in the survey, over the 12-week period. This kind of information on the veterans is what needs to be meaningfully visualized to the mentors, with the use of a mobile application, for early crisis detection and decision-making. The bars representing each of the twelve weeks are coloured red for a worse state; yellow for the same state showing no difference in state as compared to the previous week; green for a better state or white for a missed survey. For the analysis shown below, 272 veterans' data was considered, with 129 of them having a PCL-5 score less than 33 and 143 having a score of 33 or more at entry into the program. The majority of participants in the survey

were younger veterans, who served during the Operation Enduring Freedom (OEF) and Operation Iraqi Freedom (OIF) era.

Veteran Mentor Experience

It's imperative to understand the experience of the Veteran mentor. Their experience highlights the effectiveness of the design and also emphasizes the opportunities for future features. We know that Veteran mentors have the most contact with veteran mentees in comparison to psychologists or psychiatrists, or other professional healthcare providers. The veteran mentor forms a close relationship with their mentee, which fosters trust allowing for mentees to feel comfortable disclosing critical information to their peer mentor. This allows the veteran mentor to gain greater insight to the daily life, warning signs and high risk environments that are specific to their mentee.

Veteran mentors have shared that these insights help them to guide their mentee toward the mentee's own view of what well being means to them, which can be useful when the veteran is interpreting the data on the mobile application. However veteran mentors sometimes struggle with memory and attention. Any recall bias can be combated by the overview of the weekly trend line displayed in the application, which is an accurate representation of the mentee's status.

Veteran Mentors' Implicit Theories of Early Warning Signs and Crisis Events

In determining what constitutes an early warning sign or a precursor to a crisis event occurring with a veteran, an intuitive decision-making approach is taken. This approach involves checking the survey responses from the veteran for the presence of two worse responses in one week. This can serve as a symptom or an early warning sign of a crisis. Also, three or more worse symptoms in one week or more than two worse symptoms over two consecutive weeks could be considered as acute crisis. Unchanged PTSD symptoms or becoming worse at the twelve-week discharge could be considered a long-term crisis.This information would need to be represented to each mentor on a daily basis, for quick and effective decision-making. In Figure 2, the result of statistical analysis necessary to make these intuitive decisions were shown for both veterans who were initially identified as having PTSD and those who were not.

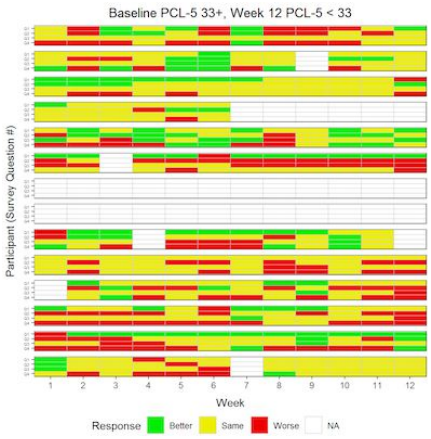


Figure 2. Representation of statistical findings from the 12-week survey data

Presented below is a figure showing the resulting visualizations for all approaches detailed here.

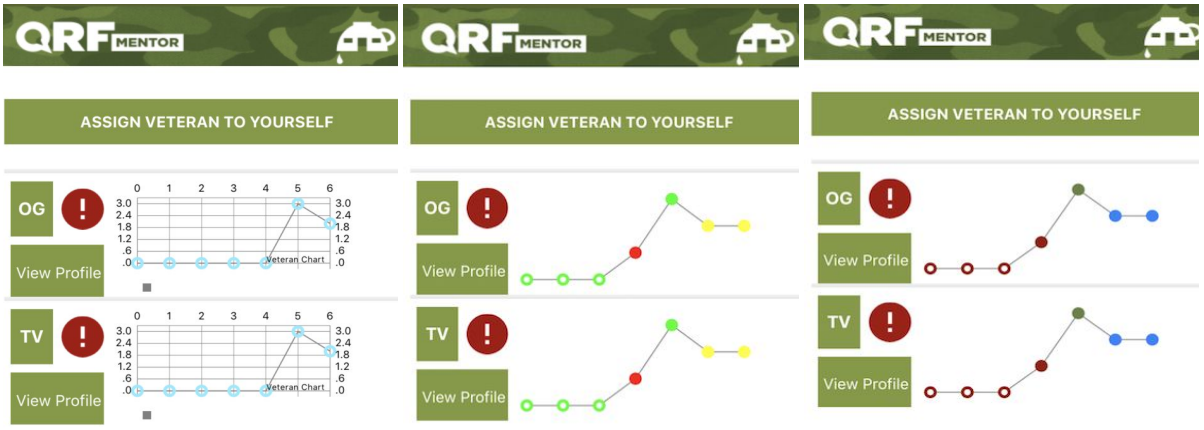

Figure 3. (a) Plotting Raw Scores; (b) Plotting an Abstraction of Scores; (c) Community-based Involvement

Plotting Raw Scores

The first approach was to plot the exact raw scores of the veteran against each day of the week to be shown on the sparkline. This showed the detail of the scores for each day, which seemed good and exact, but the graph plotted was quite rough, as the different scores shown, were without any other visual cue. All of the background lines of the graph were shown and this made it visually cumbersome. Also, the axes were labelled and considering the limitation of space in a mobile device, there needed to be more work done on the visualization to make it better fit for the representation intended. From Figure 3(a) above, the scores are plotted with no clear distinction as to what state the veteran might be in. The generic light-blue colour says nothing more and is simply a graphical decoration. Also, the presence of lines in the graph make it cluttered. That said, the veteran mentor would not be able to deduce vital concrete information, in good time in order to make the necessary intervention.

Plotting an Abstraction of Scores

Considering the inadequacies of the first visualization, a mock-up was designed for the visualization, with different options for the look of the sparkline. An option that eliminated the noise caused by lines and numbers was chosen. Also, there was the addition of visual cues, such as colours to represent each state of the veteran, as opposed to a general colour, which gave no additional information about the data being displayed. The colours green, yellow and red were used to denote good, fair and bad states, respectively. For empty points, a green circle with an empty hole within it was used. This approach involves plotting the raw scores of the veteran for each day with colours to give an impression of the state of the veteran. This was good but there were still subtle issues with it. As stated earlier, the initial approach showed the raw score with a general colour, to indicate the state of the veteran. However, this was not so helpful because of the lack of distinction between the colours. Also, the raw scores allowed for subjective interpretation. This was deemed a design flaw, as the technology and system should be designed to present the mentor with accurate and most vital information. What was done next was to abstract the scores data to the different levels: good, same, and bad. So, rather than have scores 1-15 being returned when the scores are fetched, a score of 0, 1, 2 or 3 was returned. The abstraction was done such that 0 was used to represent missing data, 1 was to represent a poor state, 2 to represent same state and 3 for a better state. Table 1 shows the categories and their colour representation.

SCORE	ABSTRACTION	COLOUR
Missing data	0	Green outline with empty circle
5-7.5	1	Red circle fully-filled.
7.5-12.5	2	Yellow circle fully-filled.
12.5-15	3	Green circle fully-filled.

Table 1. Table of Scores Abstraction

With this, only four possible values were returned and these were used for the sparkline. This approach was good for the following reasons:

1. The scores were more succinctly represented by state values and so, not all the scores, which might be too much information, were presented to the mentor.
2. The introduction of colours for the different abstractions changed the generic light-blue colour initially used, giving a more specific representation.

After these different options were chosen, another look was presented, as seen in Figure 3(b). Initially, a green outline and empty circle was used to indicate a missed survey. After careful consideration, the initial green outline with an empty circle was seen as misleading, as it was concluded that mentors might think, based on intuition that the veteran was doing well, without actually realizing that the survey was missed. This was due to the use of the green colour in the outline, which is more closely associated with a stable state of rest, growth and flourishing (Grant, 1879), with no perceived sense of danger or urgency, as opposed to the intent here. A missed survey might constitute a warning signal. However a veteran stated, during the deliberation, that if he were viewing the sparkline in a hurry, it might be easy to overlook the empty circle and assume a good state. Since the intent was to communicate to the mentor that the veteran missed the survey for the day, a green coloured outline was inappropriate for the intent because this could lead to a misinterpretation of the data. After deliberation, it was decided that the colour needed to be changed and replaced with one depicting a sense of urgency or possibly immediate danger. Obviously, the colour "red" would be a good fit for the situation.

Also, noted in the visualization arrived at after the second approach, the same state of the veteran, being represented by the yellow colour was seen to be quite inappropriate for the following reasons:

1. The yellow colour was too light, quite inconspicuous on the device and could be easily overlooked in an environment of high light intensity. Moreso, visually-impaired mentors could dismiss it.
2. The colour, though known to represent a warning sign (as in the case of traffic lights and other alerting systems), was still not seen as the best fit for the "same" state representation.

It was therefore arrived at that both the green outline for denoting missed surveys and the yellow colour for denoting "same" state had to be changed to colours more appropriate for communicating the intended state. With this, a third approach was decided upon. This approach was a community-based approach in getting a more appropriate visualization, based on the opinion of the community of veteran mentors.

Community-based Involvement

This last approach built upon the second approach, modifying the visual cues, based on a survey carried out that engaged the veteran mentors, who would be using the mobile application. The colour representation for a missed survey was changed to a red outline with an empty circle, instead of the previous possibly misleading green outline with an empty circle. Also, the colour for the same state was changed to blue, based on the veteran community input.

SCORE	ABSTRACTION	COLOUR
Missing data	0	Red outline with empty circle
5-7.5	1	Red circle fully-filled.
7.5-12.5	2	Blue circle fully-filled.
12.5-15	3	Green circle fully-filled.

Table 2. Table of Modified Scores Abstraction

The survey contained questions about which colour was preferable for a neutral state. Choices presented included yellow and blue. More responses were in favour of the blue colour, which was originally suggested by the expert anthropologist on the team. Also, the respondents (mentors) were presented with choices of shades of the blue and yellow colours preferable for the state. In addition, the respondents were presented with choices of shades of red and asked their preferences for the representation of the bad and missing states.

In general, the responses tended towards the use of the darker shades of colours and these were applied to the application. The resulting sparkline is presented in Figure 3(c). This was the finally agreed-upon visualization for the veteran data on the mentor view of the application. The focus was on designing and implementing an appropriate visualization for data regarding veteran health, which may be generalized to clinical decision systems. This was in line with a design effect mentioned in Febretti *et al.* (2014), which states how mutual reinforcement of grouped CDSS features can affect a caregiver's acceptance of care suggestions. Also stated is the positive effect of increasing the number of caregivers, if the designed interface steers users towards relevant features.

From the presentation, it is seen that the mentors can take decisions, without being burdened by information overload. They also do not have to make many assumptions or fill in many gaps for lack of information. The colors used were widely known colors that depict a particular information or emotion and these served as an enhancement to make decision-making easier and faster, as based on intuition, the mentors know the meaning of those colours.

CONCLUSION

The design of any clinical decision support system must be well thought-out and implemented. The employment of informatics approaches in building solid clinical decision support systems makes it much more effective and if well-designed provides a much greater impact on care administration efficiency, decision-making for crisis situations and patient results in terms of response to care administered and health status.
In the design of any system, relying upon the visualization of data for decision-making, the visualization tool used to represent a particular set of data may make or mar the progress of the decision system. As Tufte (1997) has stated, the key questions on the principles for the design have to be asked and answered, before an appropriate visualization tool or technique is used. It is therefore imperative to understand the data, the persons from whom the data are collected, the cause and effect relationship in the data and to provide the right tool for the data representation.

The work presented here, which is a portion of an on-going project with different phases of achievement, shows the importance of data visualization for decision making in crisis situations. We presented the path taken and noted key design elements involved in creating a data visualization component for timely crisis detection and decision-making. With reference to the design of the mobile application stated, several factors were considered: the combat-dressed figure in the welcome screen, the application menu bar army-green colour, the title of the application and other application components were selected to portray a military style. The words used in the

application were also purposefully selected in order to appeal to the army veterans and to make the system more welcoming to use. All of these choices took into consideration the trust issues the patients had with power authorities and persons of higher hierarchies. The system was designed outside of any elements that could conflict with the patients' perceived sense of security and trust and that could deter their effective use of the system. All these in addition to the subtle, but necessary details in the visualization of the patients' data had to be attended to and these would be further carried on in phases to come.
In future phases, enhancements to the application such as intervention tracking could be incorporated. With this enhancement, any interventions made by the paraprofessional caregiver could be tracked from the system. Then, the effect of the intervention could be measured over time, by observing how the patient's health state varies, based on the health scores after the intervention. Further modifications to the visual presentation might also be necessary for quick conveyance of vital information about the patient.

ABSTRACT

Information and supporting information systems is a key element in an effective emergency response. From creating situational awareness to informed decision making, information enables responders to optimize their decisions and operations. Today, with the increased availability of information technology around the globe, a new active player in the field of information management is emerging as communities are becoming increasingly active in the field of information gathering, analyzing and sharing.

However, communities may have specific requirements and approaches to using information systems in crisis situations. Moreover, connecting information systems between communities and responder pose specific challenges due to the different information needs, capacities and incentives to use them. In this paper we build on the DERMIS premises and explore through a case study if and how these principles apply to inclusive information systems. We present the initial findings of this work of designing information systems involving both communities and formal responders.

Keywords

Information Systems, Community Engagement, Participatory Systems, Systems Design, Inclusive Systems

INTRODUCTION

It has long been recognized that information plays a pivotal role in the response to disasters (Comfort et al. 2004; IFRC 2005). Information and communication technologies have fundamentally changed the availability and exchange of information before, during and after a crisis. Since the Haiti earthquake marked the beginning of disaster relief 2.0 (Crowley et al. 2010), there is a surge in information systems specifically designed for disasters (Neef et al. 2014; Piccolo et al. 2018; Streefkerk et al. 2014). Equally prominent is the use of platforms such as Twitter, Facebook, WhatsApp and other social media and instant messaging systems during disasters. In recent events, such as the Sulawesi earthquake/tsunami in Indonesia and the 2015 Nepal earthquake (Basu et al. 2017), WhatsApp was extensively used by both responders and the affected communities. In these and other disasters, WhatsApp became a critical information sharing platform in which a plethora of groups were formed for various coordination groups (Debnath et al. 2016; Meesters 2014; Sebastian et al. 2017).

The increased availability of information and the expanded reach of information networks bring about new challenges: information is gathered and shared across a wider network, a more diverse audience, and with more speed than ever before (Comfort et al. 2004; Gralla et al. 2013). As such, the requirements for systems that support effective information management also change. For example, systems need operate in a more distributed manner, allowing different user(groups) to connect, share and use information (Baharmand et al. 2016; Nespeca et al.). In addition, communities and individuals play a more prominent role. While these groups have long been recognized as the pivotal in effective disaster response (Twigg 1999; Weiss 1999), the increased profusion of mobile technology, digital literacy, and accessibility of ICTs have also opened up opportunities for them to directly engage in information processes (Comes 2016c; Harbers et al. 2014; Meier 2014; Munro 2012; Okolloh 2009).

All the more it is important that information systems in the Disaster 2.0 era are designed to provide the right information, at the right time to the right person. Turoff, Cumer and Van de Walle in their seminal paper "The design of a dynamic emergency response management information system (DERMIS)" examine requirements and design principles for information systems to be used during crisis response and emergency management

(Turoff et al. 2004). The DERMIS principles and premises have provided an important frame of reference for both the design of information systems themselves, as well as for the academic studies around those systems.

The focus of these design premises is on information systems used by formal emergency responders operating in an official or mandated capacity. Premises such as the 'need for training' or 'free exchange of information' are based on the analysis of information systems and processes in use by organizations and individuals with a formal role in the crisis management operations. In short, the scope of the DERMIS premises are the emergency response systems that are being designed, established and used by responding organizations.

The above-mentioned trends of the increasingly active role of communities in the information management during crisis response along the emergence of various day-to-day communication platforms show a fundamental shift in the design and use of information systems in crisis response. As information systems open up, 'common' applications are being used, and new actors enter the information eco-system, a re-examination of the DERMIS design premises is warranted.

In this paper we present the findings of an exploratory field study on today's use of information and information systems in crisis response and disaster management. The aim of this research is to uncover the explicit and implicit requirements of inclusive information system. Using the DERMIS premises for information systems design as an analytical lens, we examine how these premises manifest themselves in information systems with active participation of communities in the gathering, analyses and sharing of information during crisis response.

In the remainder of this paper we outline the methodology used, specifically focusing on our approach to revise the requirements and premises laid out in DERMIS to include community groups. Subsequently, we present a revision of the DERMIS principles to include the role of communities based on literature and interviews. Subsequently, we test and revise these adopted premises using a qualitative case study approach.

RESERCH APPROACH

This study combines theoretical and empirical work, as highlighted in Figure 1. The starting point was the development of a theoretical framework by mapping the DERMIS principles against the requirements brought about by the wide diffusion of ICT. These requirements were elicited through a literature review as well as through interviews with professional responders and digital volunteers. From there, we designed a first set of principles.

In a second step, we tested and revised the new principles in a field research case study in Jakarta / Indonesia. The study area was chosen because the population is frequently exposed to floods and crises. At the same time, there are active local communities that use digital tools to self-organize and improve their resilience, for example through community driven risk mapping or self-designed disaster preparedness measures. Our interviewees were selected to be representative for the main actors (communities, NGOs and public authorities). Throughout the field work 70 respondents were reached through 11 interviews, 2 focus groups and 3 workshops.

To focus on key drivers of change since the original DERMIS principles were published, we rooted our research in theories of coordination; information sharing; decision-making and resilience. The interviews aimed at investigating three main points: situations faced, and decisions made, information management (collecting, analysis and sharing), and the tools used to facilitate information exchange and communication. In combination with this semi-structured approach, we included open questions in an exploratory approach to investigate the priorities and requirements that of the actors identified based on their own experience with disasters. All details of the approach and interview guidelines are documented in the Deliverable 2.1 of the European Project COMRADES[1]. This interview protocol is centered around decisions and decision making processes, the use of information in these processes, and the information tools and methods to obtain and share this information (Lipshitz et al. 2001). To complement this approach for eliciting requirements for new technologies, we also used an Ushahdi-based[2] instance for crowd sourcing to demonstrate the possibilities of crisis mapping in hands-on tutorials in workshops. The workshops aimed at triggering critical thinking about the current situation compared to the platform capabilities and receive feedback from the actors on the platform design. The data gathered from the interviews and the workshops was then analyzed to update and revise the integrated DERMIS principles.

The data collected from the various interactions and observations, such as interviews, field visits and workshops has been recorded in a case-study based field research approach. The collected recordings and notes have been transcribed and subsequently tagged using the adapted -integrated- DERMIS premises, serving as example design and implementation elements of information systems that contribute to a more integrated information system between communities and formal responding organizations.

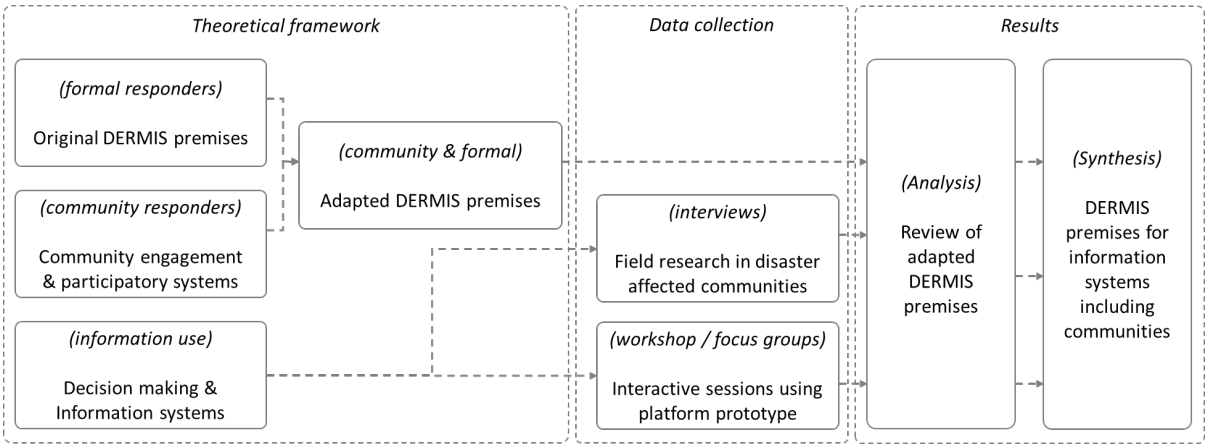

Figure 1: Research methodology

DESIGNING INTEGRATED DERMIS PREMISES

Building on the existing DERMIS premises, we examine how information systems emerge, are designed and used during emergency response in which the affected communities play in active role in the disaster preparedness and response. For this we design the DERMIS premises to be integrated with the existing literature on decentralized coordination, decision making and the use of information systems in such contexts.

Decentralized coordination and decision-making

In the following, we highlight three characteristics of the decentralized coordination and decision-making in disaster relief 2.0 that need to be considered in designing principles for information management: (i) the lack of formal decision support; (ii) the fragmentation and poly-centricity; and (iii) the need to embrace emergence and to design for the context.

(i) Particularly at community level, the decision-making processes for decisions established via analytical models or optimization are often too rigid, too consumptive in terms of resources and cognitive capacity, or simply ineffective. As a result, operational decision-makers typically find themselves engaged in intuitive forms of decision-making (Comes 2016b). Such naturalistic decision-making (Lipshitz et al. 2001) and the connection between sensemaking and decision-making (Gralla et al. 2016; Muhren et al. 2008) or sensemaking and coordination (Van de Walle et al. 2016) have not been translated yet into formalized guiding principles that help design decision support or information sharing taking into account the conditions and requirements of the field.

(ii) A key feature of crisis situations is the multiple agents and units who will perceive themselves, rightly or wrongly, to be in a leadership position or a vital element in the formal chain of command. Dave (2012) in his assessment of ICT for disaster risk reduction in India highlights for example the complex web of government institutions that are involved in handling disasters. Similar phenomena have been observed for different instances of crisis response in Europe (Noori et al. 2016). More recently, Wolbers et al. (2018) introduce the idea of fragmentation in crisis response, highlighting the need for decentralized and local decision-making even for professional responders.

(iii) Frustration with tools owing to lack of coverage and access, complicated interfaces or language barriers will lead communities of reporters, but also professional responders and volunteer & technical communities to revert back to the simplest possible means of communication, particularly in the immediate response (Altay et al. 2014; Comes et al. 2015; Landgren et al. 2007; van den Homberg et al. 2014). The design of information systems must take into account how workflows and processes emerge in the field rather than striving to change patterns that are deeply rooted in cultural and behavioral structures.

DERMIS premises & adaption to decentralized coordination

In the paper by Turoff et al. (2004), based on the various requirements and design approaches, the authors present 9 premises that have been found to be key considerations in the design of information systems used in management of a crisis response. For each of these 9 premises we consider how they can be adapted to reflect the three characteristics of decentralized coordination and decision making listed above.

Premise 1 - System Training and Simulation: "A system that is not used on a regular basis before an emergency will never be of use in an actual emergency."

The operational circumstances of an emergency will allow little room for users to acquaint themselves with a new system. Therefore, authors state that if a system is not used frequently, it will likely not be used during an emergency as users may not be or no longer are familiar with the system. The adoption of systems by communities is driven from different motives then those of formal responders. Where formal responders can be trained in certain systems and processes, or exercise with them during exercises, communities need to rely on different approaches for the adoption of systems (Craig et al. 2002). As communities and community members will not have access to or infrequently use bespoke systems for crisis management, systems that are part of the 'daily life' in communities will be used.

> *Adapted Premise 1:* "Community information systems during crisis response build on systems used in daily (normal) life."

Premise 2 - Information Focus: "Data and information needs to relate to the users dealing with the disaster."

Information systems need to include operationally relevant information. This information needs to be easily accessed, retrieved and represented in a useful format. This includes interactive approaches and dynamic maps, in which users can customize the information they see. Information streams generated to support professional response are currently dominated by advocacy and programming decisions (Comes 2016a). However, information should be relevant to the end-users, as this generates an incentive for user to keep contributing information. It is important to consider activities in communities and examine how these could be strengthen or improved through information. In other words, information in the platform has to be relevant and tailored to a specific user, for example agriculture information may only be relevant to farmers, whereas weather information (alerts) is relevant to the wider community (Paulus et al.).

> *Adapted Premise 2:* "The resilience platform needs to subscribe to the principles of reciprocity and make relevant information available to users at community-level"

Premise 3 - Crisis Memory: "Learning and understanding what actually happened before, during, and after the crisis is extremely important for the improvement of the response process."

A culture of continuous learning should be implemented. This includes a culture of collective mindfulness, and the willingness to learn from past failures (Weick et al. 1999). There are too few reflections and lessons learned due to the reactive nature of crisis interventions and lack of professionalization and training at local level, as well as the lack of an easy to use platform that tracks and monitors events and actions as they unfold over time. Moreover, communities have significant and relevant knowledge about their community, including risks and opportunities related to their resilience (Mayunga 2007). Systems could enable communities to make this knowledge explicit and accessible to both the community and external stakeholders. Communities can also serve as the institutional memory due to their continued presence, the past experiences, and local knowledge.

> *Adapted Premise 3:* "Support the communities in knowledge capture and create an institutional memory which can be shared with other stakeholders."

Premise 4 - Exceptions as Norms: "Almost everything in a crisis is an exception to the norm."

Systems need to be able to adapt to the respective context, in terms of language(s) or pictograms; coverage and network; key issues and needs in the crisis; expertise, skills, and time available of the user. Crisis response information systems rely on standardized products and tools, resulting in the (relatively) rapid and predictable production of e.g. maps, reports, contact lists. Information tailored to the specific context of a disaster, however, is typically not produced, and only available by direct requests. Information systems need to become flexible and agile to adapt to the respective context, in terms of language(s) or pictograms; coverage and network; key issues and needs in the crisis; expertise, skills, and time available of the user (Streefkerk et al. 2014). Furthermore, the systems should also be able to scale up and down, in crisis situations. This is for example an increased flow of information and data, but also multiple (different) users, such as international agencies who can 'plug into' the platform and integrate their systems, making the platform a bridge between the community and other stakeholders (Muhren et al. 2008).

> *Adapted Premise 4:* "Any system developed needs to be able to adapt and be a good fit and tailored to the local context with relevant connections with other systems."

Premise 5 - Scope and Nature of Crisis: "People, authority, and resources need to be brought together at a specific period of time for a specific purpose."

Platforms should support joint data collection and sharing. Despite discussions on interoperability and joint efforts, NGOs and agencies alike are still being asked to fill in different data collection forms across communities. Multiple assessments take place in some areas and no assessments in others; data is collected in different formats by different agencies; and information is not being shared effectively. Information and communication technologies enable contributions from remotely working experts and volunteers. However, with the increasing intervention of people not familiar with the context, control and "ownership" of a crisis may shift towards remote levels. At the same time, communities can contribute important information but require other information to support their decision-making process and maintain their own ownership (Tran et al. 2009).

> *Adapted Premise 5:* "While working on and contributing to a shared set of information, a system can serve different stakeholders each with their own information needs."

Premise 6 - Role Transferability: "It is impossible to predict who will undertake what role. The actions and privileges of the role need to be defined in the software, and people must be trained for the possibility of assuming multiple or changing roles."

Processes and procedures need to be established that give authority to collect and process information to specific roles. Particularly tacit privileges, norms and codes of conduct need to be made transparent through better training and good governance, bringing together tools and practices. At the same time communities undergo changes, so a system should be transferable and aligned with community structures, rather than individual persons. Moreover, the platform should also be able to adopt incoming stakeholders and provide them with the correct role and acces to a system, as well as the information management practices in the community (Smith et al. 2000).

> *Adapted Premise 6:* "Communities undergo changes, so the platform should be transferable and to ensure sustained adoption the platform should fit into community structures and processes."

Premise 7 - Information Validity and Timeliness: "Establishing and supporting confidence in a decision by supplying the best possible up-to-date information is critical to those whose actions may risk lives & resources."

Information cycles need to become predictable and transparent, such that decision-makers can deliberate if the information is sufficiently reliable to decide, or if it is worthwhile to wait for more. This requires that data about the time of the information collection, and its inherent uncertainty, as well as potential implications in terms of humanitarian needs is clearly represented and communicated. Standardized products are available in a relatively short time, though sometimes at the cost of not fulfilling specific information requests. For more specific information needs, it typically takes a longer time to collect, compare and process information. A system should support not only single updates but support a continuous information management process to support forecasting (Kapucu 2008; Thompson et al. 2006).

> *Adapted Premise 7:* "Enabling users to continuously exchange information will add a temporal factor to the information, allowing users to identify trends and developments over time"

Premise 8 - Free Exchange of Information: "Crises involve the necessity for hundreds of individuals from different organizations to freely exchange information, delegate authority, and conduct oversight, without the side effect of information overload."

Shifting formats and the use of different languages hamper access to information, particularly for local actors and emerging actors that do not comply to international humanitarian norms and rules (Harmer et al. 2005). In conflicts, information is often not shared, not even with partners or within the same organization. Standardization and inter-operability of tools and platforms need to be improved, enabling easy access, and offline-modes of work. Common Operational Datasets (CODs) and other information need to be made commonly available and updated at community level. Clear protocols and procedure for sharing information need to be established.

> *Adapted Premise 8:* "Standardization and inter-operability of procedures, tools and platforms are critical, enabling easy access, and offline-modes of work."

Premise 9 – Coordination: "The crux of the coordination is that the exact actions and responsibilities of the individuals cannot be pre-determined."

Research has shown that decisions for disaster coordination are mainly facilitated through organizational structures, collaborative decision processes, and the contribution of advanced information and decision-support systems, all of which are highly interdependent (Chen et al. 2008). While exact actions cannot be predetermined, coordination relies on feedback on the prevalent situation. Response plans are therefore subject to constant change and updates as new information becomes available. Policies that will be developed here will therefore take into

account this flexibility, in order to avoid "threat rigidity", i.e., people following pre-defined, rigid responses while not taking into account the reality of new threats in the crisis situation (Staw et al. 1981). Communities are actively working on their own resilience and have developed structures to support themselves and each other in disaster situations. Rather than supporting a complete or fixed resilience building process, the platform should provide various bits and pieces that communities can use, integrate and apply as they see fit.

> *Adapted Premise 9:* "Any system should not be directive in nature, but rather be flexible to adopt to the structures and process of a community and support self-developed process and goals of the community."

CASE STUDY

To validate the above-mentioned adapted DERMIS premises, with the inclusion of community participation, a case study has been conducted as part of a larger research project related to development of community driven information systems and approaches. The case study is centered around Jakarta, Indonesia, home of 10 million people and it is considered as the fastest sinking city in the world (Chaussard et al. 2013). It has the Java Sea and about 13 rivers running through the city, this continuous influx of water, compounded by the rapid and dense urbanization of the city the capacity of the city makes the city prone to flooding (Abidin et al. 2011).

The study was conducted in November 2018, shortly following the Sulawesi Earthquake and Tsunami and amidst the ongoing efforts of local, national and international agencies to provide assistance to the affected communities in Palu. While our research did not focus on the Sulawesi disaster, the presence of many international agencies and coordinating bodies provided unique opportunities to evaluate the use of information systems in real-time and reflect on the use of information and information systems in these events with the interviewees.

Interviews & Observations

Overall a total of eleven interviews were conducted within two communities in different regions of Jakarta. One situated in Marunda, a frequently affected coastal area which faces both tidal and riverine flooding. And the second in Kampung Melayu, affected by frequent riverine flooding. The interviewees included community leaders of both areas, various community members from diverse backgrounds, including teachers, (factory) workers, youth, families, and elderly people. The interviews took place in the neighborhoods themselves, using a semi-structured approach following the above introduced interview protocol centered around the topics of decisions and decision making, the related information required for these decisions (sources, availability, reliability etc), and the information management approaches and technologies used to facilitate this information exchange.

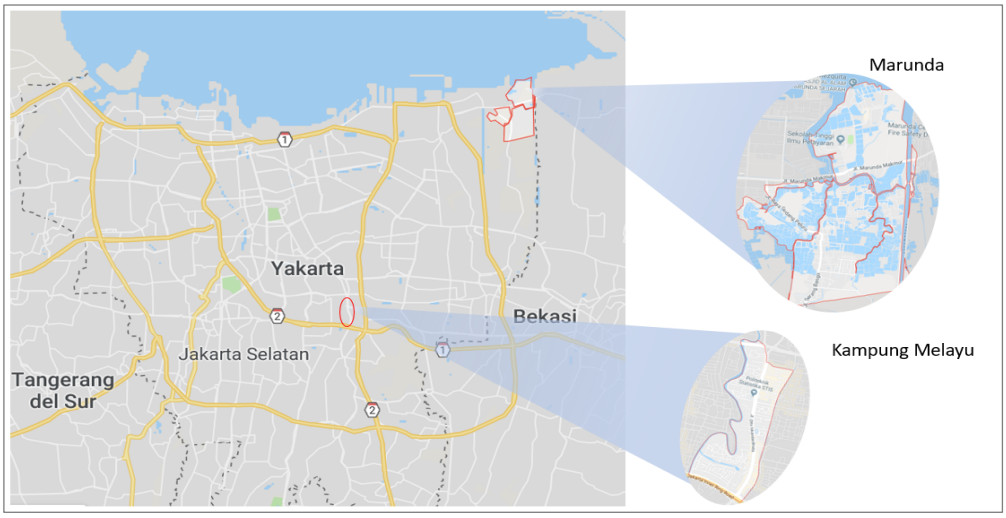

Figure 2: Location of the case studies

Focus Groups & Workshops

In addition to the interviews, the case study also involved focus group sessions with members from (previously) affected communities and formal responders. One focus group was held with five members of a community group actively mapping hazards and risks in their area using the Ushahidi-based COMRADES platform. The second focus group involved a 'Community Coordination Team' responsible for enhancing community disaster preparedness and response.

Furthermore, three workshops were held with members from the V&TCs and affected community to assess and reflect on the usability of an information system designed to exchange information with communities. One workshop was with members of Humanitarian OpenStreet Map, an experienced actor in the field of open mapping for enhancing humanitarian action and community development. A second one was with organized at Pulse Lab Jakarta, a joint initiative of international and national governmental agencies with expertise in the field of big-data and real-time analytics. The final workshop was organized with students from the University of Indonesia. While the first workshops provide insight from experts, which are generally equipped with the required knowledge and skills for information systems design, the latter provided the perspective from local community members.

RESULTS

Using the results from the interviews, workshops and focus groups we review the adapted DERMIS premises. In the following section we review each of the premises and examine if they can be identified in information management approaches and information systems used by communities in the response to crisis situations. Additionally, we look for examples in information systems that are used to exchange information with communities to further if and how these design principles can be manifested in specific examples.

Adapted Premise 1 - Integration into 'daily'' information systems.

The approach of gathering relevant information, according to different community members, is highly personal. Young adults may use social media networks like Twitter or Facebook to search for information while elders rely on their personal knowledge or obtain information from traditional media such as TV. Nevertheless, communication between community members is performed through WhatsApp where they are connected through different groups to family members, community leaders, and in some cases, government officials. The interviews illustrated that in emergency situations, there is usually neither time nor capacity to implement unfamiliar mechanisms. Systems need to be adapted to local the context and capacities and should thus be developed in close collaboration with local partners and integrated in regular and commonly used information systems.

Nov 6, 2018 - Marunda, North-East Jakarta, Indonesia, a community Leader is showing WhatsApp on his mobile phone:

"When flooding occurs, we use mobile phones to inform and be informed by the people in our community. WhatsApp and Facebook are our most important communication tools"

Figure 3: WhatsApp groups used in the community during flooding

Adapted Premise 2 - Reciprocity and offer relevant information

The interviews illustrated that people require specific meaningful information to actively use in decision-making. For instance, the mention of an expected flood holds limited value for a community member, unless the height of the water at the flood gate is mentioned too, as this is used by individuals to assess the likelihood of being affected. At the same time various responders noted that their content is not designed to specifically meet the needs of the affected communities but rather about compliance with standard operating procedures or accountability. With the increased availability of information during crisis situations, one of the challenges is to ensure relevant information is identified and presented to the communities. For this active consideration of the information needs of other information users is needed. While these needs differ between communities and crisis, the ability for a system to support addressing specific information needs should be a key design consideration.

Oct 30, 2018 – South Jakarta, Jakarta, Indonesia, Humanitarian OpenStreetMap team Indonesia

"COMRADES and the new services helps us to better understand unstructured information and find relevant information for different users"

Figure 4: Humanitarian OpenStreetMap using the platform for analyzing community provided reports

Adapted Premise 3 - Support the communities in knowledge creating and capture

The interviews illustrate that there is a vast amount of tacit knowledge developed through past crises on which communities rely to identify and assess the potential impact of crisis or hazard. Information systems can make this tacit local knowledge available to other key stakeholders to identify important of information about the local context. Vice versa, systems can support the community members in effective use of their local knowledge when the right information is delivered. An example thereof, mentioned by community members, is the lack of information regarding possible secondary effects. During recent floods for example, additional rises in the water level occurring after the first flood event were not known to the community, although this did happen in the past. If information about the water levels was continuously provided, community members would possibly make different choices such as evacuation as they had done in previous longer lasting flooding events.

Nov 4, 2018 – South Jakarta, Jakarta, Indonesia, Community Member illustrating floods

"We know what water levels are normally expected when a flood is announced, and we have taken measures to deal with these. However, we don't always have the information to determine if this is going to be worse or not"

Figure 5: Community member illustrating the height of previous floods

Adapted Premise 4 – Tailoring to local context

The communities in our case study are regularly affected by small floods, and therefore not every flood may be cause for alarm or a larger scale response. This example illustrates the need for an information system to be tailored to a local context. Building on the other points of ensuring that information systems are relevant and integrated into community structures, information systems should be able to deal with a range of expectations: the next disaster can fit the regularity of past ones, but it can also be a lot more destructive. In other words, the systems need to be designed in a way that they address frequent emerging information needs in the local community. This enables people to become familiar with information systems and sharing approaches throughout the community.

Nov 4, 2018 – South Jakarta, Jakarta, Indonesia, Community Leader

"It is difficult for me to manage the community response because everyone was doing their own thing without sharing information, eventually leading to a lack of information for decision making."

Figure 6: Community leader along with several community members

Adapted Premise 5 – Tailored presentation and analytics for different stakeholders

Interviewees indicated that allocation of people, authority and resources in case of disasters are a combination of predefined protocols and roles, but also on-the-fly adaptation. In each disaster and community, different people may fulfill a certain role, for example community leaders may share information with community members and/or mediate within other communities and government agencies. Formal responders indicated it would be valuable to identify specific roles of community members in a response, for instance to collect and share information on community needs as this allows the design of information systems to support these roles. However, flexibility in this approach is required since relations and roles differ greatly between communities and disasters. Therefore, a tailored information provision approach, designed for a specific role or decision-making process, is needed.

Nov 4, 2018 – South Jakarta, Jakarta, Indonesia, Community Leader

"We have risk and flood maps provided to us by government agencies, but not everyone has access to the map, knows how to read them or understands what is means for them."

Figure 7: Risk map of community on display in community hall

Adapted Premise 6 - Fit into community structures and processes

The interviews portrayed strong community structures that play a crucial role during emergencies, for example community leaders play an important role in the coordination and exchange of information. In one community a youth group was tasked to use Ushahidi to collect data on risks and hazard in the community. This newly formed group was formed by the community and support by the information system to execute their task. To ensure sustained adoption the system should fit into and support the community structures. The technical complexity of an information system however, requires certain capacities not present in the community themselves, but could be provided by technical volunteers, NGOs or government agencies.

Nov 6, 2018 – North Jakarta, Jakarta, Indonesia, Youth Risk Mapping Group:

"We are using (mobile) technology to continuously asses the risks in our community and use that information to update our disaster preparedness plans"

Figure 8: Youth Risk Mapping group during a focus group discussion

Adapted Premise 7 - Enabling users to continuously exchange information

Interviewees indicated the need of people to have real-time information. An interview with an NGO specialized in the mapping of data for increased resilience indicated furthermore that only real-time usage of data prevents misinformation or information overload. Information provided should focus on the information required for decision-making in that situation. A professional responder with vast experience also indicated that beneficiaries should not be kept in the dark when information is unknown. Information systems should support communities in not only once-off sharing of information but rather managing a continuous stream of information to and from other stakeholders, including other communities' members, NGOs and government agencies.

Nov 7, 2018 –Jakarta, Jakarta, Indonesia, University of Indonesia. A student assuming the role of community leader during a simulation:

"During the simulation it was difficult to maintain an overview as messages from our community members keep coming in via WhatsApp, the situation was constantly changing"

Figure 9: Students building a situational overview during a simulation

Adapted Premise 8 - Standardization and inter-operability of tools and platforms are critical

Communities have information that is relevant to various other stakeholders, such as experiences from previous crisis events, information about the local context and knowledge on their capacities and vulnerabilities. This local knowledge, while valuable, can be disconnected from the formal response. As communities are increasingly also active in the gathering of data as multiple interviewees indicated. A system should assist communities in the connecting their own information management approaches to formal responses. Vice versa, information available to formal responders and their agencies should be shared back to communities.

Nov 9th, 2018 –Central Jakarta, Jakarta, Indonesia. After a demonstration of connecting to the Facebook Messenger and the Humanitarian Data Exchange:

"By connecting to Facebook and the Humanitarian Data Exchange, COMRADES show how to bridge gaps across communities and international organizations"

Figure 10: Demo sharing data via Facebook Messenger with the Humanitarian Data Exchange

Adapted Premise 9 - A system should not be directive in nature

Communities are actively working on their own resilience and have developed structures to respond to disaster situations, often with already set actions and responsibilities and communication channels. However, specific approaches are dependent on the disaster and cannot be fully predetermined. Agency of decision-making lies with community members and complexity increases when information is not available. A system can assist in coordination of non-predetermined actions and responsibilities by informing users on who is doing what and provide checks for accountability. In both the response and preparedness, the information provided serves as trigger and support the decision-making process. I.e. the information provided does not prescribe a certain action but rather supports the user in making informed decisions.

Nov 4, 2018 – South Jakarta, Jakarta, Indonesia, Sunday school Teacher

"Based on the information and support we have received on the risks (flood maps) in our community we have designed our own evacuation routes that we maintain ourselves"

Figure 11: Community designed & maintained evacuation routes

DISCUSSION

The results show that the various DERMIS premises and considerations are relevant and important to the design of information systems in which communities are an active stakeholder and user. Nevertheless, with the existing DERMIS premises mainly focused on the design of information systems for formal responders, the involvement of communities requires a revision of these design principles. While the results above are based on a limited case study through anecdotal evidence, the adapted premises are recognized among both communities and formal responding agencies. Moreover, the results highlight the importance of reconsidering the design principles when involving communities directly in the gathering, analysis and exchange of information. Even though these collected data needs to be closer examined, and the findings further validated, these initial results indicate important considerations for the design of information systems that recognize the role of communities in the information management process.

DERMIS premises applied to community-included information systems

The inclusion of communities as a key stakeholder requires the re-examination of the design principles. The results show that the while the initial ideas of the DERMIS principles still hold true, there are additional implications to be considered. Aside from the above listed results for each of these premises, we found that throughout the interviews, workshops and focus groups several discussions were recurring.

In the design of information systems for community involvement trade-offs have to be made. In contrast with formal responding agencies, communities have other concerns, priorities and core activities (Mayunga 2007; Paton et al. 2001). As such the design, use and maintenance of information systems designed for emergency response management has to be contrasted with these other activities. This requires a balancing trade-off in investments (time, financial, resources) with the prospected benefits of such as system (Liu et al. 2004).

Adoption & Reciprocity

These considerations are closely linked to the adoption of a system. Throughout the interviews and other interactions various other design elements that have proven to be crucial for ensuring an effective information exchange between communities and formal responders have been identified. Finding partners and the embedding of an information system in the community is a key aspect to ensure that these systems are adopted by communities. This applies to communities even more than formal responders, as there is no often mandated need, formal procedure, or 'pressure' to force communities to adopt and use a certain system or information sharing approach (Kapucu 2008; Neef et al. 2014). Nevertheless, there are several measures that can be taken to lower the adopting barrier. First and foremost, building on existing systems, familiar concepts, and in line with existing capacities reduces the need for training and capacity building (Butler et al. 2002).

The recurring and key elements throughout all our interviews however is the engagement and reciprocity of a system. Ensuring that a system provides an added value for the community, ideally on a regular basis and in frequent recurring activities in contrast to systems designed to be used solely during exceptional events. Furthermore, to establish this reciprocity, information systems should cater to the different information needs of users and stakeholders (Janssen et al. 2010).

Emergent nature & adaptive design

Designing information systems for crisis response and disaster management with the inclusion of communities is challenging. First, communities across the globe have different characteristics, not only in terms of the hazards faced or their resilience to withstand them, but also in their capacities and capabilities to provide, use and maintain information and information systems. In short, different disasters affect different communities differently, and due to the volatile and unpredictable nature of disasters the exact requirements of these systems cannot be pre-determined (Kapucu 2008; Maguire et al. 2007). Secondly, at the same time technologies and their use in communities also rapidly change. All these factors combined make it difficult to plan and design information systems for the inclusion of communities ahead of time. Rather it requires deployers of information systems to tailor to the specific requirements of one or more communities before but even during an emergency response.

Although including communities in the design of information systems requires a significant amount of flexibility, adaptability, and resources of information systems and their users, the return of these investments are not only the improved information flows which in turn support the decision-making process. They also support the creation of a more comprehensive and inclusive information system in which different stakeholders -not in the least the communities themselves- have access to and the ability to update relevant information (Craig et al. 2002). Finally, we note that an information system should *trigger* community engagement on response, recovery and long-term

preparedness, but not necessarily organize these efforts in the long term as this often done by communities themselves using their own knowledge, structures, capacities and capabilities. In other words, a system should not be directive or prescriptive but rather provide input, feedback and support into community-based decision-making processes (Almedom 2008; Mayunga 2007).

CONCLUSION

The critical role of communities in disaster response and emergency management is increasingly recognized by various agencies and initiatives. Even when affected themselves, communities have the potential make a valuable contribution to effective disaster response for example by providing access, resources or local knowledge. Today, communities, more than ever before, have options to actively engage and exchange information with responding agencies and the wider public (Crowley et al. 2010).

As information and communication technologies become increasingly more common throughout the world, more and more people gain access to new opportunities to collect, analyze and share information. These developments are supporting the increased democratization of information, not in the least during emergency responses. An increasing number of platforms, initiatives and projects emerge that support and encourage new and old players to participate in information management processes in the response to a disaster.

These increased trends of active participation in the decision making and information processes of communities, require a re-examination of the design and approach used in information management systems. When properly designed information systems not only facilitate the information exchange between different groups such as communities, formal agencies and volunteer organizations, but contribute to a more efficient and effective response by actively addressing information gaps, transforming data into actionable information and presenting relevant information to empower different users in their decision-making processes (Comes et al. 2017; Kapucu 2008).

Limitations & Future research

The work presented in this paper reveals the initial results of the ongoing work for community inclusive information systems design for crisis response and management. Building on the DERMIS premises for the design of information systems for emergency response, we have re-examined these design principles in light of the developments of increased participation of communities in information management processes and activities.

The results presented in this paper are based on a single case study conducted in Indonesia in the wake of 2018 Sulawesi Tsunami. Future work would not only focus on strengthening these results by verifying these findings in multiple studies including different contexts, but also extend beyond the current DERMIS principles. The scope of the planned future work includes the identification of possible additional principles, some of which -such as reciprocity- are highlighted already in the discussion. Future study would there focus on a more grounded approach towards identifying critical design elements and success factors for inclusive information systems. Additionally these studies would also examine the trade-offs between various design principles as well as the fit with local circumstances, capacities and resources in particular in the aftermath of a disruptive event.

While this single case-study and the preliminary results do not provide a comprehensive review of the DERMIS design principles in light of community inclusion, the results do indicate important findings that warrant further examination. Especially in light of the ongoing democratization of information and information systems, with more and more communities gaining access to and the ability to share information during disaster responses.

Acknowledgements

We thank the various groups and interviewees for their time and insights. In particular we thank Humanitarian OpenStreetMap Team (HOT) Indonesia, KARINA Yogyakarta, and the communities in Jakarta for their support.

ABSTRACT

Humanitarian organizations are increasingly challenged by the amount of data available to drive their decisions. Useful data can come from many sources, exists in different formats, and merging it into a basis for analysis and planning often exceeds organizations' capacities and resources. At the same time, affected communities' participation in decision making processes is often hindered by a lack of information and data literacy capacities within the communities. We describe a participatory disaster risk analysis project in the central Philippines where the community and a humanitarian NGO worked towards a joint understanding of disaster risks and coping capacities through data integration and IT-supported analysis. We present findings from workshops, focus group discussions and semi-structured interviews, showing the reciprocal effects of the collaborative work. While the community valued the systematically gathered and structured evidence that supported their own risk perceptions and advocacy efforts, the humanitarian NGO revisited established work practices for data collection for analysis and planning.

Keywords

Reciprocity, Resilience, Disaster risk analysis, Community engagement, Organizational effectiveness, Data integration

INTRODUCTION

To prepare for the events of natural hazards, stakeholders of climate change adaptation (CCA) and disaster risk reduction (DRR) programs try to understand capacities and vulnerabilities of potentially affected communities (Mercer et al., 2010). This requires gathering and understanding data from various sources (Kawasaki et al., 2017). Useful data can come from many sources, exists in different formats, and merging it into a basis for analysis and planning often exceeds organizations' capacities and resources. Household surveys are frequently conducted by DRR program stakeholders and are a well-established tool to capture field realities. They provide information on demographics, education levels, income types and salary levels (Morin et al., 2016). And they can capture people's perceptions of risks and capacities in their neighborhoods (Sullivan-Wiley & Short Gianotti, 2017).

Official data from government agencies, e.g. censuses, are increasingly published openly in light of open government initiatives (Janssen et al., 2012). Recently, aid organizations increasingly publish and share data on their activities (IATI, 2017; UNOCHA, 2018), which in turn can be useful information for other organizations (Crowley et al., 2011). Examples are data created through the International Aid Transparency Initiative (IATI)[1] and the Humanitarian Data Exchange (HDX)[2]. In combination with organizations' own data creation efforts, this leads to an increasingly difficult task of data integration and sense making.

[1] https://iatistandard.org
[2] https://data.humdata.org

Problem statement

While these initiatives are deployed to increase the data availability, analysis and use in decision making processes, these initiatives are often centered around humanitarian organizations, their objectives and requirements. Notwithstanding the objective of humanitarian organization to alleviate human suffering and strengthening communities by increasing their resilience to disruptive events (Weiss, 1999), often the main focus of data collection and processing is to ensure effective humanitarian operations, informed decision making or provide accountability on an organizational level (Comfort et al. 2004; Gralla et al. 2013). Subsequently, with the rise of technologies and data in the humanitarian field, various platforms, tools and systems have been provided to humanitarian organizations to support their needs assessments, operations and impact evaluations (Crowley et al. 2011).

Consultations of affected communities are the fundament of most CCA and DRR programs. Data are gathered from assessments and then analyzed and interpreted by organizations to plan their program implementation. This often moves communities into passive roles as data providers who are excluded from analysis, interpretation and decision making processes (Streefkerk et al., 2014). This stands in contrast with arguments from the social resilience literature (Comes et al., 2017) that emphasizes the importance of building resilience by increasing community capacities, resources and ownership (Maskrey, 1989).

With the increased importance of data and IT-tools in humanitarian operations, such capacities become critical elements for the empowerment of communities to self-organize preparations and responses to disasters (Baharmand et al., 2016; Kapucu, 2008; Kendra et al., 2007). However, communities - in contrast to humanitarian organizations - often have less access to specific technologies and resources to implement and use supportive systems. Their capabilities to employ data-driven assessments remain limited (Piccolo et al., 2018; Streefkerk et al., 2014).

Research objective

We examine how, through the use of modern technologies, this discrepancy can be resolved. Specifically, through (1) building an understanding of information needs and offers of communities and organizations, (2) streamlining data gathering and analysis, and (3) a redistribution of processes around data that builds on and strengthens local capacities.

In the remainder of this paper we first discuss the current state of research around data-driven humanitarian operations which leads to the uncovering of the above briefly outlined research gap: how can communities and humanitarian organizations jointly build an understanding of risks, vulnerabilities and capacities to support community-driven resilience and mitigation efforts? We then describe our research approach, using a prototypical process implemented in a CCA and DRR program in the Philippines, of how such joint efforts could be shaped in practice. This is followed by the description of results, both solely technical as well as reciprocal, meaning the mutual influences between system, community and organization. We conclude the paper with a discussion of the results and prospects for future research.

PREVIOUS RESEARCH

In previous research Van Den Homberg et al. (2014), Gralla et al. (2015) and Comes et al. (2017) investigated information needs of humanitarian organizations and affected communities. We argue that information needs identified by them, also apply to CCA and DRR program stakeholders in our case study. In the field of humanitarian logistics Link et al. (2015) stressed the importance of data integration during disaster preparedness activities and structured humanitarian logistics information into three categories which determine when certain information is needed: during the rapid response, ongoing response or preparedness phase. Horita et al. (2014) developed the humanitarian logistics infrastructure and resource model to integrate volunteered geographic information into humanitarian logistics processes. The usefulness of the integration of data initiatives like IATI and HDX for humanitarian organizations and affected communities was suggested by Paulus et al. (2018). They outlined an information system design approach to address questions that arise during different phases of humanitarian activity. Muhren et al. (2010) and Van de Walle et al. (2016) stressed the role of information on situational awareness, sense making and decision making and formulated fundamental design principles for data systems that support individuals and groups in these activities. Information systems, according to DeLone and McLean (2003) are comprised of a multitude of factors, and not only describe technical artifacts. They also include the human and organizational factors, that should not only be considered as part of the design and performance of

an information system but are in fact an integral part that determine the effectiveness of such a system to achieve organizational goals. Formalized community engagement principles like the empirically-based EnRiCH community resilience framework for high-risk populations have emphasized empowerment and collaboration as crucial drivers of adaptive capacity (O'Sullivan et al., 2014). While the importance of community engagement in disaster preparedness efforts is acknowledged and success factors have been defined (Mays et al. 2014), surprisingly few studies analyzed the reciprocal effects of disaster information systems and community engagement efforts (Ahmed et al. 2012).

From these previous findings we draw that the reciprocal effects of data-driven and IT-supported methods for community-centered disaster risk reduction projects have not been investigated substantially. In this paper we will therefore assess these effects by employing the development, testing and evaluation of a software prototype for data integration and analysis into a DRR program.

SELECTED CASE

The research was conducted within a CCA and DRR program in Jagobiao, an urban poor community of approximately 14.000 people near Cebu City, Central Philippines. The implementing organization had established close ties to the Jagobiao community, local government authorities, local faith-based groups and the local disaster risk management office over the past years. The community, administratively divided into several districts, held frequent self-organized gatherings during which risks and capacities were collected and potential mitigation and supportive measures were discussed. One outcome of these gatherings were hand-drawn maps per district and per hazard with color-coded households according to the perceived risk level for each household. The maps further contained community capacities, for example evacuation centers, hospitals and water wells. Another community-driven activity was the conducting of household surveys of the community's youth group. The surveys captured per household demographics and characteristics, for example building material, proximity to shoreline and household income. These community-driven activities to capture local knowledge lead to a volume of data that the program stakeholders were unable to process, analyze and interpret effectively.

RESEARCH APPROACH

As per the case description, data integration and analysis became the major concern of the program stakeholders and hindered the development of a common understanding of the community's risks and capacities. The process towards a more streamlined approach to data integration and analysis through the incremental development of a supportive software prototype is described in this section. We start with describing the process through the lens of Action Design Research (ADR) by Sein et al. (2011). Table 1 summarizes the process.

Table 1. The development process from ADR perspective. Adapted from (Sein et al. 2011)

Stages and Principles		Artifact
Stage 1: Problem Formulation		
Principle 1: Practice-Inspired Research	Research project was initiated to identify concrete information challenges and possible information system solutions in the selected DRR project.	***Recognition***: Existing work practices, used tools and available data did not satisfy organizational objectives to understand risks, vulnerabilities and capacities of the local community.
Principle 2: Theory-Ingrained Artifact	Participatory disaster risk assessment.	
Stage 2: Building, Intervention, Evaluation		
Principle 3: Reciprocal Shaping	Indicator definitions and survey data was either lacking or not systematically created. Continuously during the research project, the stakeholders collaborated to design processes and requirements to address both issues.	***Alpha Version****:* The prototype should streamline the data integration and analysis process.
Principle 4: Mutually Influential Roles	The group of stakeholders consisted of researchers, NGO staff, local government agency officials as well as representatives of the local community and a local faith-based organization. Thus, scientific, practical and policy perspectives were taken into account.	***Beta Version*:** The analysis offered by the prototype should be based on systematically created indicators and data.
Principle 5: Authentic and Concurrent Evaluation	First evaluations were conducted by the researchers and NGO staff and then with the other stakeholders. Also further international offices of the NGO tested the prototype during development.	
Stage 3: Reflection and Learning		
Principle 6:	The NGO recognized potentials for improving work practices regarding systematic data collection and analysis. The local	***Emerging Version and Realization***: Additional requirements for the

Guided Emergence	government agency reflected on use cases for a broader roll-out of the system within its mandate area. The community valued the novel approach as an additional source of evidence for their own advocacy campaigns. System design requirements for the different stakeholders emerged.	prototype, especially regarding the multi-hazard context of the community. More dynamic and flexible prototype structure needed.
Stage 4: Formalization of Learning		
Principle 7: Generalized Outcomes	Concrete requirements for a first prototypical system version and for a more advanced later version were captured. Regarding the system as an integral future tool for analysis and planning of DRR programs.	***Ensemble Version***: Due to time-constraints, the development remained in the prototype stage.

Requirement analysis

Specific requirements for the prototype were continuously generated and adapted from discussions, workshops, interviews and observations with the DRR program stakeholders during field visits to the case area and remotely. General requirements were drawn from information system design literature and previous studies on information system development for DRR and crisis response (Turoff et al., 2004). According to the technology acceptance model, perceived usefulness and perceived ease-of-use are the major influential factors that determine if new information systems will be used (Davis, 1989; Davis et al., 1989). In the case described here, involved stakeholders IT literacy and experience varied strongly: from advanced experience within the government agency to mid-skilled humanitarian NGO staff to local community people with rather low IT literacy. The development process of the prototype needed to take this capacity diversity into account to facilitate adoption (Maiers et al., 2005). It became evident that a successful approach would need to consider processes and tools already implemented and used by the program stakeholders.

Development and Feedback Process

The prototype was developed with three core components: 1) a dashboard acting as the tool for analysis, 2) the data processing layer and 3) an API layer to retrieve external data and allow integration with other applications. A feedback process was set up that included stakeholders of the CCA and DRR program. Table 2 lists the participants and their involvement in the feedback process. Feedback data collection was conducted through semi-structured interviews, focus group discussions, workshops, field observations as well as e-mail and Skype conversations.

As a foundation for the development of the prototype, a dashboard previously developed by UNOCHA was used. It was open to adaptation, fulfilled sufficient aspects for dashboard design (Janes et al., 2013) and already provided some of the main requirements needed for the prototype. This included the interrelation of charts, a map and processing functions for household survey data on demographics, capacities and vulnerabilities of communities. During the parallel development and evaluation process we added the selection of hazards, the simulation of hazard intensities, substantially more charts on household capacities as well as dynamic map features and more interrelations between the charts and the map.

Within the data processing layer, the prototype does not store any data. Rather, the user needs to be in the possession of the data at all time. This eliminates the possibilities of malicious system infiltration and leakages of sensitive data. JavaScript code is sent by the server to the user and executed on the user's machine. Thus, when using the dashboard, both data and application are running on the user side. The decision on this form of data handling was made due to concerns raised by the community. Some members regarded the data being used by the prototype as too sensitive and personal and expected this additional security feature to prevent malicious actors from accessing it unauthorized. The decision is further supported by recent arguments within the debate on data management in humanitarian operations. Especially in political sensitive contexts, household and demographic data can be highly valuable for the different conflicting parties (Greenwood et al. 2017).

Three datasets are needed to run the prototype:

- Survey data (csv-file): Can be created in Excel or from a KoboToolbox[3] export, or any other survey platform. The internal data structure and terminology of the prototype needs to be followed.
- 3W data (csv-file): Can be created in Excel. It comprises local knowledge from DRR program stakeholders on relevant organizations, groups and networks. To complement the 3W data, information from IATI and HDX are fetched.
- Geographic features (kml-file): Can be created in Google Earth. Includes local knowledge from DRR

[3] https://www.kobotoolbox.org/

program stakeholders on important geographic features in the case area, e.g. evacuation centers, wells and water flows.

The choices for the data creation tools, Microsoft Excel, KoboToolbox and Google Earth, were made during stakeholder discussions and successive testing of the prototype during development. The three tools were well-known by most of the stakeholders. No additional training was needed.

Table 2. Methods of feedback collection and relations to stakeholder affiliations.

Group or organization	Interviewee affiliation (n)	Feedback collected via
International humanitarian NGO	Head of mission (1) Data analyst (1)	Interviews, focus group discussions, e-mails, Skype
Local disaster risk management office	Data analyst (1)	Interviews, focus group discussions
Local faith-based organization	Data analyst (2)	Interviews, focus group discussions
Local community	Priest (1) District representatives (5)	Focus group discussions

RESULTS

We present the results in the following first from a purely technical perspective, followed by the observed reciprocal results of the effects between system prototype development, community and organization.

Technical results

The prototype's visual user interface is a single-page dashboard made up of a map, charts, tabularized information and buttons as control elements. The three main components are depicted in figures 1-3. Figure 1 shows how the prototype visualizes community demographics. The bars and slices in the charts are clickable to allow the selection of a certain kind of data only. For example, clicking on a single district (i.e. a slice) in the Sitio pie chart, manipulates the gender pie chart in a way that it only shows the gender proportion within the selected district. Selecting multiple districts leads to the gender chart showing the combined gender proportions within all selected districts. All other charts are affected at the same time: the age chart shows the age structure and the affiliation chart shows the job title distribution within the selected districts. This works in all ways, e.g. starting from selecting affiliations or age groups instead of starting from districts. Data categories can be combined by selecting various slices from various charts. Users thereby can answer questions like: *how many females above 60 years of age live in Sitio Santa Cruz?*

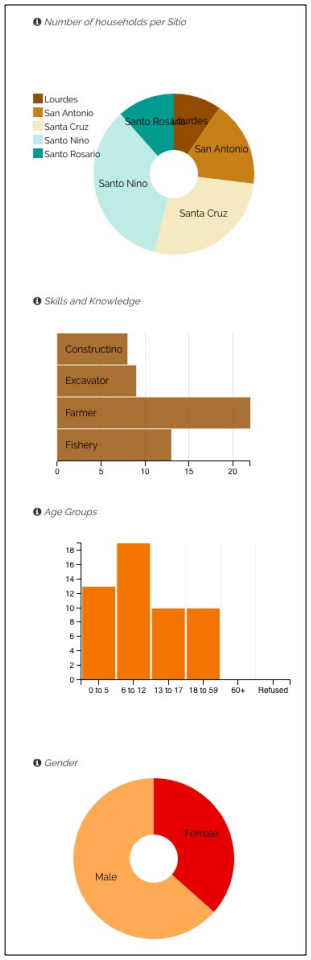

Figure 1. Community demographics charts.

Figure 2 shows the mapping of households at risk of being affected by different hazards within the community. Implemented were the main hazards identified by the stakeholders: flood, fire, typhoon and drought. The colored buttons below the map allow for simulating the intensity of those hazards, which in turn has an effect on the number of households potentially affected and highlighted on the map. Via the map legend, features like evacuation centers, wells and water flows can be added to the map. Clicking on a household dot shows its key information including age structure and income level. Making selections via the demographics charts, for example selecting only those households with small children, renders the map new, only showing households that match the selection criteria.

Figure 3 shows two example charts that visualize capacities and vulnerabilities of households in the community. These had been identified during the workshops and discussions with the stakeholders. Again, these charts are intertwined with the demographics charts and the map. Allowing users to answer questions like: *what districts have the most small children and elderly people living in light material housing in low elevation areas?*

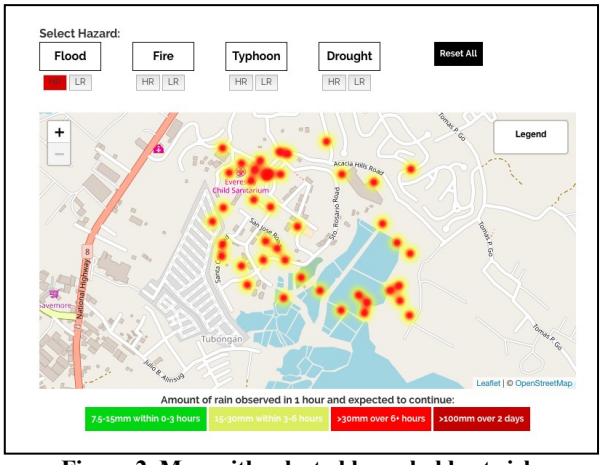

Figure 2. Map with selected households at risk.

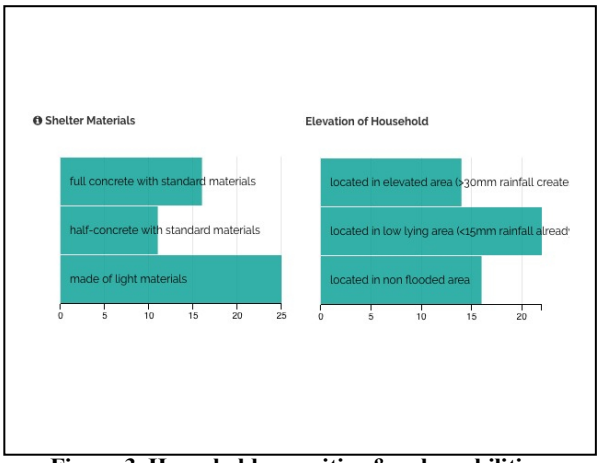

Figure 3. Household capacities & vulnerabilities.

Reciprocal results

Within the NGO, the work on the systematic creation of indicators and the collection of data lead to a reconsideration of established work practices. Figure 4 depicts how the organization tried to assess risk levels prior to the work on the prototype. The amount of data collected and the complexity of relations between capacities, risks and vulnerabilities blurred the organization's view on what the key issues were in the community and what caused them. As shown in figure 4, the previous mapping approach included a number of data layers but their integration was lacking. It didn't allow answering questions like: *how many elderly people and children under five live in light-material buildings in typhoon prone areas?* This was only possible with the new prototype where combining variables for integrated analysis became possible. The community members valued the prototype and the development approach leading to it, as helpful in their objective understanding of the risks they face as well as a validation of their subjective risk perception. They acknowledged the prototype as a supportive vehicle that could facilitate their own community-driven initiatives to raise awareness of their case at the local government level. The local government agency mentioned that a final version of the prototype could be rolled out to the whole province of Cebu, covering an area of approximately 3 million people. The agency stressed the importance of a flexible system open to future adaptations and implemented through technologies already employed by the agency.

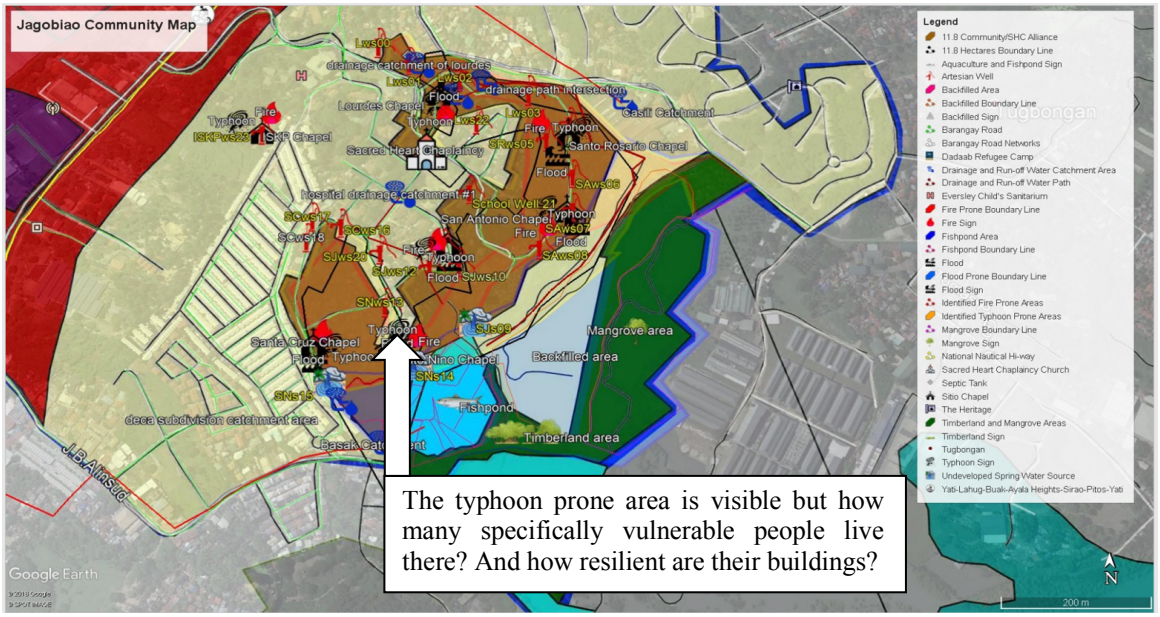

Figure 4. Layered map created and used by the NGO for DRR analysis prior to the prototype development.

DISCUSSION

Throughout the participatory approach towards designing the system prototype, we uncovered critical elements for the continued engagement of the community in the data management processes. Taking these design considerations into account enables communities to not only gather data themselves but also analyze it and support their own, internal, sense making and decision making processes. The inclusion of the community in the design, development and testing of the system does not only improve adoption but also supports the building of key capacities and data literacy skills. The end goal of data preparedness therefore is not merely the creation of data-sets but rather a collaborative learning process in which the community examines their information needs, capacities and tools needed (Norris et al. 2008). Data preparedness activities therefore should not only focus on making communities visible on maps, but build necessary capacities that lead to community-driven, collaborative programs and an active exchange of data and knowledge.

These capacities are critical for community resilience as they enable them to actively participate in the decision-making processes (Nur et al. 2015; Onencan et al. 2018). They can build a stronger evidence-base by continuously generating and sharing information that places these empowered communities firmly in the local, regional, national and even international stakeholder landscape (Kapucu 2008; Mayunga 2007).

All interviewees stressed that it is of major importance to understand and comply with data rights of communities and affected persons. This does not only include data privacy and security. But also, the rights of data subjects to get access to information about them when requested, to have information about them changed when wrong, to be informed about how information about them is stored, processed and used and to what purpose and result.

The joint disaster risk analysis and prototype development have created a paradigm shift in the role of the community in the overall information management process. Where initially the role of the community was primarily the one as data provider, the new design has led to a more collaborative information gathering, analysis and dissemination approach in which local actors play a more empowered role. Figure 5 depicts this shift, with the former data relationships between DRR program stakeholders on the left side and on the right side the new, joint cooperation to build a common understanding of risks and capacities. The dotted lines represent the newly formed communication and collaboration links between the community and the NGO, and all other previously established forms of collaboration and exchange further exist.

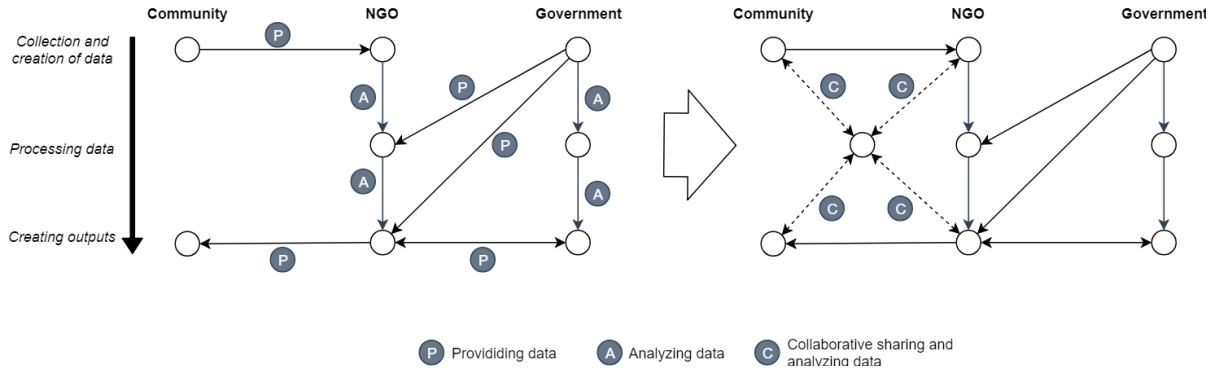

Figure 5. How data relationships changed from the traditional model of data collection, analysis and provision to the novel, joint assessment model.

CONCLUSION

The most striking observation was that the community and the humanitarian organizations recognized significant reciprocal effects between the development of the prototype and their work practices. They revisited established data collection and analysis practices while seeing the prototype advance, testing it and giving feedback on it. The stakeholders acknowledged that the existing data gathering, and creation processes were not systematic enough to lead to robust risk and capacity indicators and variables.

We used prototypical software development and a diverse feedback collection process to study what information needs communities and humanitarian organizations have and how streamlined data integration and analysis can

help in addressing these needs. We found evidence for the usefulness of data integration for various stakeholders of DRR programs: humanitarian organizations, local communities, government agencies and faith-based organizations.

The increased availability of data to support humanitarian operations, spurred on by the profusion of information technologies that facilitate data collection, analysis and sharing, have led to a *data revolution* in the humanitarian field. Increasingly, organizations, donors and policy makers place a strong emphasis on the use of data for effective operations, evidence-based decision making and accountability. At the same time the potential of data in the humanitarian field has also led to an increased attention for communities to become prepared and 'data-ready'. As a result, more and more datasets become available, strengthening the potential of data to ensure effective aid delivery to those in need.

Throughout our participatory approach towards designing a novel disaster risk analysis prototype, we uncovered critical elements for the continued engagement of the community in the data management processes. Taking these design considerations into account enables communities to not only gather data themselves but also analyze it and support their own, internal, sense making and decision making processes. More important than the design of the system itself however, is the inclusion of the community in the design, development and testing of the system as this does not only improve the probability of adoption but also supports the building of key capacities for local disaster risk mitigation, preparedness, response and recovery efforts.

LIMITATIONS AND FUTURE RESEARCH

The work presented in this paper is limited to a single case study, and in our future work we aim to expand our work to other regions and settings to further validate the findings presented in this study. In addition to the further validation of the work, a key aspect is the continued exploration of the participatory design of data management processes and information systems. Specifically, various approaches towards capacity building and training, also raised during interviews and focus group discussions, need to be further investigated. Another interesting further endeavour is to study how decisions from humanitarian organisations are affected by how the evidence that results from the streamlined data integration and analysis approach is presented and communicated. That is, recent empirical research shows that decision making in complex situations can be influenced by how information is being framed (e.g. de Vries, 2017).

ABSTRACT

Information and Communication Technologies (ICT), and particularly Social Media, drastically changed communication channels and organization during a crisis response. In this context, new forms of citizen initiatives appear, contributing to situational awareness, providing new profiles of stakeholders and broadening the scope of volunteerism in disaster situations. Thus, given the increasing need to understand and take citizen initiatives into account, this article provides a taxonomy of volunteerism types in crisis contexts, based on a literature review on the subject. Mapped on two main dimensions: the *status* (who they are) and the *focus* (what they are doing), multiple types of volunteers are presented on this taxonomy. Then, the article deals with possible use of this taxonomy towards integration of citizen initiatives into the crisis response.

Review, Volunteers, Taxonomy, Social Media, Citizen Integration

INTRODUCTION – FROM UNDERSTANDING TO INTEGRATING CITIZENS INTO CRISIS MANAGEMENT PROCESSES

Recent events in France (e.g. 2016 and 2018 floods in Loiret and Aude, 2015 and 2016 terrorist attacks in Paris and Nice) have confirmed the opportunities and challenges raised by social media in crisis management. Ordinary citizens are usually the first on the scene during an emergency to take care of victims, conduct search, organize solutions on-site, and they remain long even after official services have ceased (Whittaker et al. 2015). As citizens are taking a growing place in the stage of crisis management, their voice is strengthened by social media, which has become a tool for them to communicate, organize themselves and act. Moreover, professionals see the increasing potential of social media to address as many people as possible, and to understand citizen behavior during crises. While "real volunteers" and stakeholders are on-site and fight locally against the effects of a crisis, the "virtual volunteers" are located anywhere and help stakeholders on the ground and crisis managers through social media (Reuter et al. 2013).

Volunteerism in crisis management covers a large panel of acceptations, ranging from the most restricted to the broadest. On the one hand, volunteers have been defined as people engaged in response to a request expressly made by a representative of an official organization (Blanchard 2008; Koob and Emergency Management Australia 1998), while on the other hand, we can see volunteerism as any freely chosen and deliberate action, be it spontaneous or organized, which is not necessarily formally regulated (Snyder and Omoto 2008; Wilson 2000; Wolensky 1979). Thus, it appears that between these opposed definitions, there might be a large diversity of volunteerism types, going from the most organized and affiliated to the most spontaneous and unaffiliated.

For example, following the growing place taken by social media in crisis response, some associations such as the Volunteer Operational Support Teams (VOST) and its French equivalent Volontaires Internationaux en Soutien Opérationnel Virtuel (VISOV) appeared. Progressively, they are playing an intermediary role between ordinary citizens and official crisis managers by filtering and processing social media data to help improving the situational awareness in real time. Although in France, the VISOV are becoming more and more institutionalized by signing agreements with official crisis response partners, they remain an association, and they are just an example amongst a growing number of diverse and varied citizen initiatives based on the great potential of ICT in crisis response.

To make the most of this potential help and support for crisis response, there is definitely a need for integration of social media in IT for crisis management (Mathioudakis and Koudas 2010; Vieweg et al. 2010). Moreover, it is essential for local authorities to recognize that in times of crisis, unsolicited volunteers will show up (der Heide 2003) and to date, there is a lack of frameworks to create a comprehensive and manageable process to ensure the most effective and safe response with the aid of spontaneous volunteers (Orloff 2011).

The research presented in this paper, conducted as part of the French National Research Agency project MACIV (Management of Citizens and Volunteers: the social media contribution in crisis situations), focuses on the diversity of citizen initiatives as they are fostered by social media in times of crisis, to understand them, and think about ways to integrate them into crisis response and management processes. In order to understand this diversity of citizen initiatives and to propose ways to integrate them into crisis response and management processes, the research is divided into two lines, which can be presented as follows:

1. Understanding the role played by citizens in times of crisis to foster organizational collaboration with official responders
2. Proposing an IT solution to orchestrate the collaboration between professionals and citizens in real-time

In this article, we will present the first research findings related to the first axis, as a requirement for the second one.

Indeed, when it comes to integrating citizens into crisis management processes (2.), the first need that rises is about understanding citizens taking part in a crisis response (1.). To answer to this question, the first step presented in this article consists in understanding who these citizens are, by creating a taxonomy of volunteerism types in crisis response and management. Then, the idea will be to describe the likelihood of the appearance of each type of volunteerism, depending on the crisis context, i.e. the disaster type, its extent, and the environment type. In this article, we argue that if we are able to categorize the citizens in times of crisis, and to give their characteristics, then we could be able to identify them when a crisis occurs. Then, we could go into further details to understand the way they are acting: what are the communication, organization and action processes that these types of volunteers put into practice to address their needs or those of the community? Given an advanced knowledge of these types of volunteers, and looking through the prism of social media, crisis responders could then be able to identify volunteer types, understand them, and take decisions regarding whether or not to integrate them into the crisis response process.

The final goal of this research would be to integrate citizen initiatives in times of crisis into a suite of tools to support collaboration in crisis management: RIO-Suite. This software, based on a generic model of collaboration, aims to instantiate every concept that can potentially take part in a crisis occurrence (environment, dangers, risks, opportunities, threats, partners, competences, resources, stakes…), to then propose an optimized plan to orchestrate the crisis response in real-time. Thus, the taxonomy of volunteer types presented in this paper will be a first step to implement the integration of citizens into RIO-Suite, but it has been created without any consideration of the software framework to remain useful for other research purposes dedicated to understand citizens engaged in crisis response.

HISTORY AND EVOLUTION OF VOLUNTEERISM IN CRISIS SITUATIONS

What does *volunteerism* mean?

Derived from the Middle French[1] word *voluntaire*, the noun *volunteer* was first used as "one who offers himself for military service" (c. 1600)[2]. Then, over time, the concept evolved beyond the military framework, to include broader forms of engagement. Described by Dynes (1970) as an "expansion of the citizenship role", volunteerism has become a vast concept with unclear boundaries.

[1] Middle French is the first form of official unified French language in the kingdom of France (14th – 17th centuries)
[2] ("volunteer | Origin and meaning of volunteer by Online Etymology Dictionary" 2019)

After reviewing several definitions, Cnaan et al. (1996) conclude that the boundaries of the term *volunteer* vary from one context to the other. They show that widely used definitions of the term range from the broadest to the purest of interpretations. According to their results, definitions vary on four key dimensions: free will, remuneration, intended beneficiaries and structure.

We can find back three of these four dimensions in the requirements of volunteerism according to the United Nations Development Programme (UNDP): "Firstly, the action should be carried out voluntarily, according to an individual's own free will, [...] Secondly, the action should not be undertaken primarily for financial reward. [...] Thirdly, the action should be for the common good. [...] The three criteria of free will, non-pecuniary motivation, and benefit to others can be applied to any action to assess whether it is volunteerism." (United Nations and EBSCOhost 2011) In this definition, the UNDP voluntarily puts aside the notion of "mandatory volunteerism" such as community service as an alternative to military duty or custodial sentences. The report also states that it doesn't consider the organizational criterion (i.e. "structure" in (Cnaan et al. 1996)) in the definition, in order to include many acts of volunteerism that take place outside of a formal context. This is in line with Whittaker et al.'s (2015) argument, who after having compared several definitions, argues that many of them "exclude those who act independently of the state or formal organisations, and obscure much of the shorter-term, informal volunteering that occurs in times of crisis." Thus, they defend the idea that "less rigid definitions of volunteerism are needed to fully recognise and value citizen contributions in the context of emergency and disaster management." (Whittaker et al. 2015)

Thus, the notion of volunteering has expanded over the years, and the field of crisis management has seen the emergence of initiatives that have pushed the boundaries of the term. In its most inclusive sense, volunteerism in crisis management can be defined as 'any willful action, be it spontaneous or organized, carried out outside the actor's working context, in which time is given to benefit another person, group or organization'.

Social Media: shifting paradigms in crisis management

Social media, and in general, Information and Communication Technologies (ICT) have drastically changed the way a crisis is managed, both on social and technical aspects. On one side, they foster inter-organizational communication, and give a voice to citizens. On the other side, they provide powerful tools for crisis responders to improve their situational awareness. Among the profusion of literature on the subject, we can quote Kietzmann et al. (2011) who identified seven functional blocks of social media (Identity, Conversations, Sharing, Presence, Relationships, Reputation and Groups), and state that every social media tool focuses on some of these blocks. In a crisis-related situation, Alexander (2014) lists some functions for which social media can be used, such as listening, monitoring, searching, crowdsourcing, creating social cohesion or furthering causes.

While traditional communication between citizens and professionals used to be "from one to one", social media are shifting paradigms, and making crisis management a many-to-many communication system. Sometimes being alternative channels, sometimes even backchannels, they play an essential role in crisis response and management, both on professionals and volunteer sides (Sutton et al. 2008). Based on Reuter et al.'s (2011) communication matrix for a social software infrastructure (see Table 1), Grant et al. (2013) state that social media can play an important role for crisis management at operational and tactical levels between organizations.

Table 1. Reuter et al.'s (2011) communication matrix for a social software infrastructure

Receiver / Sender	**Organizations**	**Citizen**
Organization	Inter-organizational crisis management	Citizen communication
Citizen	Integration, aggregation and validation of citizen-generated content	Self-help communities

Whether it is online or offline, official crisis responders know that citizens will always act during a crisis event. The very structure of communication and information sharing dynamics is changing both for emergency managers and the public (Alexander 2014). Thus, there is a value for both professionals and citizens to become aware of others' needs and behaviors, and contribute together to situational awareness.

Between citizens on the ground acting on different forms within different social structures, and citizens using social media to provide and organize information about the situation, there is a large range of crisis-related volunteerism types. From a volunteer firefighter acting within an official organization and receiving a

remuneration, to an individual spontaneous unaffiliated citizen using Twitter to share an information, volunteerism in crisis situations include a wide range of initiatives that we will need to classify if we want to think about integrating them into crisis management processes.

Categorizing the different forms of volunteerism in crisis situations

Based on previous work by Quarantelli (1966), the Disaster Research Center (DRC) at Ohio State University focused on the type of structure taking part to the response (old or new) and the type of tasks undertaken by the responders (regular or non-regular) to propose a first typology of organized response to disasters, presented in Table 2.

Table 2. The DRC typology of organized response to disasters (Dynes 1970)

	Regular tasks	**Non-regular tasks**
Old structure	Type I: Established	Type III: Extending
New structure	Type II: Expanding	Type IV: Emergent

Although today's crises are mainly managed by official organizations, it seems that spontaneous volunteerism is the first form of crisis management in history. Indeed, people spontaneously helped each other long before creating organizations to do so. (Orloff 2011) Thus, we can expand the DRC typology to other forms of volunteerism that appear outside of organizations. Stallings and Quarantelli (1985) define emergent groups as "private citizens who work together in pursuit of collective goals relevant to actual or potential disasters but whose organization has not yet become institutionalized." These groups include a more specific type: *spontaneous volunteerism*: "people who offer assistance following a disaster and who are not previously affiliated with recognized volunteer agencies and may or may not have relevant training, skills or experience" (Cottrell 2010). Although emergent volunteerism can appear at any phase of the crisis cycle, spontaneous volunteers are a specific form of volunteerism that only appears in the response phase, once a crisis occurs. (Whittaker et al. 2015)

Based on this distinction between anticipated and spontaneous volunteers, and distinguishing the volunteerism whether it is within an organization or not, Shaskolsky (1965) proposes four different types of volunteerism, with examples to illustrate the four cases. See Table 3.

Table 3. Examples of the different types of volunteerism (Shaskolsky 1965)

	Individual	**Organized**
Anticipated	Doctor	Regular volunteer firefighter
Spontaneous	Search and rescue by bystander	Non-regular volunteer firefighter

As presented by Cnaan et al. (1996), the intended beneficiaries, i.e. the interests that the volunteer has in mind, are also a criteria to take into account. Based on the opposition between altruism and egoism, described by Durkheim (1933 p. 198) as "two sides of conduct [that] are found present from the beginning in all human consciences", Wolensky (1979) distinguishes the motivations of volunteers between public and private interests, to present four types of "post-impact" volunteerism in Table 4.

Table 4. The four types of "post-impact" volunteerism (Wolensky 1979)

Social Form / **Motivation**	**Emergent**	**Organizational**
Public Interests	Altruistic	Communalistic
Private Interests	Egoistic	Mutualistic

Here are some insights regarding these volunteers' motivations:

- **Altruistic volunteers** have a genuine concern for human safety and neighborly aid;
- **Egoistic volunteers** put their private interests before those of the community;
- **Communalistic volunteers**' action is aimed at the entire community, its members and their problems;
- **Mutualistic volunteers** provide help primarily to fellows sharing common characteristics.

PROPOSAL – CATEGORIZING VOLUNTEER TYPES TO FOSTER CITIZEN INTEGRATION

When looking at the several attempts to classify the different forms of volunteerism, it appears that different dimensions are used. The Table 5 below presents the previously-used dimensions to categorize volunteerism types, their semantic equivalents, and corresponding references.

Table 5. The various dimensions that have been used to distinguish between volunteerism types

id	Dimension	Equivalents	Examples in literature
1	Affiliated / Unaffiliated	Formal / Informal; Official / Unofficial; Organized / Individual; Organizational / Emergent; Old / New Structure	(Cnaan et al. 1996; Dynes 1970; Shaskolsky 1965; Whittaker et al. 2015; Wolensky 1979)
2	Action / Information	Real / Virtual; On-site / Online	(Reuter et al. 2013)
3	Skilled / Unskilled	Regular / Non-regular tasks	(Dynes 1970)
4	Anticipated / Spontaneous		(Shaskolsky 1965; Whittaker et al. 2015)
5	Public interests / Private Interests	Intended beneficiaries: Others / Relatives / Oneself	(Cnaan et al. 1996; Wolensky 1979)
6	Remuneration: None / None expected / Expenses reimbursed / Stipend, low pay		(Cnaan et al. 1996)
7	Free will / Relatively uncoerced / Obligation		(Cnaan et al. 1996)

As showed before, volunteerism is a broad concept. Thus, the classification dimensions depend on the angle of view from which the concept is viewed (i.e. from which stakeholder we want to understand volunteerism) and on the filter that is placed on the lens (i.e. the objective we have in mind). Indeed, the research goal here is not to decide whether or not a citizen behavior should be considered as volunteerism, as it was for Cnaan et al. (1996), but to help official crisis responders to take decisions regarding whether or not a citizen initiative should be integrated to the crisis response.

To do so, the first categorization dimension that seems essential, and present in almost every literature, is the social structure in which the citizen initiative takes place (1). Although the term and its meaning are not exactly the same in every reference ("structure" for Cnaan et al. and Dynes; "organization" for Shaskolsky, Wolensky and Whittaker et al.), it appears that every author deals with the formalism level of the citizen's social structure.

Secondly, it is important to make a distinction between information and action (2). As Reuter et al. (2013) stated, whereas "real" volunteers are directly acting on the ground, "virtual" ones provide information about the situation, and help to understand what happens on the ground. In that sense, whereas citizens' will and ability to act in times of crisis have always been present, the emancipation of ICT, and in particular social media, has disrupted the construction and circulation of information during a crisis event.

Thus, given a volunteer initiative, the two first questions we want to answer are the following:

- **Who?** Are these citizens acting by themselves, in group, or are they registered within an organization? This volunteer initiative's social structure will be called *Status*.
- **What?** Are these volunteers focused on improving the situational awareness thanks to information, or are they focused on the action on the ground? This dimension will be called *Focus*.

Although the skill level (3) is an essential criterion for crisis responders to take decisions about whether or not to integrate a volunteer initiative, it doesn't appear as a convincing criterion to distinguish two volunteers in a taxonomy. Indeed, amongst the unaffiliated volunteers, each can be divided in two sub-categories depending on the skill level for this specific task. Thus, the skill level can be seen as a third dimension in the taxonomy, whether it is a binary or continuous axis, and knowing it given a citizen initiative, it could help the decision taking regarding this volunteer. In addition, the boundary between dimension "Skilled / Unskilled" (3) and dimension "Anticipated / Spontaneous" (4) is thin. Indeed, if we look at Shaskolsky's interpretation, we can consider that a citizen having skills for a specific task will be considered as an anticipated volunteer to do it, whereas a citizen acting without any skill regarding the task he/she is doing will be considered spontaneous for this task. In this way, a third dimension in the taxonomy could join these two aspects (dimensions 3 and 4) as a degree of the volunteer's inclination to help.

Given the integration objective, it doesn't appear to be useful to take into account several dimensions of the Table 4 above, such as the remuneration (6), or the free will (7), which were dimensions used to identify if a given behavior should be considered as volunteerism or not. Finally, regarding the interests (5), further discussions with crisis management stakeholders will need to be done to state about the relevance of this dimension.

A two-dimension taxonomy of volunteerism types: Status and Focus

When dealing about the volunteers' status, the main distinction that appears is about the degree of formalism of the volunteer initiative, which we divided in four levels:

- **Individual volunteers** are citizens taking decisions by themselves regarding their behavior in the crisis management;
- **Group volunteers** are citizens acting together and taking common decisions to address specific needs;
- **Organized volunteers** are citizens officially affiliated to an organization or registered through an application;
- **Formalized volunteers** are organized volunteers whose organization or application has been officially recognized by crisis responders.

Regarding the focus, we divided the volunteers depending on if they are focused on information or on action. This is an equivalent of what Reuter (2013) called "virtual" and "real" volunteers, but considering that even citizens using traditional communication channels (e.g. phone calls) are considered as "information volunteers". Thus, we identified four types of focus:

- **Organizing information** are volunteers focused on the information filtering, analysis and organization to provide an insight on the crisis situation;
- **Sharing information** are volunteers using the communication tools in their possession (social media, phone…) to spread information that might help to improve situational awareness;
- **Managing action** are volunteers that take decisions regarding who should do what, to assign tasks to other stakeholders;
- **Doing action** are volunteers carrying out actions on the ground.

Given these two dimensions, the Figure 1 presents different examples of volunteerism, depending on the level of status and the type of focus.

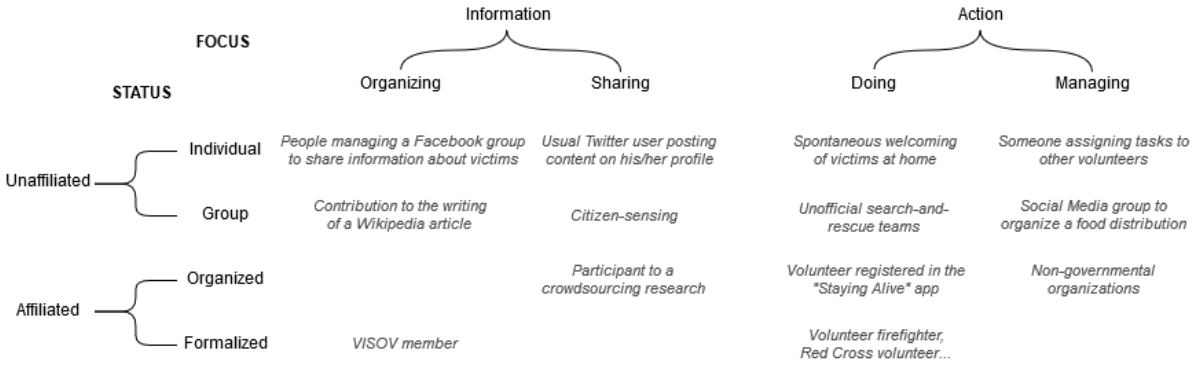

Figure 1. Taxonomy of volunteerism types with examples

One interesting example is the status of the VISOV association in France. Indeed, the association started with a group of people looking at social media in times of crisis to find useful information and share it with the crisis responders. It then became an association, and progressively signed agreements with official crisis management institutions in France, such as the Ministry of the Interior or several regional fire brigades, becoming then a formalized association. Now, when an important event happens, the VISOV are 'activated' as an official intermediary organization between citizens and crisis responders.

Moreover, in this matrix, we can find some groups of volunteers identified in previous literature, as presented in Figure 2. For example, any volunteer focused on sharing information is providing *User-Generated Content (UGC)*, which is "media content that is created or produced by the general public rather than by paid professionals and is primarily distributed on the Internet." (Daugherty et al. 2008) A sub-category of UGC is the *Volunteered Geographic Information (VGI)* (Goodchild 2007; Zook et al. 2010): "spatial data that are produced and disseminated by individuals or non-official institutions, i.e. by ordinary citizens using appropriate tools to gather and disseminate their views and geographical knowledge on the web" (Horita et al. 2013). As another example, on this map of volunteer types, we find the Intermediary Organizations, described by Zettle et al. (2017) as "a voluntary association of individual and/or collective civil society actors and acts as an intermediary between public authorities and the civil society."

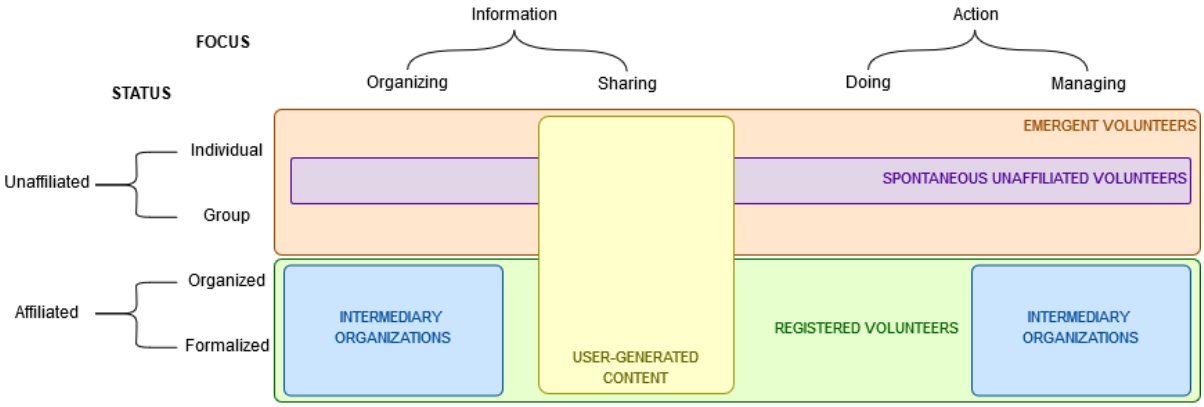

Figure 2. Different forms of volunteerism represented within the frame of the taxonomy

Towards integration of volunteerism into crisis management processes

The first thing that we can notice about this taxonomy is that the *status* axis can be seen as a degree of reliability of the citizen initiative. As official responders communicate closely with formalized organizations during the crisis response, it becomes more difficult for them to integrate those at the lower level of the status axis, i.e. the individual unaffiliated volunteers.

If we look at the *focus* axis, considering the current situation in France, and based on exploratory interviews we have conducted with crisis responders (from the Ministry of Interior and the Var region fire brigade), it appears that professionals tend to pay attention in priority to forms of volunteerism that focus on organizing information, such as VISOV. As the crisis gets worse, they will progressively broaden their attention to raw information shared by citizens. Then, in extreme cases, they will think about integrating less formal volunteers managing and doing actions on the ground. Indeed, for professionals, integrating volunteers to the response is risky. Firstly, when it comes to integrating information provided by citizens, especially from social media, several challenges appear,

regarding data quality, trust and format, and social media can lead to rumor propagation, panic, or rise new ethical challenges (Alexander 2014; Crawford and Finn 2015; Rizza and Pereira 2014). Secondly, interviews we have conducted with crisis responders show that integrating citizen action remains the most challenging part for professionals. Whether it is about supporting or just letting the action being done by a citizen is for professionals a risk of endangering an individual whose own objective should be his/her own safety.

Last but not least, first discussions with official crisis responders, volunteers and researchers in the field tend to indicate that as the crisis situation becomes more complex, the professionals' decision-making process tends to be disturbed because of stress, uncertainty, time pressure, heightened public scrutiny and cognitive overload, which could result in tunnel vision and information bias (Cao et al. 2008; Schraagen and van de Ven 2008; Svedin 2011). Thus, in a highly chaotic crisis, we can assume that a large range of volunteerism types will be present, bringing a lot both on the action or on the information side, but the professionals might close their cooperation doors to focus on a small range of tasks they have to accomplish with partners they already know.

Given these considerations, we make the assumption that there are different levels of severity of the crisis at which it could be relevant for professionals to take citizen initiatives into account. The more complex the crisis, the more diverse the citizen initiatives will be. At the same time, it should be considered that the more complex the crisis, the more opportunities professionals will have to integrate these initiatives, starting with the most formalized and information-focused ones, and progressively opening their mind to less formal, more spontaneous and action-focused initiatives. Thus, based on the taxonomy presented before, we can develop a map of levels of opportunities of volunteer consideration in the crisis response, depending on the severity of the situation (i.e. the "degree of chaos"). This map is presented in Figure 3.

Note that in this hypothesis, the "degree of chaos" is a notion that might rely on a diversity of parameters that can affect the complexity of the situation. As a first attempt to specify this *degree of chaos*, the influencing parameters could be the crisis type, its duration, the variety and volume of the needs professionals have to address, the professionals' competences and resources, the ethical, legal and social aspects regarding the integration of a citizen, or the risk that this integration might represent. The *degree of chaos* can be seen as an extension of Franco et al's "disaster impact index" (2008), and further research is needed to clarify this concept.

Future research will be conducted to refine the parameters influencing these opportunities, and to understand professionals' needs, to help them converting an opportunity into a concrete integration of an initiative.

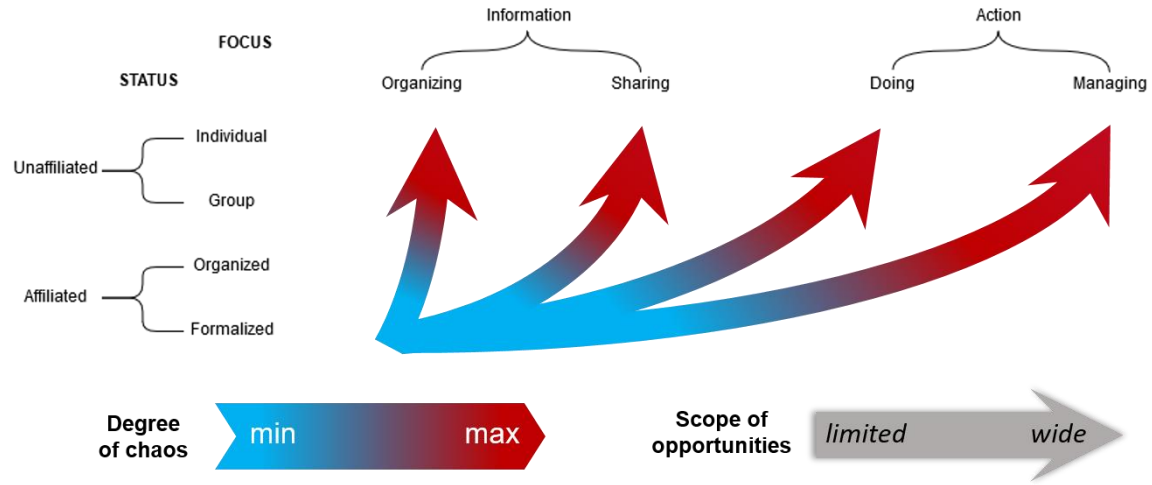

Figure 3. Scope of opportunities of volunteer consideration by professionals, regarding the degree of chaos of the crisis

ANALYSIS AND DISCUSSION

Regarding the taxonomy itself, one important dimension that doesn't appear is the skill level of the volunteer regarding the action he or she is doing (i.e. *regular* / *non-regular tasks* (Dynes 1970)), combined with the spontaneity of the initiative. As presented before, these parameters could be joined as a third dimension in the taxonomy, representing the volunteer's inclination to help.

Having in mind the goal of integrating citizen initiatives, or at least be aware of them during a crisis response, it could be relevant to think about prioritizing the volunteerism forms that might be relevant to take into account.

To do so, other interviews will be conducted with official crisis management stakeholders, to understand their needs regarding the understanding of citizen behaviors. In addition, it could be relevant to identify the likelihood of the presence of the several types of volunteers in each kind of crisis, in each kind of environment, to complete the official responders' needs and help to prioritize the focus on several volunteerism types. Specifying the decision-makers' needs could also help to dispel their tunnel vision and cognitive overload by providing relevant advice, and thus make them more open to the integration of new initiatives.

Moreover, developing a taxonomy is always a risky exercise, as it should be kept in mind that the objective is to help the understanding of the types of volunteerism to help the professionals' decision taking, and not to lose the subtlety of human behavior by putting a label on a volunteer profile. Thus, given a citizen initiative, the only fact of identifying its status, its focus, or its skill level will not be comprehensive enough to describe precisely this initiative. In future research, more details will need to be provided regarding this initiative, based on the professionals' needs.

As volunteerism is a constantly evolving concept, it is important to remain aware that the diversity of volunteerism types will evolve as quickly as the crisis will do. The inventiveness and improvisation of citizens in times of crisis might always bring to the light unpredictable types of volunteers. Thus, whatever method is used to understand and integrate citizen initiatives, it must be sufficiently inclusive not to close the door to these emerging forms of volunteerism.

CONCLUSION

Resulting from a diversification of citizen initiatives thanks to the development of social media, volunteerism in crisis situations is a vast concept that official crisis responders need to comprehend in order to improve their situational awareness, and at the same time, their response to the crisis. The taxonomy of volunteerism types presented in this article is mainly based on a literature review regarding volunteerism in crisis situations, and previous attempts of categorizing the volunteers.

Given the objective to provide crisis responders an insight on what citizens are doing during a disaster, this article presents a two-dimension matrix of volunteerism types. The first dimension – the *status* – aims to identify the social structure in which the initiative takes place, going from an individual unaffiliated behavior to an affiliated, organized and officially recognized initiative. The second dimension – the *focus* – is dedicated to the type of initiative, depending on whether it concerns *information* that can improve the situational awareness, or *action*, which has a direct impact on the ground.

Future interviews and field observation will be conducted with official crisis responders to refine their needs regarding the understanding of citizen initiatives, and thus to refine the taxonomy presented in this article. For example, having more details regarding the skill level, the spontaneity, or even the motivation of citizen initiatives might be relevant parameters for the professional's point of view.

To make use of such a taxonomy, the research can then think about the parameters that can influence the professionals' decision making regarding the integration of a citizen initiative. As an example, based on exploratory interviews conducted with official crisis responders, this paper presents the idea of a hypothetic "degree of chaos" which might rely on a diversity of parameters linked to the crisis situation, and that might be deterministic for professionals' decision about taking into account or not this or that citizen initiative. However, the information overload faced by crisis managers in complex situations reminds that there is a significant gap between having the opportunity to integrate an initiative, and concretely integrating it.

As the decision making in crisis centers relies mainly on the information professionals have, the next steps in this research project will be to conduct interviews with both professionals and volunteers in order to 1) understand professionals' needs regarding the understanding of volunteers; 2) present a comprehensive map of volunteers' contribution in crisis situations and 3) find relevant information to provide to the crisis responders regarding the real-time citizen initiatives, and help them to take decisions about their integration.

ABSTRACT

In an emergency, getting up-to-date information about the current situation is crucial to orchestrate an efficient response. Due to its objectivity, preciseness and comparability, time-series data offer broad possibilities to manage emergency incidents. Since the Internet of Things (IoT) is rapidly growing with an estimated number of 30 billion sensors in 2020, it offers excellent potential to collect time-series data for improving situational awareness. The IoT brings several challenges: caused by a splintered sensor manufacturer landscape, data comes in various structures, incompatible protocols and unclear semantics. To tackle these challenges a well-defined interface, from where uniform data can be queried, is necessary. The Open Geospatial Consortium (OGC) has recognized this demand and developed the SensorThings API standard, an open, unified way to interconnect devices throughout the IoT, which is implemented by the **FR**aunhofer-**O**pensource-**S**ensor**T**hings-Server (FROST). This paper presents the standard, its implementation and the application to the domain of crisis management.

Keywords

Sensor data management, Time-series data, Data storage and retrieval, Open-source software, SensorThings API, OData, REST, MQTT, FROST

INTRODUCTION

The situational awareness of emergency managers relies on up-to-date and correct information. One possibility to retrieve most accurate and objective data is the utilization of sensors collecting time-series data, for example water levels of a river, wind speed or temperature. Monitoring a single sensor alone might not offer much benefit; however, the monitoring of many sensors targeted at a linked causality brings valuable insights. If these sensors are connected to a network, one speaks of the Internet of Things (IoT), which is rapidly growing: due to narrow production costs and huge potential in the field (Lee & Lee, July-August 2015), more than 30 billion connected IoT-devices are expected in 2020, growing to 75 billion devices in 2025 (Statista.com, 2019). One of the most promising prospects of IoT is the comparatively simple collection of vast amounts of data. Through a large number of devices monitoring different natural phenomena, an unlike larger amount of data can be collected. Still, since several different manufacturers produce these devices, the access to data is hindered through different data models and access protocols. In detail, data coming from IoT-devices is characterized through several traits. Firstly, the data comes from different sources and is heterogeneous, it is unstructured and without clear semantics. Without preprocessing, the data is not interoperable in the first place. Secondly, the large number of devices causes a mentionable amount of data that requires an annotation with metadata, which provides semantic information, to make them reusable. Lastly, the flexibility of IoT devices allows the collection of data at different points in time at different places offering spatial-temporal correlations (Li, Liu, Tian, Shen, & Mao, 2012).

The Open Geospatial Consortium (OGC) has recognized these challenges and developed the SensorThings API. It is a standard for the collection, storage and retrieval of time-series data. The data can be collected through IoT-devices, but it is not limited to these: the number of available sand packs during a flood event at a specific location or the number of manufactured items in a production line could be collected through other devices and subsequently be integrated, too. The standard defines a model for sensor data and its metadata, as well as an interface for both data storage and retrieval. The service can be queried with powerful filters, including geospatial search possibilities. The goal of the SensorThings API is to offer a unified way for the usage of sensor-data and to facilitate the development of data-driven applications. The Fraunhofer Institute of Optronics, System Technologies and Image Exploitation IOSB adopted this standard and has developed an open-source Java implementation of the SensorThings API. This implementation, called FROST, is fully compliant to the standard and certified by the OGC. FROST has been deployed in several projects where it forms the single point of managing time-series data.

This paper introduces the OGC SensorThings API in detail; explains the data model, the query options and interfaces. Subsequently, the FROST implementation and supplementary software is introduced. In a further section, it presents two EU-funded projects located in the domains of Climate Change and Crisis Management, in which FROST was successfully applied. Before the conclusion, a short passage highlights further developments and the relevance of this research.

RELATED WORK

The Sensor Observation Service (SOS) bases, like the SensorThings API on the OGC Observations and Measurements standard (O&M). It is, just like the SensorThings API a standard of the OGC and has been published in 2012 (Open Geospatial Consortium, 2012). It defines a web service interface, which allows querying observations, sensor metadata and representations of observed features. It defines means to register new sensors and remove obsolete sensors. The interface is realized by using the Simple Object Access Protocol (SOAP). The data itself is encoded in the Extensible Markup Language (XML). SOS offers at least three service operations: *GetCapabilities*, *GetObservation* and *DescribeSensor*, whereas the first will retrieve a description of SOS itself, describe further operations (if available) and state what kind of measurements are recorded. The second will retrieve specific observations and their metadata. The third gives explicit information about a sensor, e.g. measurement parameters etc.

The following abstract highlights the differences between SOS and the SensorThings API. The interested reader can find a full comparison in (Jazayeri, Liang, & Huang, 2015). In contrast to the *Representational State Transfer Principle* (REST), which is used by the SensorThings API, the SOAP interface used by SOS is in general more complex to use and has a bigger entry hurdle (zur Muehlen, Nickerson, & Swenson, 2005). The SensorThings API instead, using the *JavaScript Object Notation* (JSON), is more efficient regarding the amount of transmitted data, than the XML-encoded data transfer of the SOS (Mumbaikar & Padiya, 2013). However, SOS can have a JSON encoding extension, just as a SensorThings Service could have an XML encoding extension. As the SensorThings API has been developed by the OGC, it is backwards compatible to the SOS on a service level: all service functions defined by the SOS can be found in the SensorThings API. In contrast, through the implementation of ODATA filters, the SensorThings API offers more query capabilities on the service level, which cannot be answered by an SOS.

SENSORTHINGS API

To ease out the integration of different devices in data driven applications, the OGC developed a flexible, easy to use standard for the exchange of information in the context of the Internet of Things. With the SensorThings API standard, a framework, which interconnects sensing devices, data and applications over the web, is provided. The standard focuses on time-series data. Time-series are measurements of the same observed property, for instance the temperature, taken at different points in time. They can be measured in a more-or-less regular interval, e.g. every hour. The sensor can have either a fixed (fixed-point) or a moving (moving-point) location. An example for a fixed-point time-series are automatic water level gauges or more general the national weather stations available throughout Europe. These sensors are located in-situ and generate data at a fixed time interval. Sensors that can be hand-held or mounted on a vehicle or drone, and therefore have a different location for each measurement generate moving-point time-series. Drone-collected meteorological values are an example of this type.

DATA MODEL

The OGC SensorThings API data model not only covers plain sensor measurements, but also metadata like the unit of the measurement, a sensor description or a location. The metadata is connected to the original data stream.

The data elements are linked to each other enabling the user to find all necessary information of interest. The data model consists of eight entities, including properties and relations, which are shown in Figure 1. The model is described in following.

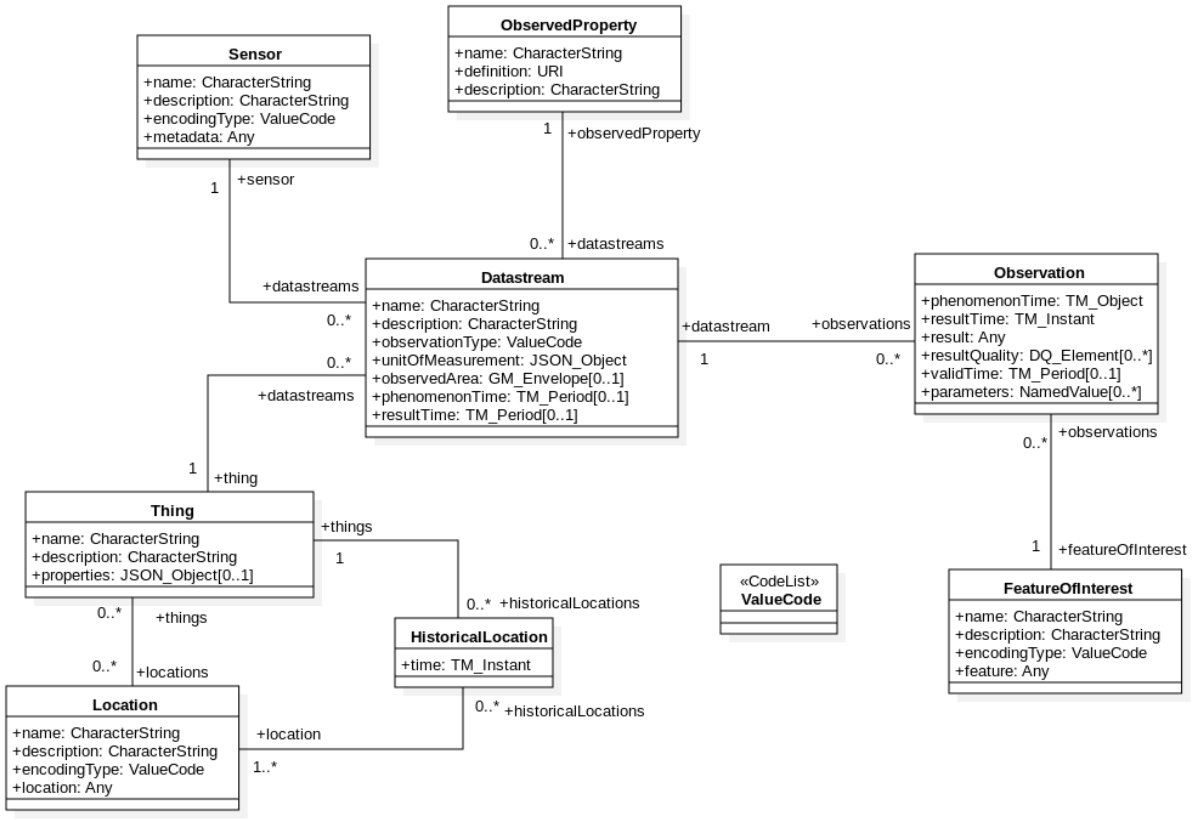

Figure 1: SensorThings API data model (Open Geospatial Consortium, 2016)

A *Thing* is a virtual or physical object. Depending on the use-case, the *Thing* can be the object being observed, like a river section, or the sensor platform, such as a satellite. *Location* describes the position of a *Thing*. A position can be described through geographic locations, encoded as points or areas. Symbolic locations, like a postal address, are possible, too. The *HistoricalLocation* is the link between a *Thing* and a *Location*, with the time indicating when the *Thing* was in a certain *Location*. A moving *Sensor* has several *HistoricalLocations*. A motionless *Thing* has none. This is defined through the SensorThings API, where the *HistoricalLocation* is created, when the *Thing* moves for the first time. A *Sensor* generates the data, which is described through the OGC SensorThings API Data Model. A *Sensor* can collect multiple *Datastreams*. A weather station for example can collect both temperature and humidity; in this example, the *Sensor* weather station would have two entities *Datastream*, one for each temperature and humidity. *Observation* contains the measurement made by a *Sensor*. An *ObservedProperty* is a characteristic of the *FeatureOfInterest* that is observed by a *Sensor*. For example, the water level in a river, or its temperature. A *Datastream* unites *Observations* of an *ObservedProperty*, which were made by a *Sensor* and are linked to a *Thing*. The *FeatureOfInterest* can be the geographic area or location for which an *Observation* was made. This can be the same as the *Location* of the *Thing*, which is often the case for in-situ sensing. In the case of remote sensing, the *FeatureOfInterest* can be different from the location of the *Thing*, dependent on what is chosen as *Thing*. The *FeatureOfInterest* is a geographical point or a polygon encompassing an area or volume, usually encoded in the format GeoJSON.

The relations between all these entities are described through the data model; this ensures finding all data entities that belong to another and only make sense in their own context.

REST

The OGC SensorThings API offers a RESTful interface for accessing the stored data. The REST programming paradigm is a well-known approach for realizing distributed systems. It is based on top of the Hypertext Transfer Protocol (HTTP), which forms the basis of the World Wide Web. REST is used for inter-machine communication and is widespread around web services. Alternatives are for example SOAP or Remote Procedure Calls.

The idea of REST was developed by Roy Thomas Fielding, published in his dissertation in (Fielding, 2000).

Fielding presents principles, which every REST-service must follow without suggesting how to implement them. The principles are described in the following. The first principle is the Client-Server Architecture, known from the World-Wide-Web. A server offers a service, which can be requested by a client. Through the usage of the widespread HTTP-protocol, a REST client implementation is available for nearly every programming language. The second characteristic of a RESTful service is its statelessness: every message sent to a REST service must contain all information needed to process this request. This brings two benefits: firstly, the service can be scaled according to the required usage. Secondly, it decreases complexity, since all information is summarized and no application state needs to be shared between two requests.

Other than its alternatives, REST demands unified interfaces. This contains for example the addressing scheme. Every entity in REST has to be uniquely identifiable, which usually is implemented through Uniform Resource Locators (URLs). The representation of entities is often achieved through JSON. Requests to the server are transmitted via HTTP. Thus, the HTTP-methods GET, POST, PUT, PATCH and DELETE are used to interact with the server. Hereby, GET is used to request information. To create a new instance of an entity the POST operation is used. By sending PUT (overriding a whole entity) or PATCH (overriding only provided attributes) messages, existing entities can be modified. DELETE is finally used to remove entities. For the SensorThings API, this means when entering the main URL of a SensorThings API server in a web browser, a GET request is issued to the server. The response of the server will contain a JSON file as shown in Figure 2.

```
value:
  0:
    name:   "Datastreams"
    url:    "https://beaware.server.de/SensorThingsService/v1.0/Datastreams"
  1:
    name:   "MultiDatastreams"
    url:    "https://beaware.server.de/SensorThingsService/v1.0/MultiDatastreams"
  2:
    name:   "FeaturesOfInterest"
    url:    "https://beaware.server.de/SensorThingsService/v1.0/FeaturesOfInterest"
  3:
    name:   "HistoricalLocations"
    url:    "https://beaware.server.de/SensorThingsService/v1.0/HistoricalLocations"
  4:
    name:   "Locations"
    url:    "https://beaware.server.de/SensorThingsService/v1.0/Locations"
  5:

    url:    "https://beaware.server.de/SensorThingsService/v1.0/ObservedProperties"
  7:
    name:   "Sensors"
    url:    "https://beaware.server.de/SensorThingsService/v1.0/Sensors"
  8:
    name:   "Things"
    url:    "https://beaware.server.de/SensorThingsService/v1.0/Things"
```

Figure 2: FROST start page

As shown in Figure 2, the response contains all data model entities, as well as their URLs. Through these URLs, each individual on the server is addressable (e.g. */Sensors(10)*). Analogous to fetching data, an instance can be created, modified or deleted by sending a POST, PUT, PATCH or DELETE command to the appropriate URL. Since the database can contain a large amount of data, only a subset of all available data is returned for a GET command. This prevents both the server, as well as the client from an overload. Further data is sent upon request.

ODATA

The previous section showed how data can be retrieved and modified by using the REST interface. For many applications, it is not sufficient to retrieve all available data. Conditional upon the large variety of stored data, powerful and expressive filter mechanisms are required to receive the data of interest. In the SensorThings API, these are realized by applying the Open Data Protocol (OData), which is standardized by the Organization for the Advancement of Structured Information Standards (OASIS). It allows projections and filters similar to the Structured Query Language (SQL), which are specified as query strings in the URL. Projections can be done by naming the queried attributes in the *$select* parameter. For example, */Things?$select=@iot.id,description* will only select the id and the description of *Things*.

By passing the *$filter* parameter, it is possible to query for specific results. For example, */Observations?$filter=result gt 5* will return all observations that have a result value greater than 5. A wide range of filtering operators are supported; an exemplary list of supported functions is shown in Table 1.

Table 1. Exemplary list of functions that can be used with OData in the URL of requests

Comparison	Mathematical	Logical	String Functions	Geospatial	Date and Time
gt (greater than)	add (addition)	and	substringof(p0,p1)	geo.intersects(g1,g2)	now()
ge (greater equal)	sub (subtraction)	or	indexof(p0,p1)	geo.distance(g1,g2)	mindatetime()
eq (equal)	mul (multiplication)	not	trim(p0)	st_equals(g1,g2)	maxdatetime()
le (less equal)	div (division)		concat(p0,p1)	st_within(g1,g2)	date(t1)
lt (less than)	mod (modulo)			st_overlaps(g1,g2)	time(t1)
ne (not equal)					

MQTT

Message Queuing Telemetry Transport (MQTT) is an open-source protocol standardized by OASIS (Hunkeler, Truong, & Stanford-Clark, 2008). It follows the publisher-subscriber pattern. Thus, it is predestinated for collecting the data of IoT-sensors. By using this pattern, subscribers can register to a topic, which broadcasts information they are interested in. The information is initially provided by a publisher that sends a message to the corresponding topic, as soon as it gets available. A message broker (included in a SensorThings API compliant server) takes care of the subscriptions and forwards the messages to all the subscribers registered to the topic. A topic is a string that can have several hierarchical levels, separated by a slash. Through this, a client receives only the information published within these topics. The naming of the topics is analogue to the URLs of the entities in the SensorThings API implementation (e.g. */Datastreams*; see Figure 2 for others).

An implementation of the SensorThings API offers, next to the RESTful HTTP interface, an additional MQTT interface. The publisher-subscriber pattern is realized twice. On the one side, a SensorThings Server subscribes to the topics, which represent the entities. Sensors can use this interface to publish new observations, which are created on the server. On the other side, a sensor or - more often - a subsequent processing component may subscribe to changes of instances: this allows the implementation of features that need to directly react on changes (for example, by subscribing to the measurements of a water level sensor, a procedure can be triggered as soon as a threshold is reached).

Figure 3 shows a simplified schematic example: The thermocouple on the top right side posts its observations of 6.03°C to topic *v1.0/Datastreams(5)/Observations.* The actuator on the lower right side subscribes to the same topic and uses it as input for further processing: in this case, the gears would turn by 22.4° and could, for example, open or close a window. Clients can subscribe to topics (like the previously shown example) or to specific instances matching a filter (see previous chapter).

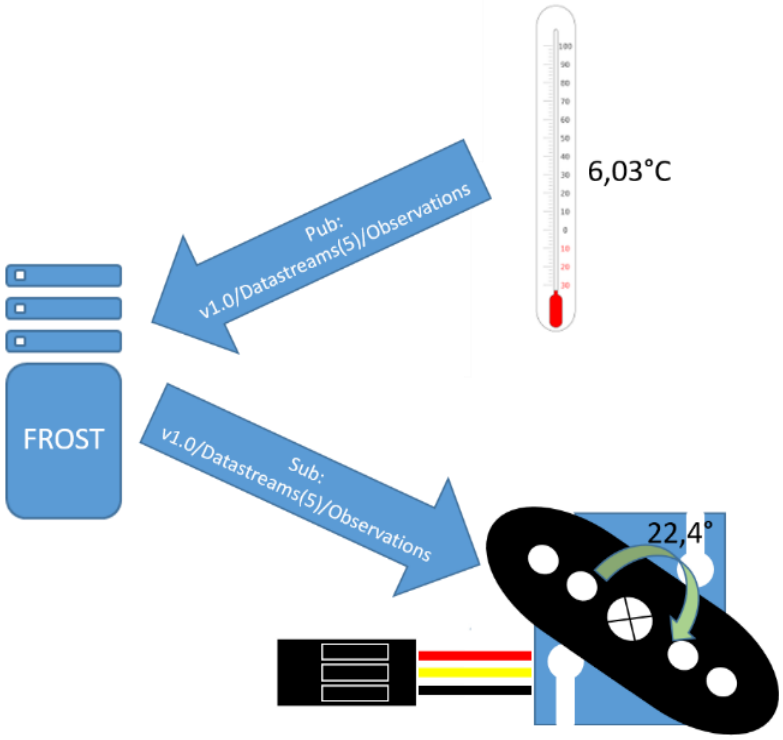

Figure 3: Using the MQTT Broker of FROST to interconnect multiple components

FROST

FROST is an open-source implementation of the SensorThings API standard, developed by Fraunhofer IOSB. The application was designed according to the SensorThings API standard and implements the named data model, REST-interface and MQTT extension and the specified ODATA querying mechanism. Therefore, the application is certified OGC compliant (Open Geospatial Consortium, 2016). The source code is publicly available on *https://github.com/FraunhoferIOSB/FROST-Server* under GNU Lesser General Public License v3.0. It is written in the Java programming language. Internally, FROST uses a PostgreSQL database for data storage, with the PostGIS extension to support geospatial queries. PostgreSQL is an object-relational database and PostGIS extends the database for spatial information. (For further information about both, please visit: *https://www.postgresql.org/* and *https://postgis.net/*).

To start an instance of FROST, different deployment possibilities exist. For example, the server is available as a pre-build WAR-file, which can be run on a web-server like Apache Tomcat or Wildfly. Both are freely available open source HTTP servers. The webpages *http://tomcat.apache.org/* and *http://wildfly.org/* will give the interested reader access to deeper information. Furthermore, FROST is available as a Docker image. This allows an easy start of an instance without the need of further dependencies, for testing and production-ready usage within a virtual environment. On *https://www.docker.com/* the software Docker is introduced. To scale out the deployment, a Helm (https://helm.sh/) chart for Kubernetes is available. Kubernetes (*https://kubernetes.io/*) is an open-source container orchestration platform, initially developed by Google, which offers the possibility to run the application in bigger cloud environments.

ARCHITECTURE

In this section, we will shortly describe the architecture of FROST. Especially when scaling the server in a cloud environment it is important to understand the four different FROST components. The different modules and their interaction are visualized in Figure 4.

The first component is the HTTP-frontend; it handles all incoming requests from the REST interface. In Figure 4 an example is shown, where this component is scaled to the number of two. Changes are directly written into the Database (second component) to have them persistent. Additionally a message is sent through an internal Message Bus (third component) to inform the MQTT components about the changed content. This fourth component evaluates if there are MQTT-subscriptions to which this information needs to be forwarded and does so if needed. In the example in Figure 4, this component is scaled to the amount of two.

There are two possibilities how the different components are bundled together. Using the WAR artifact or the "All-in-One"-Docker image, all components, except for the PostgreSQL-database are running inside a single instance of a Java Virtual Machine (JVM) as monolithic application. With an increasing number of requests, there might be the need to scale FROST. Since this horizontal scaling is not possible within a single JVM instance, there is the possibility to run all components separately. Even if there is only one instance of the database and the message bus needed, the MQTT and HTTP components can be scaled independently. Since all state is handled inside the database, those two components are stateless.

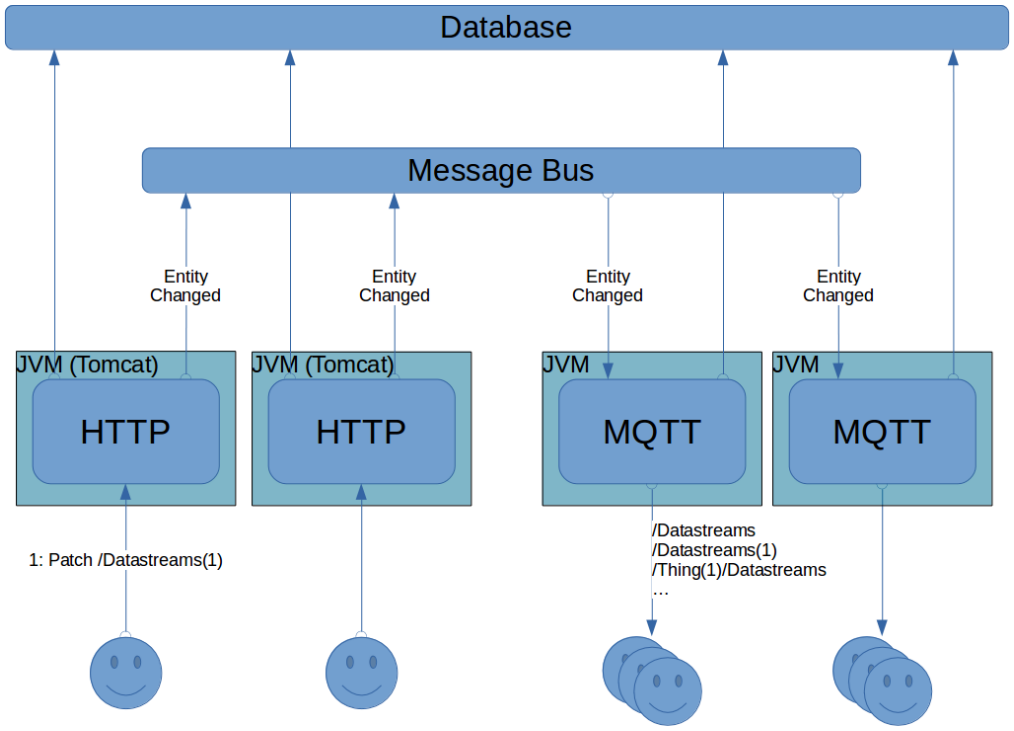

Figure 4: The FROST architecture

COMPATIBLE SOFTWARE TOOLS

Although the SensorThings API is comparatively new, the number of software tools around it is growing. In the following, we present a short list of freely available open-source software, which is compatible with FROST.

CHILLImport

The software is meant for application cases, where collected data is stored in a rudimentary file format and cannot be uploaded by an automated task. This for example is the case, for every sensor placed in a region without internet connection.

CHILLImport is a web-application whose main task is to offer a graphical interface to import data, whereas the software is flexible regarding the input file format and structure. The software converts the measured data into the SensorThings API data model and subsequently imports it into a FROST instance. To adapt different file formats and structures, the software can store and retrieve the configurations for the input file. The configurations can be reused, in case measured data with the same structure needs to be imported again. Configurations can be created by IT-affine users, whereas it is quite complex for an unexperienced user. During the import, an automatic duplicate check between the data to be imported and data stored within the server is conducted. This prevents redundant data within FROST. If an import fails, due to a corrupt import file, loss of connection or similar, CHILLImport prints out a file, in which the user can find all the data that was not imported.

The software is freely available under MIT license and can be found at GitHub:
https://github.com/Chillimport/ChillImport.

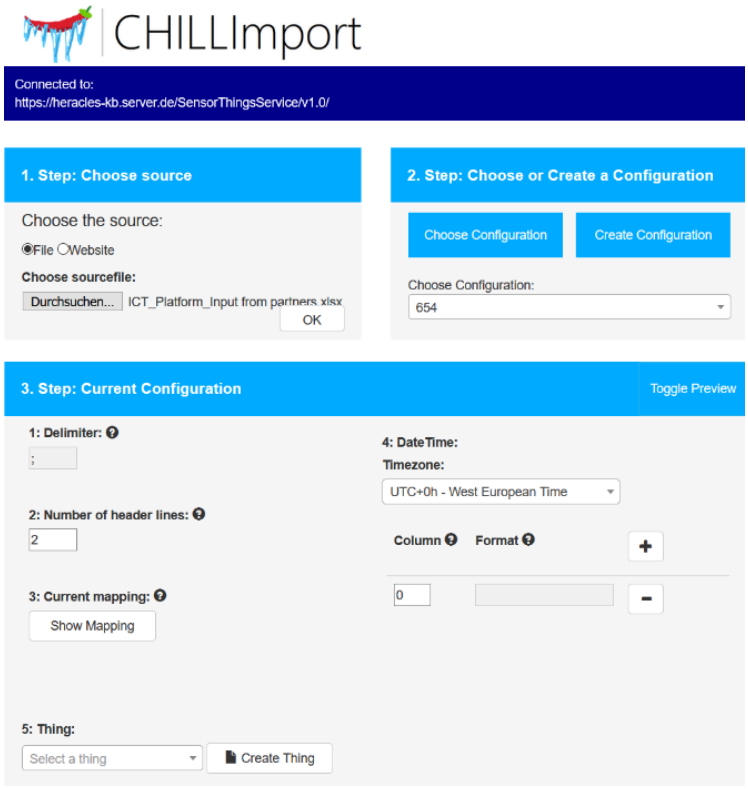

Figure 5: The CHILLImport user interface

FROST-Client

The FROST-Client is a Java library facilitating the interaction with servers and aims to simplify the development of SensorThings enabled client applications. It provides the possibility to connect to a server, which implements the SensorThings API, identified through a URL and create, read, update or delete data. These operations are available through Java classes and methods and therefore allow the easy integration of sensor data into an application.

It is freely provided under MIT license and can be found here: *https://github.com/FraunhoferIOSB/FROST-Client*.

The code snippet in Figure 6 shows a code snippet in the Java programming language, to connect to a FROST instance, posting a new *Thing*, updating it and finally deleting it by using the FROST-Client library.

```
URL serviceEndpoint = new URL("http://example.org/v1.0/");
FROSTService service = new FROSTService(serviceEndpoint);

Thing thing = ThingBuilder.builder()
    .name("Thingything")
    .description("I'm a thing!")
    .build();
service.create(thing);

// get Thing with numeric id 1234
thing = service.things().find(1234l);
// get Thing with String id ab12cd
thing = service.things().find("ab12cd");

thing.setDescription("Things change...");
service.update(thing);

service.delete(thing);
```

Figure 6: The FROST-Client

FROST-Manager

The FROST-Manager expands the FROST-Client through a graphical user interface managing data on any SensorThings Server. After configuring the URL of a FROST instance, it offers simple means for creating, retrieving, updating or deleting entities.

FROST-Dashboard

The FROST-Dashboard is one possibility to visualize data from the FROST-Server. It can display graphs showing sensor data over time or a visualization of alert levels in traffic lights, as shown in Figure 7. Further, it offers bar graphs, gauges or thermometers from which the user can configure the appropriate visualization.

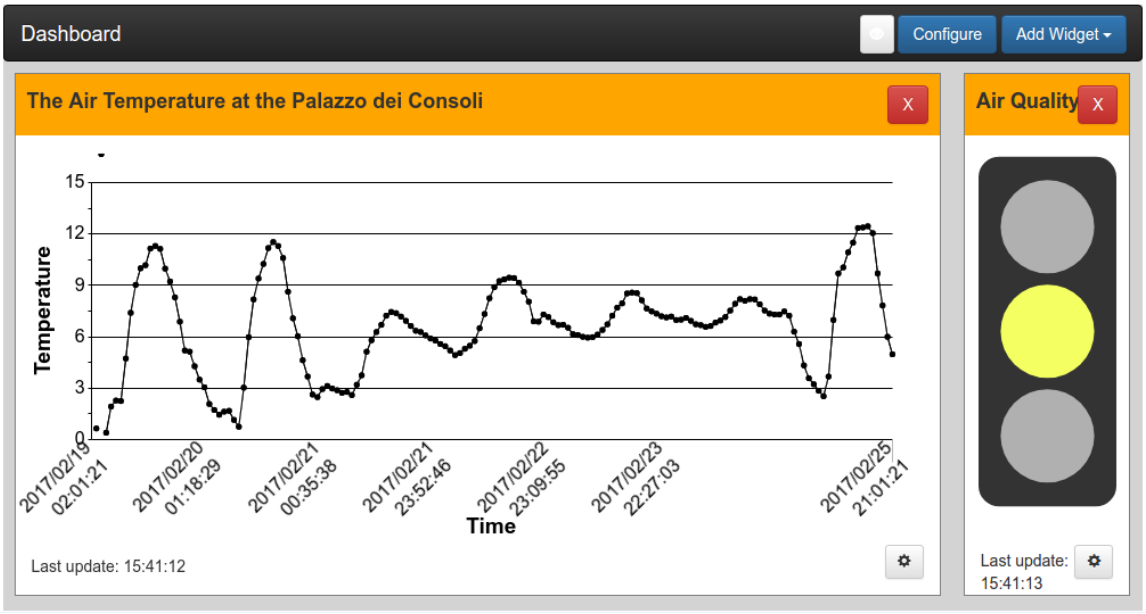

Figure 7: The FROST-Dashboard

Grafana-Dashboard Plugin

Grafana is a well-known application for displaying various kinds of time-series data. Especially for displaying metrics (e.g. of computer hardware or an application) it is very popular. It is also usable for displaying sensor data. A plugin is available to integrate data from a SensorThings API server, which can be found at the Grafana webpage: *https://grafana.com/plugins/linksmart-sensorthings-datasource.*

APPLICATION

This section presents two EU-funded projects, namely beAWARE and HERACLES, in which FROST is integrated as a central component within a bigger Decision Support System (DSS). By presenting both projects, we demonstrate the utilization of the SensorThings API in a practical way and prove the applicability in a hands-on context.

BEAWARE

The main goal of beAWARE is to develop a novel framework for crisis management that manages and supports authorities and end users before and during crises caused by extreme weather events. Up to now, the emergency management landscape consists of many splintered solutions for different problems. This leaves emergency management agencies with the task to integrate the best solutions for them into their system and to make sure that they properly work together. However, this represents a huge effort that many agencies are not able to make. The holistic approach to realize a crisis management framework provided by beAWARE shall help in this regard. The integrated solution of the DSS will include forecasts, early warnings, transmission and routing of the emergency data, aggregated analysis of multimodal input and management of the coordination between the first responders and the authorities.

FROST IN THE CONTEXT OF BEAWARE

Sensor data plays an important role in generating early warnings and gaining situational awareness. This could be for example meteorological data (temperature, humidity and rainfall), or the water level of a river section as well as weather forecasts. Depending on the use case, different sorts of sensors are available and their data can vary strongly regarding their type, frequency and format which makes the integration into a single platform difficult. FROST helps to solve this problem since it provides a unified interface for the sensor data. Further, it takes care of the sensor data management and offers rich querying mechanism, based on, for example, location of the feature of interest, time, type of sensor, and/or observed property.

When applying the SensorThings API model to beAWARE, for example to a water level gauge in a river section, the *Thing* could be the river section of which a *Sensor* measures the water level. The *Thing* would have a *Location*, with a polygon describing the layout of the river section. Since river sections usually do not move much, there would be no *HistoricalLocation*. The *Sensor* entity would describe the exact properties of the water level gauge, like brand, type and accuracy. *ObservedProperty* would be named "water level" and contains an exact reference to a water level definition. For this set of *Thing*, *Sensor* and *ObservedProperty*, there would be a *Datastream* that groups the water level observations of the sensor. Each value measured by the *Sensor* would be stored as an *Observation*. Since the *Sensor* is static, each *Observation* is linked to the same *FeatureOfInterest*, which has the exact coordinates of the *Sensor*. For a temperature sensor located at the same spot as the water level gauge, the same *Thing*, *Location* and *FeatureOfInterest* entities would be applied. Only the new entities *Sensor*, *ObservedProperty* and *Datastream* would have to be added.

In Figure 8, the locations of all sensors around Vicenza, a city in the north east of Italy, that are available in the server are displayed on a map.

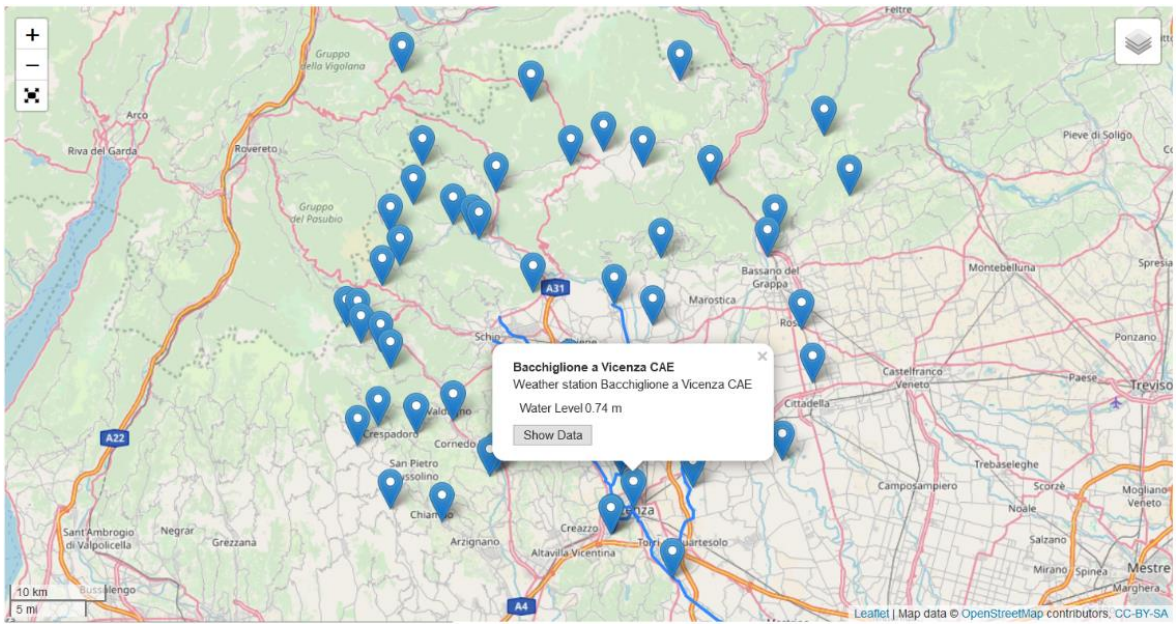

Figure 8: Map with water level and weather station sensors

By clicking on a sensor in the map, the data of the sensor, which is stored in FROST, will be visualized in a graph (see Figure 9). By selecting several sensors or by choosing several *ObservedProperties* more than one graph can be displayed in the diagram, which allows for a direct comparison of the data.

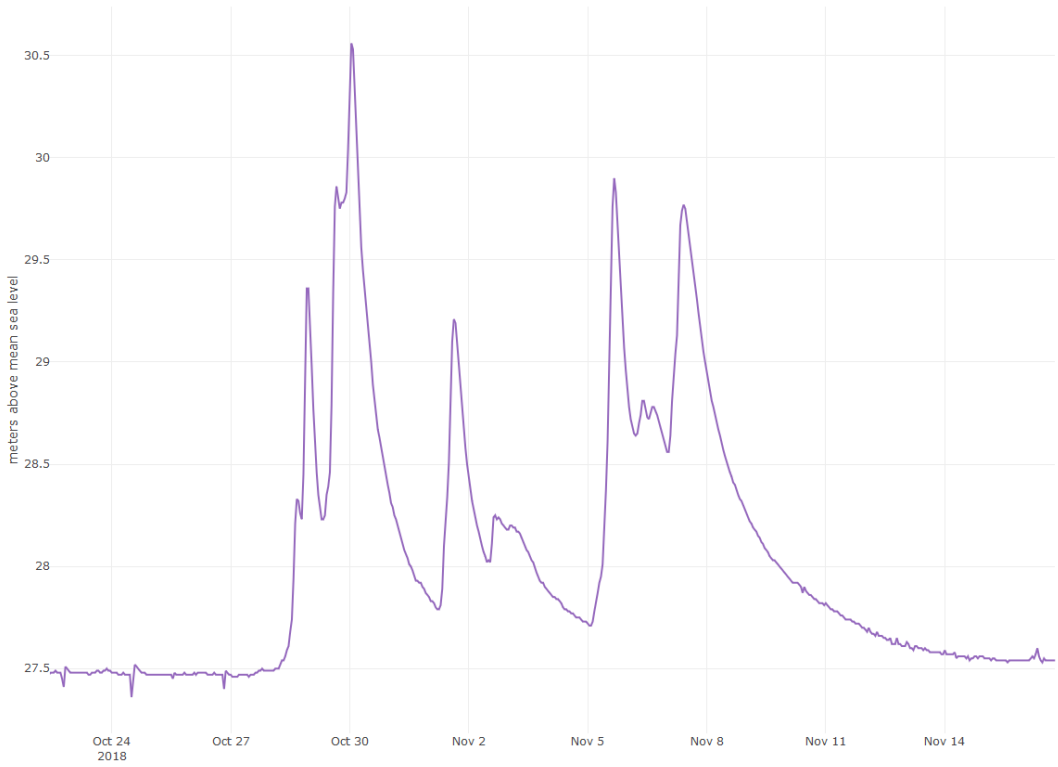

Figure 9: A graphical visualization of water-level values

HERACLES

The main objective of the HERACLES project is to design, validate and promote responsive systems and solutions for effective resilience of Cultural Heritage (CH) against climate change effects, considering as a mandatory premise a holistic, multidisciplinary approach through the involvement of different expertise (industry, scientists, conservators, social experts, decision, and policy makers). This is pursued through the development of a system exploiting an ICT platform able to collect and integrate multisource information in order to provide complete and updated situational awareness and support decision making for innovative measurements improving CH resilience, including new solutions for maintenance and conservation. The HERACLES effectiveness is validated in two test beds, namely Heraklion in Crete with the Knossos palace and the Sea Fortress and Gubbio in Italy with Palazzo dei Consoli and the medieval town walls. These test beds represent key study cases for the climate change impact on European CH assets.

FROST IN THE CONTEXT OF HERACLES

All time-series data collected in the HERACLES Project is stored in a FROST instance. Live data coming from sensors installed by the project-partners in the test-bed locations are automatically imported into the server. As in beAWARE, the sampling frequency of the sensors can differ a lot, for example, one data point per minute from a weather station to several 100 data points per second for an accelerometer. Therefore, automatic aggregations are applied for each sensor, in hourly and daily intervals. A visualization component in the HERACLES user interface will automatically choose the aggregation level that fits best to the time interval the user wants to see.

The following picture shows a crack on a building (Crack *C1*) that is monitored in the context of the HERACLES project. A thermocouple *T1* measures the surrounding temperature, while the linear variable differential transformer *LVDT1* measures the width of a crack (see Figure 10). The exceeding of threshold values or the predicted exceeding of a threshold alerts the cultural heritage manager, who triggers appropriate conservation or mitigation actions.

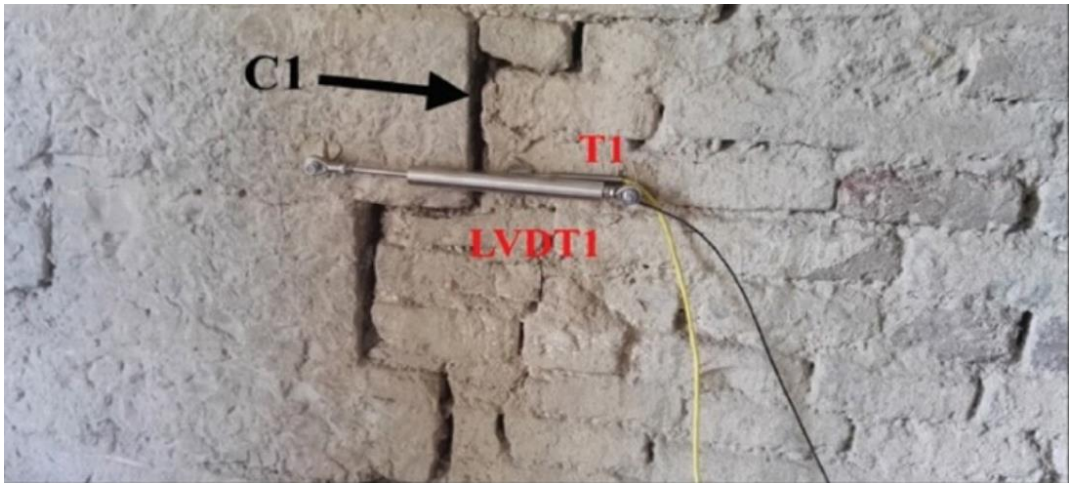

Figure 10: The observation of a crack by measuring temperature and crack width

The changing environmental parameters are collected through the sensors and posted once per day through an HTTP-POST request to the FROST instance deployed within the HERACLES cloud environment. The project partners can access both the raw data stored on the server for further analysis, or access a graphic visualization generated within the HERACLES user interface.

FUTURE DEVELOPMENT

The SensorThings API standard is comparatively new but the number of products implementing the standard is growing quickly. In parallel, the OGC continues developing the SensorThings API standard. Until now, by using the term SensorThings API, we referred to the first part of multiple specifications. We only considered the management of sensors, their metadata and measurements. Still, in the context of IoT more and more devices appear that not only monitor the environment but also manipulate the real world, by executing tasks. The OGC specification "OGC SensorThings API Part II - Tasking Core", released for public comment on February 20, 2018, adds actuation to the SensorThings API (Open Geospatial Consortium, 2018). In terms of the SensorThings API Part II - Tasking Core standard, such a device is called an *Actuator*. This can be any entity that accepts a defined parameter and uses it for further processing. Thus, an *Actuator* is not limited to hardware devices; an actuator can be anything that accepts a task to be executed, including, but not limited to, mathematical models (e.g. calculating min/max or the average of measurements during a time interval). The generic approach is analogue to the presented SensorThings API. The genericity allows the integration of many different devices as *Actuators* and it is possible to describe all necessary parameters to control actuators, and to define tasks that an actuator can execute.

The Tasking Core adds three entities to the SensorThings API: *Actuator*, *TaskingCapability* and *Task*:

- **Actuator:** A hardware or software component that can execute tasks.
- **TaskingCapability:** Describes the parameters that can be supplied to a task.
- **Task:** A task to be executed, with values for the parameters described in the linked *TaskingCapability*.

In the context of Crisis Management, Part II of the SensorThings API promises a lot of potential that needs to be investigated. Since every crisis needs a specific and tailored-to-its-needs response, the used equipment differs from crisis to crisis. In the context of IoT, new tools for first responders emerge such as remote controlled or autonomous robots. Rigos et al., for example, discuss the usage of a remote controlled robot that can crawl into collapsed buildings. The usage of state-of-the-art tools during a crisis is desirable, but imposes challenges: as we already motivated in the introduction, just like sensors, actuators require a standardized data model. This allows making efficient use of many actuators and unfolds synergy effects through their coordinated operation. These synergy effects can be exploited, when a single point for command and control exists, where the management of every controllable piece of equipment is possible. Another use-case is the automated response upon certain events: if a sensor posts an observation to a FROST instance, that exceeds a specific limitation, a standardized operation procedure can be executed upon this. Set the case, a water level sensor observes a value over a certain threshold; the automatic routine could imply the opening of a floodgate within the river area, to reduce the water pressure against its riverbed. The FROST development to support Part II of the specification is already ongoing. A generic data model for actuators could act as base for this single command and control point.

EXERCISES AND INSTRUCTIONS

The live demo will be split in two sections focusing on both technical users and end-users.

Firstly, the installation of a FROST instance will be demonstrated with the help of a Docker image. The link to the required image can be found under *https://github.com/FraunhoferIOSB/FROST-Server*. Secondly, sensors will be inserted into the data model. Thirdly, a short script in the will post data via HTTP to FROST. Instead of using live sensor data, a random generator will provide data values. An example query to retrieve data will be executed.

After that, more sophisticated use-cases from the beAWARE project will be presented, like accessing live data weather data or analysis results. Access to sensors will be provided through maps; with the help of graphs and forecasts, end-users can intuitively assess the situation and give a suggestion, if preparedness actions should be started for a city.

CONCLUSION

In this paper, we have motivated the use of an open standard to manage time-series data in emergencies to enhance situational awareness and to organize an efficient response. We argue that time-series data bears huge potential but also challenges. Though the challenges imminent in IoT-data are complex, they can be overcome by rigorously adopting standards and implementing a uniform interfacing concept. In this context, the standard SensorThings API has proven itself beneficial, since it provides an open, geospatial-enabled and unified way to interconnect sensors, data and applications of the Web. The FROST implementation is a lightweight and open-source implementation of this standard and can be utilized to collect and disseminate time-series data in an emergency. The exploitation of the data improves situational awareness in different settings, including natural disasters. The applicability of FROST has been demonstrated in the projects beAWARE and HERACLES. Furthermore, through the open-source approach of FROST, a vibrant ecosystem has already formed and supplementary software is publicly available.

ACKNOWLEDGMENTS

Funding: The project leading to this application has received funding from the European Union's Horizon 2020 research and innovation programme under Grant No. 700395 and Grant No. 700475.

Conflicts of Interest: The funders had no role in the design of the study; in the collection, analyses, or interpretation of data; in the writing of the manuscript, and in the decision to publish the results.

Robust Private Web Maps with Open Tools and Open Data

Bas Lijnse

b.lijnse@mindef.nl
Radboud University Nijmegen
b.lijnse@cs.ru.nl

ABSTRACT

Crisis management information often has a geospatial dimension that allows it to be visualized on a map. As more and more systems are developed as web-based applications, maps have also become a common sight in such applications. The de-facto solution to add maps to web-based applications is to integrate a third-party service. For web-based crisis management information systems, this approach has two disadvantages. First, the third-party service must be available and reachable. Second, by using third-party services you implicitly share what you are viewing, with the risk of unintentionally exposing sensitive location information. In this *Tool Talks* paper, we show how to create a robust and private alternative for web-based maps using open source tools and open data.

Keywords

Web Maps, Web-Based Systems, Tools, Open Data, OpenStreetMap

INTRODUCTION

Many crisis coordination systems, such as incident response or command and control systems, deal with geospatial information. The stereotype image of a command centre typically features a map projected on a large screen. When designing such crisis management information systems, one of the important design decisions is to choose what tools to use for this geographic visualization.

A general long-time trend in the development of information systems is to move towards web-based systems. Modern web-browsers, protocols and standards are powerful enough to build every conceivable application. Even complex desktop applications such as office suites are now available as web-based versions. With more software development moving to web-development, it is safe to assume that a significant share of future crisis management systems will also be developed as web-based systems.

Integrating maps into web-based information systems is trivial. Search giants such as Google and Microsoft's Bing provide free application programming interfaces (API's) that let you integrate their maps easily. Additionally there are dedicated commercial providers such as Esri or Mapbox that have similar offerings but also offer more options, services and customizations. A well-known open-source alternative is OpenStreetMap (OpenStreetMap Contributors 2018b) that can be integrated just as easily.

Integrating these online third-party API's is a quick and easy solution for integrating a map into a web-based information system. It also has the added benefit of not having to manage your own map data. However, they also have some inherent properties that may be problematic for crisis management applications. The first and obvious property is that they create a dependency on an online third-party provider. Without an internet connection the maps do not work. This is not an issue for public online systems, which are not available in that case anyway. But for crisis management systems, that despite being web-based may run on a local network without a reliable connection to the internet, this can be a serious liability.

Another property that may be less obvious, is that using a third-party map provider is a potential privacy concern. Web-maps are typically not loaded all at once, but incrementally. By retrieving specific parts of a map, you implicitly share with the map-provider which geographic region you are looking at. Depending on the level of

network security, this information could be seen by additional third parties. How sensitive this information is depends on the specific context, but in crisis management applications one cannot simply assume that it is not sensitive at all. For example the OCHA policy paper "Humanitarianism in the Cyberwarfare Age" (Gilman and Baker 2014) states:

> Information about places and objects, such as pre-positioned stocks or medical facilities, is critical to a humanitarian response, and may be very sensitive.

Although this paper considers protection of personal information to be a more important concern, it still acknowledges the potential sensitivity of location information.

An alternative to using third-party map providers in your web applications is to serve your own map content. This approach enables several options to improve robustness. You can provide a map service inside a local area network, making it independent of internet connectivity. Moreovere, for situations where local network infrastrucure cannot be relied upon, it enables the possibility to bundle maps for offline use. When you use your own map service, accidental sharing of sensitive locations with a third-party is also not an issue, because no third-parties are involved.

Creating, and serving your own web maps is not as easy as integrating a Google Maps widget, but is not as difficult as you might expect. With many open sources of geographic information publicly available and a wealth of open-source tools for storing this information and rendering maps, this is a viable alternative to third-party map providers. You need a basic understanding of geographic information, but you do not need to be an expert in geographic information systems (GIS) expert to setup and use these tools.

For this *Tool Talks* paper we consider the situation in which you are only interested in a relatively small geographic area and do not need frequently updated maps. In this case the simplest tool-chain suffices: you prepare the maps once using a batch process, and integrate them in an application using a Javascript library and any basic web server.

The first time we applied this tool-chain was for the Incidone system (Lijnse et al. 2012). This was a prototype incident coordination system based on the operations of the Netherlands Coast Guard. This system was designed to be able to operate in a closed network without reliable internet connectivity. Online map services were therefore not an option.

Since this first prototype the tools that were used to create the such maps have evolved, but the basic process has stayed the same. In this paper we aim to explain the tool-chain and how to use it to create your own private maps. We aim for a high enough level of abstraction that it will stay applicable even as details of the specific tools continue to evolve. Additionally we provide a practical section that helps you set up the tool chain with the latest software versions (at the time of writing), and helps you understand the roles of various components.

We consider the main contributions of this paper to be:

- An explanation of the necessary tools and process to create your own private web-maps from open data.
- A practical guide to get started, with exercises to further understanding of the tool chain
- A convenient script that automates the process for a concrete example

Because this paper is a *Tool Talks* paper, it is organized as a practical guide: We start with an explanation of the necessary preliminary concepts of GIS and web-based maps in "Preliminary Concepts". This is followed by a detailed explanation of th tool chain in "The Tool-chain". We conclude with the practical exercises in "Exercises" and final remarks in "Conclusion".

PRELIMINARY CONCEPTS

To set up and use the tool chain we describe in this paper, you do not need to be a GIS expert. However, you need to have a basic understanding of how maps, and in particular web-based maps, are constructed. In this section we cover those basic concepts.

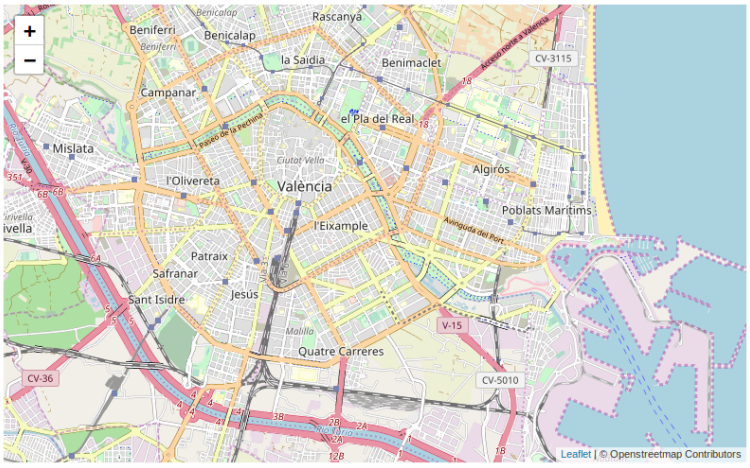

Figure 1. Example of web-based "Slippy map"

Map Basics: Layers, Points, Lines and Polygons

Essentially, a map is nothing more than the projection of *things* that have a location onto a flat two-dimensional surface. The basic data model that underlies any map is therefore fairly simple. The simplest thing you can put on a map is some point in space. Using points you can show the locations of objects. This representation is by definition an approximation, because a point is infinetely small and any object, even small ones take up some space. The next entity we can represent on a map is sequence of points, a line. Lines can be used to represent things like roads or waterways. Another interpretation of a sequence of points is a polygon. In a polygon the points define the outline of something. This can be used to represent areas: For example plots of land, or the outlines of buildings. Points, lines and polygons are the basic types of things you can put on a map. The final concept we need is a way to compose all these features. This is done using the concept of a layer. A layer is simply a collection of lines, points or polygons. A map is then defined as a stack of layers. Because the mapped objects are projected on a two-dimensional plane, a layer adds a third dimension. Layers define the order in which a map is drawn. Typically from bottom to top. This grouping makes it possible to specify that a set of lines that represent roads is drawn on top a set of polygons that define the underlying land areas. In interactive GIS applications the concept of layers also makes it easy to interactively show or hide collections of related features.

Storing Geographic Information

Because the data model is very simple you need little to store a geographic dataset. A small collection of points could easily be stored in a basic spreadsheet with three or four columns. One to hold a (unique) identifier and at least two more to represent the coordinates of the points. Depending on the type of data the coordinates can have two or three dimensions. The elevation of points is not always considered. Sometimes elevation has no meaning for that type of data, but for certain computations, such as determining an accurate distance between two points, the third dimension is necessary. One thing to note here is that there is more than one way to represent coordinates. There are different coordinate systems and to interpret a location correctly you need to know the coordinate system that was used. Luckily these coordinate reference systems are well standardized and documented, but you need to be careful to interpret the coordinates in the correct reference system.

A simple spreadsheet is enough to store small datasets, but for larger datasets dedicated file formats and relational databases with geographic extensions are commonly used. Such extensions add additional data types for storing coordinates in a normal relational database table and add support for querying based on geographic properties. In this paper we use two file formats and a relational database.

Because of the simple unified data model of layers, points, lines and polygons it is straightforward to create maps with multiple layers in which the data of the different layers comes from different data sources, even using different coordinate reference systems. As long as you can select coordinates and map them to a common reference systems you can combine layers in a single map. Many GIS tools allow you to combine information in this way.

Styling and Drawing maps

To draw a map from geographic data we need a program that takes all the geographical features as input and computes where and how they should be drawn on a two-dimensional canvas. To do so, a database with geographic

Figure 2. Zoom level 0: The whole earth on a single tile

features alone is not enough. Whether we use an interactive GIS or a batch program that renders a map to a file, we need to specify additional information. For lines, we have to decide what color, or shade of gray they have to be. We also have to know how thick they should be and what type of lines they should be. Dotted, dashed or solid for example. For points, we need to draw some kind of marker. This can be a simple dot, or a complicated image. Either way you need to specify what points will look like. For polygons, we also need to define how they will be drawn. This could again range from a simple solid fill color, to a complex shading or gradient. A final styling issue that we should mention is the styling of labels. Maps often contain textual labels on the map itself. Labels are used for things like street names, city names or other noteworthy features. A map rendering program needs to know how to draw them. It needs to know what fonts and colors to use, and where to align the labels in relation to the feature.

What is possible in terms of styling depends on the software you use, but to understand the map rendering toolchain it is important to know that map rendering typically needs these two orthogonal types of information. What features to draw on the map, and how to style them.

Slippy Maps

The previous sections have introduced concepts that apply to all types of maps. In this paper we are primarily interested in maps for web-based applications. The way these typically deal with maps is different from desktop GIS applications. Typical online maps you may be familiar with, such as Google maps or the `openstreetmap.org` home page, use a technique for creating maps called a slippy map. In these maps only a few layers of the map are dynamically rendered in the web browser. These layers contain the dynamic parts of the map, such as the locations of your search result, or a visualization of a proposed route. All other layers (landmasses, streets, buildings etc.) are rendered in aggregation by a server and downloaded by the browser as a collection of images. These images are called "tiles" and are typically 256 by 256 pixel images. The map application in the web browser only downloads the necessary tiles for the region of the map the user is looking at, and stitches them together to create a single bitmap layer. This so called "base layer" is an efficient way to offload the computationally expensive rendering to a centralized server. Another advantage of this approach is that the tiles do not need to be rendered every time a browser needs them, but can be cached as pre-rendered images. Tile images and the libraries and applications that use them use a standardized format. This format is based on a three-dimensional coordinate system. The first dimension is the zoom level. On the lowest zoom-level, level 0, the map of the entire earth fits on a single square tile (See figure 2). When zooming in a level, both the width and height of the map are doubled. This means that at zoom-level 1, the whole map fits on a 2x2 grid of 4 tiles. At zoom-level 2, a 4x4 grid of 16 tiles is used and so on. The remaining dimensions (x and y) are needed to indicate the column and row on the grid for the given zoom level. When requesting tiles from a server a standard pattern is used for URL's. Tile images are requested as URL's that end with `<zoom>/<x>/<y>.png`. For example the URL `http://tiles.example.com/4/3/2.png` refers to the tile at the second row in the third column at zoom level four. This standard pattern makes it possible to use standard web servers to serve the tiles as long as the images are organized in the right directory structure. When using the tiles, the Javascript slippy map libraries compute which tiles are needed to stitch together the piece of the map they want to display.

It is important to note that in this scheme, the number of tiles quadruples at every zoom level. This exponential growth means that at detailed zoom levels, the amount of images for the entire planet becomes unfeasible large to render in advance. For tile servers that provide such large numbers of tiles, such as the main OpenStreetMap tile

servers, specific web server software is used that renders tiles on demand, but caches tiles that have been requested before. When the area you want to cover is not that large, pre-rendering a collection of tiles is possible and is a simpler strategy.

A statically rendered base map usually serves as the lowest layer of a dynamic map. In an application that uses this map you typically can add dynamic layers that contain the the objects that are relevant to the application domain on top of it. All of the common slippy map libraries allow you to this.

THE TOOL-CHAIN

The goal of the tool-chain we explain in this paper is to create a pre-rendered tile-layer that can be used locally. We approach this by illustrating how to replicate a relevant subset of the collection of tiles that make up the OpenStreetMap "Standard Tile Layer" (OpenStreetMap Contributors 2018c). We largely use the same tools as are used by the main tile servers of `openstreetmap.org`. These official tiles are created using definitions from the openstreetmap-carto project (Allan et al. 2018). Because this is our starting point, we often refer to tools or resources found in the public repository of this project troughout this section.

In the remainder of this section, we explain the tasks that need to be completed to accomplish our goal without going into specifics. We do not show the exact details of the programs and scripts that need to be executed. These details can be found in "Appendix: Script",

Preparing Basic Infrastructure

To create the tile collection we do not use a single integrated tool. The tool-chain consists of different programs and scripts that tie them together. Most of those tools work on multiple operating systems and do not necessarily need to be deployed together on a single machine. For sake of simplicity we assume a single machine configuration running the Ubuntu Linux 18.04 operating system. On this Linux distribution most of the software we use is available in its standard package repositories. It is also the operating system on which we have tested and used the tool-chain.

Aquiring Geographic Data

The first thing we need is the geographic data that will be put on the map. There are various providers of open geographic data that publish free datasets. Because we are recreating the OpenStreetMap tiles, the primary data set we use is the OpenStreetMap database. The full database is available from `planet.openstreetmap.org`, but is fairly large (43GB at the time of writing). Depending on your application, you may not need data for the entire planet. In that case you can download an extract from a provider such as GeoFabrik (Geofabrik GmbH 2018) that offers many regional extracts.

To exactly recreate the standard OpenStreetMap tiles, just the OpenStreetMap data is not enough. We need several additional data sets from Natural Earth (*Natural Earth* 2018). These provide relatively static features such as as country borders and land masses. We also need a set of preprocessed data that is derived from the main OpenStreetMap data. These contain, for example, coast-line polygons that are simplified to create smoother maps at lower zoom levels. The openstreetmap-carto repository contains a script that automates downloading and indexing these additional data sets.

Aquiring Additional Style Resources

As explained in section "Preliminary Concepts", we also need styling definitions, marker images and fonts to be able to render the map. With the exception of the fonts, these are all included in the opentreetmap-carto repository. The fonts used in the style definitions should be installed on the operating system such that the map rendering tools can find them.

Storing and Preparing the Geographic Data

The tool that actually renders the map cannot work with the distributed form of the OpenStreetMap database directly. The planet dataset (or an extract) is published in a compressed format that is optimized for distribution. It is not structured to allow efficient querying of the data which is needed to create the map. To use the data it needs to be stored in a form that can be easily queried. The standard solution for doing this with openstreetmap data is to use the PostgreSQL database management system (The PostgreSQL Global Development Group 2018) with the PostGIS (PostGIS Contributors 2018) extension. Using a tool called "osm2pgsql" you can import an

openstreetmap dataset into a PostgreSQL database. When used on an empty database it will create a standardized database schema to import the data to. To create the standard tiles the osm2pgsql import tool is run with a customized script from openstreetmap-carto that filters and and transforms the data during import. Data from the data set that is not shown on the map is not even imported into the database. This is efficient, but also means that it limits your ability to customize the map later on.

The additional datasets are in "shape file" format and do not need additional processing. They can be used by the map rendering software directly.

Preparing the Map Style Configuration

The last piece of preparation that needs to be done is to create the configuration that will drive the map rendering process. Which layers will be drawn on the map, what data is needed for those layers and how the layer will look needs to be defined. The rendering tool, that is explained in the next section, relies on a single XML document as its configuration. For tiles as complex as the openstreetmap standard tiles, writing such a single document directly is not very user friendly. CartoCSS (MacWright et al. 2018) is a style language very similar to Cascading Style Sheets (CSS), the standard for styling web pages. The openstreetmap-carto project uses the CartoCSS language to define the style of the tiles in a modular collection of style files. A special compiler named "carto" is used to translate these CartoCSS styles into the XML document needed for rendering.

Rendering the map

Rendering the map, the creation of the collection of tile images, is done using a tool called "Mapnik" (Pavlenko 2018). Unlike the other tools in the chain, Mapnik is not a standalone program. Mapnik is a software library that you can use in your own programs. It provides interfaces for different programming languages, but we only need the interface for the Python programming language. More specifically, we customize a Python script from the OpenStreetMap project (OpenStreetMap Contributors 2018a) that uses Mapnik to render a collection of tiles. This script is exactly what we need to achieve our main goal. By default the script creates tiles for a number of hardcoded example regions. To use the script, the only additional step is to replace these regions by the regions that we want to create maps for.

Testing the Map

The last stage of the tool-chain is using the tiles in a web application. This requires two components. The first is a slippy map Javascript library that ties the dynamic data from your web application to a static tile-based layer. To test the maps we use Leaflet (Agafonkin 2018). This slippy map library is also used on the main `openstreetmap.org` website. Embedding a Leaflet map in a webpage is straightforward and the Leaflet website offers examples on how to create a map and add tile-based layers. The second component needed to test the map is a basic webserver to serve the tiles, the leaflet library and a web page that glues them together. Because the collection of tiles is just a directory structure of image files, it can be served by any web server software.

Using the Map

In the original Incidone use case, and in other applications where we used these tools, we used the iTask Framework. (iTasks Contributors 2018) This framework comes with a built-in web server that can serve the pre-rendered tiles. It also provides tight integration with the Leaflet library that enables the manipulation of the maps through an abstract datastructure without the need to program the low-level Javascript details. Similar integrations are available for other programming languages and web-application frameworks.

EXERCISES

The intend of this paper is to help you understand the tool-chain, and to enable you to customize it to the needs of your applications. In this section we provide some exercises to challenge you to explore and learn how to use the tools.

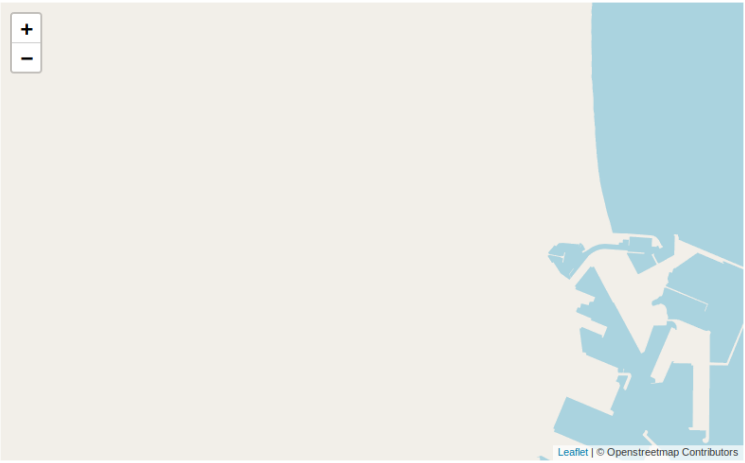

Figure 3. A mimimal rendering without the openstreetmap data

Set up the tools

The first exercise is to actually get the toolchain set up, to generate some tiles, and to view them in a simple web page. To help you get started we have created a basic shell script that executes all the necessary steps to set up the tools, to download the required data, and to render a first map. It is included as an appendix to this paper in "Appendix: Script".

With this script you should do the following:

- Prepare a machine running Ubuntu Linux 18.04,
- Download the script,
- Run the script, or to learn what's involved, execute all the steps in the script manually.

When succesful, you now have a basic set up for creating tile collections that you can change to your liking.

Simplify the Map

The standard OSM tiles contain many layers. Their definition may be overwhelming at first. In this exercise the goal is to reduce the map to the bare minimum and remove all the layers that use the OSM PostgreSQL database. To do this:

- Find the file that defines the layers of the openstreetmap-carto style,
- Figure out which layers are created from the shapefiles and which are created from the PostgreSQL database;
- Create a copy of the file with all the database-based layers removed;
- Create a Mapnik stylefile from this copy;
- Re-generate the tile collection with this alternative style.

When you test your map, you should now only see a basic map without any streets, buildings etc. as shown in figure 3.

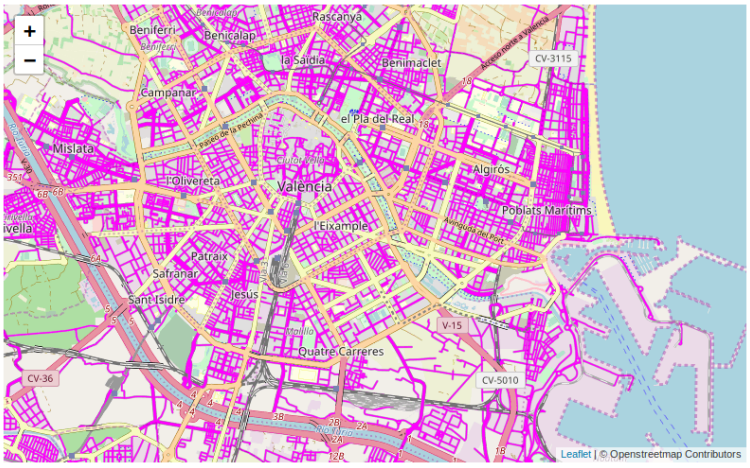

Figure 4. A brightly colored alternative map styling

Change the Map Style

The OpenStreetMap standard layer is a well designed map, but your own local maps can look any way you want. By using the openstreetmap-carto style as a starting point you can tune it to your liking. In this exercise the goal is to change the way a common feature is rendered.

- Find out where the color of city streets is defined;
- Change the color to something bright and recognizable;
- Re-create the Mapnik stylefile;
- Re-generate the tile collection with this alternative style.

Your map should now be rendered with your new favorite color, similar to figure 4.

Change the Map Data

When you have followed the script, your database will now contain (part of) an up-to-date OpenStreetMap data set. Having a local copy of this data allows you to modify it before you render your maps. In this exercise the goal is to explore the PostgreSQL database and modify or remove some of the data.

- When viewing your map, choose a point of interest. For example a streetname or building;
- Figure out how this feature is represented in the PostgreSQL database;
- Update or remove those records from the database;
- Re-generate the tile collection.

For example, in figure 5 you see a map of the city of Valencia that has been aptly renamed for the occasion.

RELATED WORK

The amount of open source tools for working with geographic information is very large. The tool chain presented in this paper is just one of many possible options for adding private maps to web applications. A large part of the specific setup of this toolchain is based on the installation instructions of openstreetmap-carto, because we chose to take the current version of the openstreetmap tiles as our starting point.

In this paper we explicitly focused on creating pre-rendered tile collections because of their simplicity, and because they are easy to deploy as bundled assets with a web application. If you are instead interested in creating a dedicated tile-server with on-demand rendering and caching of tiles, the “Manually building a tile server” guides from switch2osm.org (Fairhurst 2018) are a good starting point.

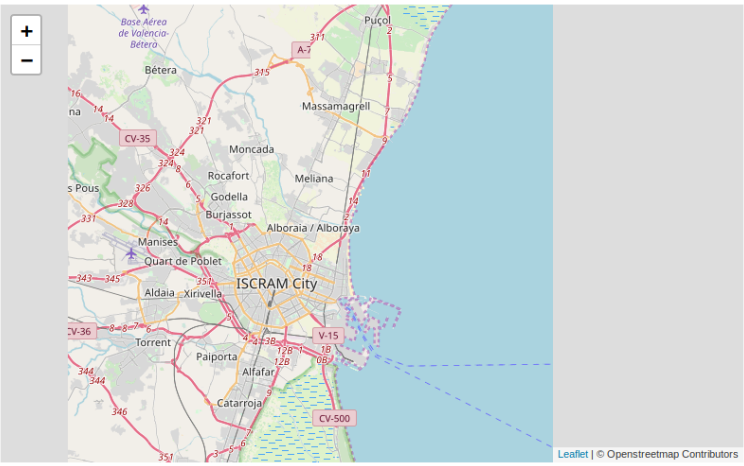

Figure 5. A custom rendering with a renamed city

The tool-chain we presented consists entirely of command line tools and scripts. This makes it very suitable for customization and automation on server machines. As an alternative, you could also use a desktop GIS application like QGIS (QGIS Contributors 2018) to define and style a map and use it to export tiles. Either through embedded scripting or by using a dedicated plugin.

This paper provides a pragmatic starting point for creating your own private maps from open data. We provide just enough background information to understand what the tools do, what their interfaces are, and how they depend on each other. It should be enough if all you need is a robust private replacement for popular third-party API's such as Google Maps. If you want to know more about cartography with open source tools, the website of the Open Source Geospatial Foundation (OSGeo 2018) is a good starting point.

CONCLUSION

In this paper we have shown the process of making your own collection of tile images from open data to use as a base layer in web-based maps. This approach enables the use of maps in web-based systems without relying on third-party online map service providers. This approach can therefore make the use of web-based maps both more private and more robust

The tool-chain to achieve this goal consists of all open source tools that are freely available. To use them together however, you need to have some background knowledge of GIS concepts thats is often implictly assumed. The aim of this paper is to explain the tool-chain, along with the necessary context, independent of specific details of the individual tools. By understanding the process and how the various pieces work together, it becomes possible to adapt to future changes in the specific tools.

Although we expect the tools to evolve, we have included a concrete example based on the tool chain at the time of writing. Additionally we have included several exercises to explore how the chain can be customized. Together with the explanation at the conceptual level, it should enable you to begin using robust private maps created from open data in your own web-based crisis management information systems.

ACKNOWLEDGMENTS

The authors of this paper are not affiliated with the authors of the tools and data sets that are being shown in this paper. We want to express our gratitude to all of these open source contributors for making their tools and data available publicly.

hpurohit@gmu.edu

ABSTRACT

An increasing number of Machine Learning based systems are being designed to filter and visualize the relevant information from social media and web streams for disaster management. Given the dynamic disaster events, the notion of *relevant information* evolves, and thus, the active learning techniques are often considered to keep updating the predictive models for the relevant information filtering. However, the active relevant feedback provided by the human annotators to update the models are not validated. As a result, they can introduce unconscious biases in the learning process of humans and can result in an inaccurate or inefficient predictive system. Therefore, this paper describes the design and implementation of an open-source technology-based learning analytics system '*EMAssistant*' for the emergency volunteers or practitioners - referred as the trainee, to enhance their experiential learning cycle with the cause-effect reasoning on providing relevant feedback to the machine learning model. This continuous integration between the cause (providing feedback) and the effect (observing predictions from the updated model) in a visual form will likely to improve the understanding of the trainees to provide more accurate feedback. We propose to present the system design as well as provide hands-on exercises for the conference session.

Keywords

Training System, Disaster Management, Active Learning, Humanitarian Technology, Social Media Mining

INTRODUCTION

There is a growing number of sources sharing situational updates during a disaster event via social media as well as other web platforms such as news feeds that lead to the phenomenon of *big crisis data* (Castillo, 2016). These situational updates include time-critical reports (Imran et al., 2013) as well as requests and offers to help (Purohit et al., 2013) such as through Facebook's recently launched 'Community Help' feature. Moreover, given the ubiquitous adoption of Internet-based communication by the public, the importance of mining the big crisis data streams in the expectation of extracting the time-critical, relevant situational information to assist emergency management agencies has grown tremendously in the recent years (U.S Homeland Security, 2014; Hughes and Palen, 2012; Hiltz et al., 2014; Meier, 2015). Also, as per recent surveys (Reuter and Spielhofer, 2017; Canadian Red Cross, 2018), there is a growing expectation by the public to seek a response from the emergency services through an online medium, especially social media. However, the characteristics of big crisis data like high volume, velocity, and variety issues can create a challenge of timely extracting situational information from social and web data streams.

Researchers in the crisis informatics and disaster management have investigated many approaches in the last two decades to understand, process, and manage the streaming big crisis data, in order to provide systematic access to the relevant information (*c.f.* survey Imran et al., 2015). The analytical approaches primarily include

mining user-level information (e.g., onsite witnesses (Starbird et al., 2012), trustworthiness (Tapia et al., 2011)), content-level information (e.g., topical categories (Imran et al., 2013), help behavior (Purohit et al., 2014)) as well as network-level (e.g., retweetability prediction (Neppalli et al., 2016)) and context-level (e.g., location (Al-Olimat et al., 2018)) information.

There have been several efforts in the last decade to develop systems that implement the above-discussed analytical approaches for assisting emergency management organizations. Such existing analytics systems incorporate multiple data sources and often with different modalities to study a disaster event in real time as well as retrospective view (e.g., TweetTracker (Kumar et al., 2011), Twitcident (Abel et al., 2012), CrisisTracker (Rogstadius et al., 2013), Truthy (McKelvey and Menczer, 2013), AIDR (Imran et al., 2014), Twitris (Sheth et al., 2017), CitizenHelper-Adaptive (Pandey and Purohit, 2018)).

However, the majority of the existing systems rely on the prebuilt machine learning models using the datasets from the prior events alone to train and set up the analytical system for a current event. It is because there are very few training data instances available at the onset of a new disaster event to build a robust machine learning model. For overcoming that, researchers have used active learning techniques to frequently update the prebuilt model with expert feedback for addressing the performance issue of the misprediction in continuous data streams (e.g., CitizenHelper-Adaptive (Pandey and Purohit, 2018); AIDR (Imran et al. 2014)). However, due to the increasing workload of the expert emergency management professionals during time-critical crisis operation, it is challenging to learn to provide effective feedback for relevant information at the same time. Additionally, given the increasing trends of leveraging help from crowdsourcing, they want to rely on operationally non-expert volunteers to do this task of providing relevance feedback on the data stream to improve the machine learning based information filtering system. Thus, covering all the aspects of training the practitioner trainees as well as volunteers can be costly both in terms of money and time for the emergency services.

Thus, we address two key problems in our proposed system design. First, the input data stream is sometimes hard to comprehend due to the changing definition of relevance (issue of concept drift), which can be mitigated by frequently informing the trainee through the effects of providing feedback to a diverse set of message instances from the ground truth. Second, the trainee/volunteer may possess certain bias in learning the patterns of what constitutes a relevant message as reflected in the feedback provided by him/her, which can be mitigated by showing the trainee/volunteer the performance of the updated (weak) prediction model frequently.

We propose *EMAssistant — Emergency Management Assistant*, an open source technology-based learning analytics system that will assist emergency management trainees to provide accurate feedback in improving a machine learning model for information filtering tasks. The system provides a web-based learning platform for the trainee by constantly re-training the model from the feedback provided by them and then visualizing a few expert-labeled data based on the error comparison of its predicted and original labels. We are also utilizing expert-labeled data along with the trainee's feedback for robust re-training of the model. As soon as the trainee observes that the error effect has been minimized consistently, they will be ready to provide the feedback in a real-time environment and contribute to the data-driven disaster management information filtering tasks. The resulting system is cost effective since it can be adapted to any social media mining problem beyond the information filtering task for the emergency services; for example, in training the student practitioners for data analytics with the state-of-the-art techniques. The rest of the paper is organised as follows. We first discuss related work on the systems designed for disaster management. We then describe the design of our proposed system architecture, followed by the analysis of the proposed tool with an illustration of the system's functionality using a past disaster event dataset. The conclusion summarizes our plan for the demo, exercises during the conference session, as well as the directions for future upgrades for the system.

RELATED WORK ON DISASTER ANALYTICS SYSTEMS

We describe state-of-the-art tools in the crisis informatics and disaster management literature.

Recent advancement in technologies has brought more engagement during emergency and disaster management for the emergency practitioners, the crowdsourcing volunteers, and the affected communities. This has led to the flood of shared information on social and web platforms that can be utilized to do what was earlier not possible in disaster management. However, since most of the incoming data is unstructured, many research works have been done to extract semantically structured information (Garcia-Santa et al, 2015).

I-REACT (I-REACT Project, 2018) is an example of one such platform that uses both mobile and web platforms to offer better anticipation of extreme weather events, floods, and fire with historical knowledge, satellite and risk maps, crowdsourced reports, and social media information. In addition, many crowdsourcing tools are used for extracting the relevant information from unstructured data streams that include a variety of methods, such as natural language understanding, multisource data collection, filtering, tagging, mapping and navigation, volunteer management, and crowdsourcing roles tools. Prior work on web-based, as well as mobile-based platforms, can be classified into 4 categories based on tools functionality: Crisis Mapping, Crisis Navigation, Volunteer Management Tools, and Ontologies (Poblet et al., 2017).

Among the web-based platforms, Twitris (Sheth et al, 2014) and iCoast (Liu et al., 2014) are two examples used for crisis data analytics and crisis mapping. Twitris involves real-time analysis of social sensing and perception for disaster response including earthquakes, hurricanes, tornados, and floods. iCoast gives a platform to volunteers to upload an informative aerial photograph of the affected area in a disaster event for crisis mapping. For crisis navigation, OSMTracker is a mobile-based application that collects track logging and navigational information from users. Similarly, many tools are available for volunteers management like GeoTag-X (Jennett & Cox, 2014), CrowdCrafting (Sánchez de Miguel et al., 2015), Micromappers (Ofli et al., 2016), Tomnod(Lin et al,, 2014), and Verily (Meier et al., 2013). GeoTag-X, for example, uses volunteers to analyse photo taken in disaster-affected areas, while Crowdcrafting is used in the analysis of data or challenging tasks with the help of volunteers. Furthermore, Micromappers uses human intelligence to get semantic information from unstructured data and Tomnod asks volunteers to identify important objects in satellite images during the crisis. In addition, Verily helps to mitigate false information spread during a disaster with the help of crowdsourcing volunteers. There are also mobile-based crowdsourcing tool like UN Assign (Bæhr, 2016), FemaApp, and FirstToSee that are used for crisis mapping by allowing the user to upload geotagged pictures in the disaster-affected area. Finally, AIDR (Imran et al., 2014) - Artificial Intelligence for Disaster Response provides a platform to create ontologies. It is then used to perform automatic classification of messages that people post during disasters into given ontologies for large-scale data at high speed.

We can observe that a lot of the existing systems depend on volunteer's contributions. Yet, there are no prior systems that tackle another core functionality of crisis management platform i.e. learning analytics system to these volunteers. Most of the system assumes that the volunteers either have significant knowledge or are trained before for better interacting with the system. However, it is not always the case and training volunteers on a large scale can be very expensive. That's why our proposed method will not only help train volunteers in scale but also in a cost-effective way. The little involvement of the humans in the proposed system makes it scalable. Figure 1 shows the architecture of our system and Figure 2 shows an illustration of our main system of providing the feedback and observing the effects respectively.

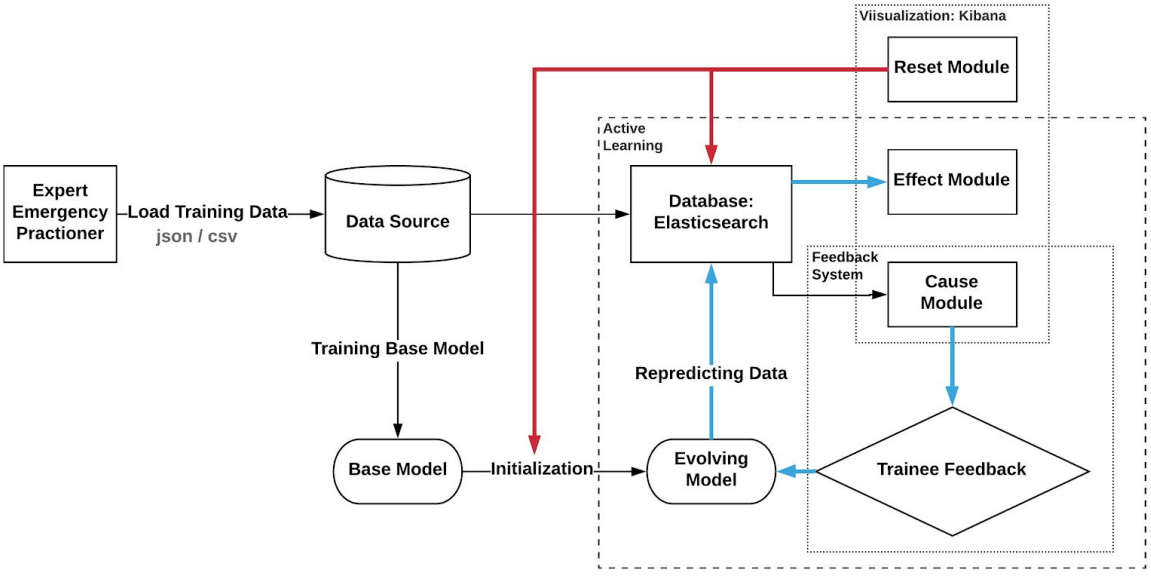

Figure 1. System architecture of EMAssistant

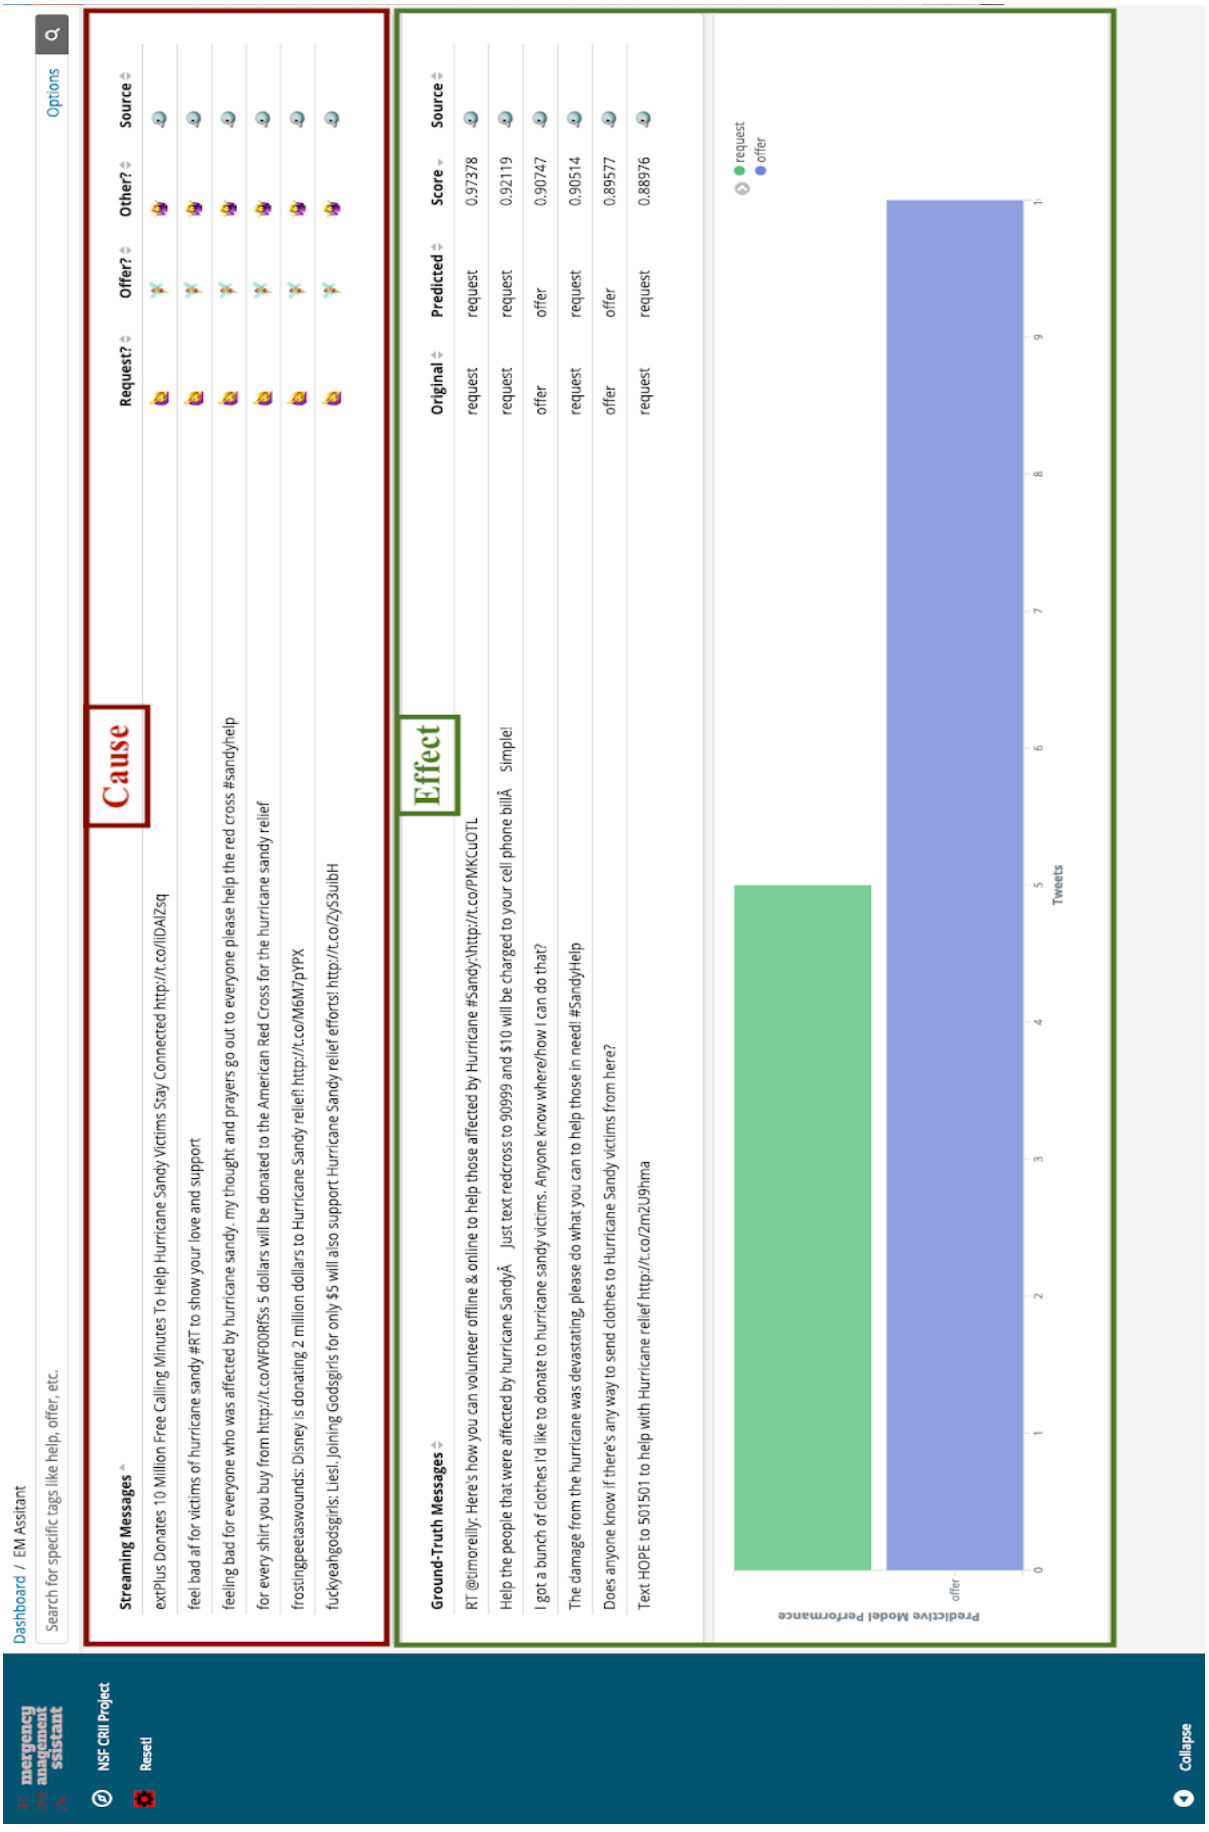

Figure 2. Illustration of analysis using EMAssistant system feedback

EMERGENCY MANAGEMENT ASSISTANT SYSTEM (*EMAssistant*)

This section describes the architectural pipeline for various features of the proposed *Emergency Management Assistance System* which provides a training mechanism to emergency practitioners using active machine learning capabilities. The system architecture of EMAssitant is shown in Figure 1. It consists of 4 main modules: *Data Loading, Training Model, Active Learning, and Visualization*. The blue arrow indicates the feedback-based model re-training cycle and the red arrow shows the effects of the reset functionality on the database and base model initialization.

A. Data Loading

We used the expert labeled data collected from Emergency Practitioners (EM). These labels in the data act as ground truth for training the model. The data is then loaded in the ElasticSearch Database. While loading the data, few of the data points were marked to observe and visualize the effects in the *Ground Truth Visualization* and *Predictive Model Performance Visualization* components of Kibana.

Both Elasticsearch and Kibana are open source projects where Elasticsearch is a searching and analytics engine that provides distributed, RESTful, JSON based search engine that makes it highly scalable and flexible for a large amount of data. On the other hand, Kibana lets us visualize data in the form of various dashboards which includes graphs and table. We have integrated stacked bar chart under *Predictive Model Performance Visualization* which assists the trainee to efficiently visualize the per class effects based on the feedback provided. Kibana and Elasticsearch work exceptionally well together and provides rapid deployment for a variety of custom visualizations as needed for various EM exercises. Kibana also provides scripted fields that can help to create custom URL links for each message object. We have used this feature to generate URLs to call an API and it acts like a button in the enhanced-table visualization that is used by both *Streaming Message Visualization* and *Ground Truth Visualization*. Trainee uses these buttons to give feedback as a result of which our API is called, which re-trains the model and update the *Ground Truth Visualization*. One more reason to choose Kibana was that the dashboards created under Kibana are automatically refreshed after every 5 seconds, thus provides a real-time visualization of the effects as per the feedback provided by the trainee.

B. Training Model

Based on the expert labels provided by the Emergency Practitioners we build a model to classify high-level content and behavior information, such as intents like request or offering help during crisis management. We first create a base model that is trained on the initial expert labels. We have ignored the messages marked for *Ground Truth Visualization for training*. For the features generation, we have used the traditional *Bag of Words* (BoW) features (Witten et al., 2016) and for training, we have used a linear logistic regression model. Now once the adequate feedback is provided, we create an evolving model from the initial training data with the updated labels (from feedback) using the same parameters of linear logistic regression classifier. This evolving model is then used to predict the intent label of the data points that were marked for *Ground Truth Visualization*.

C. Active Learning

We have designed a feedback-based active learning approach for the trainee to continuously learn based on visualizing the cause and effect due to the feedback provided on the training model. For instance, considering the data in an emergency situation, whether the incoming messages are classified as a request, offer or other intent. For making the model train and evolve actively, the trainee will first provide the feedback in the *Streaming Message Visualization* and then observe the effects under *Ground Truth Visualization*. More specifically, we have used two parameters in our ground truth messages visualization: original and predicted. Based on the feedback provided by the trainee, the system will update the training data with the new labels and retrain the model. We use this evolving model to re-predict the data existing in the *Ground Truth Visualization* table and store the updated labels in *Predicted* column whereas the *Original* column remains the same. In this way, the trainee can see the effects of the updated model through comparison between predicted labels and original ground truth labels under *Ground Truth Visualization* table. Every time based on the volunteer action, the model will be retrained and changes will get reflected in the dashboard, which acts as a continuous learning process until the trainee observes no change in the original and predicted values and that's how bias possessed by the trainee will be removed and the trainee is ready to provide accurate feedback in real time operational environment.

D. Visualization

We have used the Kibana visualization framework for interacting with the analyzed data. Figure 2 represents our system's visualization. Our visualization has been divided into four main sub-components.

1. Streaming Message Visualization
2. Ground Truth Visualization
3. Predictive Model Performance Visualization
4. Reset Functionality

1. *Streaming Message Visualization*: This visualization will provide an interface for the volunteer to provide feedback on the messages and annotate it as a relevant label category. It contains 5 columns. The first column represents the text that shows the message text. Second, third, and fourth columns show a link to provide the feedback of request, offer, or other intent categories respectively. Finally, the fifth column contains the link to the original Twitter source of the message.

2. *Ground Truth Visualization*: This visualization will act as a learning interface for the trainee where one will see the impact of the feedback provided under the *Streaming Message Visualization*. Each message under this visualization will show the original and predicted values where original stores the ground truth and predicted stores the labels predicted by the re-trained model. Apart from these, the score field will store the confidence score calculated by the prediction probability method of the model for each message in which the higher average scores of correct predictions represents better feedback provided. The volunteer will keep on providing feedback until the original and predicted labels become the same and the overall average confidence score increases or reach to its *best* possible value.

3. *Predictive Model Performance Visualization*: This is represented through a stacked bar chart visualization that displays out of each ground truth labels, how many were correctly predicted in the intent label.

4. *Reset Functionality*: Volunteer can go back to the initial stage of learning using the reset button. This will take the model back to its initial stage and reset the intent label back to the ground truth label in the Elasticsearch as a result, the evolving model will be replaced by the base model.

ILLUSTRATION OF LEARNING ANALYTICS USING *EMAssistant*

For the analysis, we have used data collected from Twitter for Hurricane Sandy, which was the most destructive hurricane of 2012 in Atlantic. Our aim is to teach volunteers to provide feedback if the messages can be classified as the intent of requesting help, offering help, or none (Pandey and Purohit, 2018). We have labels validated from emergency experts and crowdsourcing workers or volunteers that will help build the base model to compare the effects. The reason why we have taken these intent labels is due to the fact that they can induce concept drift. For example, tweet like *"I am 9 ft above water levels, why am I told to evacuate now? Please advise"* is of a request for rescue intent category. On the other hand, tweet like *"Wow didn't realize how bad this hurricane was. #SandyHelp donate 10 dollars to help. Text REDCROSS to 90999"* is of a request for donation intent category. We can observe that even both the message should be under the *request* intent category, their semantics are different. These concept drifts can confuse the trainee and make it hard for them to comprehend and classify both the type correctly as "request" intent in the first go. Thus, to overcome this challenge, our learning analytics system helps the trainee to understand this change in concepts by providing a diverse message to get feedback and observe the effects continuously until they learn. As a result, we propose a case study where we visualize the effects of the feedback provided on the machine learning model. For illustration, we will visualize the *Ground Truth Visualization* to observe the comparison between original and predicted intents and the scores by which the intents have been predicted. We have provided 3 snapshots of the *Ground Truth Visualization*, which represents the effect due to "bad", "good", and "best" feedback respectively. The *Ground Truth Visualization* constitutes of 5 fields: *Tweet Messages*: displays the incoming messages, *Original*: displays the ground truth label associated with message, *Predicted*: displays the predicted intent label based on the updated model from feedback, *Score*: displays the confidence score of the predicted intent label, and *Source*: which redirects to Twitter for that specific message. Figure 3 represents the *Ground Truth Visualization* due to *"bad"* feedback. As we can see, apart from the 4 tweet messages of *offer* intent category, every other message has been incorrectly classified to *other* intent category. Even the ones that are classified correctly, have very low confidence score. In Figure 4, which represents the *Ground Truth Visualization* due to "good" feedback, we can see that every message has been correctly classified. The overall confidence score is also much higher as

compared to the *"bad"* feedback. Finally, in Figure 5, which represents the *Ground Truth Visualization* due to the "best" feedback, we can see every message has been correctly classified with high average confidence score compared to the one due to *"good"* feedback (Figure 4). The trainee will continue to be in a situation corresponding to any of the 3 effects until they reach a point when they will finally observe the effects due to *"best"* feedback consistently and thus, will get trained.

CONCLUSION AND EXERCISE PLAN

We have introduced a learning analytics tool *EMAssistant* to assist the trainees based on cause and effect visualizations from the data labeled by the experts during the emergency situation. The system will create a base model that will be actively re-trained from the feedback provided by the trainee. This will make the trainee adaptive to handle any upcoming emergency situation. The gradual learning process will make the trainee unbiased, which further makes them confident to provide feedback in real time environment. We plan to further design and evaluate learning modules guided by the human learning theories from educational psychology.

We will provide a hands-on of the *EMAssistant* tool during the conference session. Also, for the live demo and hands-on exercise session, we will provide the attendees different expert-labeled training datasets for many downstream applications of crisis management, such as topic classification (Olteanu et al., 2015), help intent classification (Purohit et al., 2013), and damage classification (Alam et al., 2018). A user survey will be conducted for the session attendees to provide input to improve the design, functionality, and the user experience of the system.

ACKNOWLEDGEMENT

Authors would like to thank Ganesh Nalluru from Humanitarian, Semantics, & Informatics lab for providing valuable feedback and proofreading. We also acknowledge the U.S. National Science Foundation (NSF) for partially supporting this research on social and web mining for disaster informatics through grant awards IIS-1657379 & IIS-1815459.

ABSTRACT

Evaluation and testing are major steps in the development of any information system, particularly if it is to be used in high-risk contexts such as conflicts. While thus far there are various approaches for testing against technology requirements; usability or usefulness, there is a lack of a comprehensive evaluation framework that combines the three elements. The lack of such a framework and commonly agreed standards constitutes a barrier for innovation, and at the same time imposes risks to responders if the technology is introduced without proper testing. This paper aims to close this gap. Based on a reviewing of evaluation methods and measurement metrics, we design a comprehensive evaluation framework including common code quality testing metrics, usability testing methods, subjective usefulness questionnaires, and performance indicators. We demonstrate our approach by using the example of an integrated system for the safety and security of humanitarian missions, and we highlight how our approach allows measuring the system's quality and usefulness.

KEYWORDS

Evaluation Framework, Software Testing, Software Usability, Software Usefulness, Humanitarian Disaster.

INTRODUCTION

Those who try to provide aid to the most vulnerable populations in the Middle East are increasingly risking their own lives and safety. According to the Aid Worker Security Database (Humanitarian Outcomes 2019), the number of humanitarian workers that fall victim to attacks continues to rise. Organizations in the field are confronted with mounting tensions as they seek to maintain access to populations in need. Thus, there is a new role for technology to support operations. Yet, these innovations and particularly the use of ICT in conflict can cause severe risks, ranging from privacy violations to threatening the lives and safety of those it is designed to protect.

Evaluation and testing is a major step in the development life-cycle of any software system, and it is a vital phase in quality assurance of the system (Jovanović 2006). Software system evaluation frameworks aim at assessing the system quality and sophistication from diverse viewpoints (Boloix and Robillard 1995). Nonetheless, there is no comprehensive evaluation framework that combines technology, functionality and usefulness tests for humanitarian conflict disasters. Such a test requires that the standards and problems of humanitarian innovation and experimentation are met (Sandvik et al. 2017) and the context of the problem is considered. In conflicts, a major challenge is dealing with sensitive information and organizational barriers to information sharing (Van de Walle and Comes 2015) and to evaluate risks as they emerge (Van de Walle and Comes 2014). The lack of such a framework and commonly agreed standards constitutes a major barrier for innovation, and at the same time may impose risks to responders if the technology is introduced without proper testing.

The goal of this paper is to compile a comprehensive evaluation framework for integrated systems in humanitarian conflicts, based on a review of evaluation standards and metrics. The framework should assist in measuring the **quality** and **usefulness** of a system, from the individual components' performance to the overall system. Software system **quality** is defined by the Institute of Electrical and Electronics Engineers IEEE as "the degree to which a system, component, or process meets specified requirements" and "the degree to which a system, component, or process meets customer or user needs or expectations" (IEEE Computer Society 1991). The International Software

Testing Qualifications Board ISTQB defines the quality in general as "the degree to which a component, system or process meets specified requirements and/or user/customer needs and expectations" ("ISTQB Glossary" 2015), whereas it defines the software quality as "the totality of functionality and features of a software product that bear on its ability to satisfy stated or implied needs" ("ISTQB Glossary" 2015). In total, the **quality** of software is about meeting the **specified requirements** as well as **user satisfaction**. The former is achieved via testing the software system components individually or together, or the whole system against the requirements in terms of specifications, use cases, design documents, etc., while the latter is achieved via testing the system **usability** and **user-satisfaction** (Nielsen 1993).

System **usefulness** means that "a product, website or application should solve a problem, fill a need or offer something people find useful" (Sauro 2011). Based on Fred Davis' usefulness construct, system usefulness is about helping users in accomplishing job tasks quicker, improving job performance, productivity, and effectiveness, in addition to making the job easier to do in general. Figure 1 shows the pillars of our suggested integrated system evaluation framework.

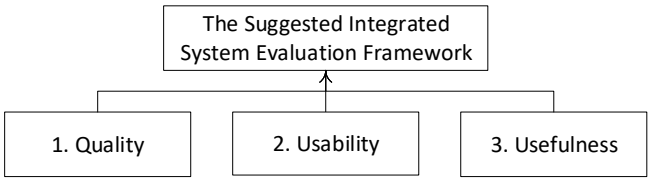

Figure 1. Suggested Integrated System Framework

The rest of this paper is organized as follows: the next section provides an overview of our methodology. The 'Results' section describes the evaluation methods reviewed and the evaluation methods selected for OUR case study in the context of the EU H2020 project iTRACK (https://www.itrack-project.eu). We conclude with a 'Summary' section.

METHODOLOGY

To achieve the goal of this paper, we surveyed relevant sources for "software testing methods" and "technology usefulness instruments" to collect quality and the usefulness assessment methods and metrics. Websites of organizations connected to humanitarian conflicts were the target of our initial investigation, such as Aid in Danger, the European Interagency Security Forum EISF, the United Nations Development Program UNDP, etc. We used a variety of keywords like: "software testing", "software evaluation", "information system testing", "information system evaluation", "software quality", "information system quality", sometimes even just using "software" and searched for relevant material in results. This search was not fruitful. To mitigate the situation, we have used the same search keywords mentioned above and broadened our search circle to include sources like:

- International Organization for Standardization ISO (https://www.iso.org/publication-list.html),
- International Electrotechnical Commission IEC (http://www.iec.ch),
- IEEE (https://www.ieee.org),
- ISTQB (https://www.istqb.org),
- Scientific publications (via Google Scholar and others), and
- Other material available on the Internet in general.

The results of this investigation were organized under the three pillars of our intended framework: quality, usability, and usefulness.

RESULTS

The quality of software, as indicated previously, is about meeting the specified requirements as well as user satisfaction. The former is achieved by testing the software system components individually or together, and the whole system against the requirements in terms of specifications, use cases, design documents, etc. The latter is achieved via testing the system usability and user-satisfaction directly with users and subjectively via questionnaires administered to them. System usefulness can be measured in terms performance indicators of an individual, a team, or an organization as a result of using the system, as well as subjectively by explicitly asking the users to provide their opinions on the usefulness of the system.

Our literature survey results were compiled under the first two main subsections of this section: 'Software Testing and Quality', and 'Software Usability'. Each of these subsections was concluded by our selected methods and metrics for the iTRACK system. The third main subsection focuses on the usefulness of the iTRACK system.

SOFTWARE TESTING AND QUALITY

SOFTWARE TESTING METHODS

All software testing methods are classified under either Black-Box, White-Box, or in-between i.e. Grey-Box (Jovanović 2006). The software testing method will be decided based on the testers access to the internal structure of the software system under test (its source code): (1) **Black-Box Testing Method** (aka. Specifications-Based, or Behavioral testing) is a software testing method in which no need to access the source code of the tested item. ("Black Box Testing" 2017). (2) **White-Box Testing Method** (aka. Clear-Box, Glass-Box, Transparent-Box, Open-Box, Code-Based testing, or Structural testing) is a software testing method to test a software item with knowledge of its internal structure, design, and implementation (source code) ("What is a White Box Testing?" 2012; "White Box Testing" 2010). (3) **Grey-Box Testing Method** is a combination of the Black-Box and White-Box software testing methods ("Gray Box Testing" 2010).

SOFTWARE TESTING LEVELS

Software testing is being conducted on four different levels: Unit, Integration, Functional, and Acceptance.

Unit Testing Level (aka. Component, Module, Program, or Structural testing)[1] ("Types of Software Testing for Dummies" 2013) is a typical Whit-Box method testing level. "Unit testing is micro testing which is done by developers to ensure that each and every individual unit of source code performing well enough to match their expectation" (Müller et al. 2011; "Types of Software Testing for Dummies" 2013). This testing level is all about answering the question of "**Did we build it right?**".

Integration Testing Level aims at examining how units/components/parts of the system work together. The different units/components are tested working together to ensure that interfaces and interactions among them or other parts of the system (e.g., operating system, file system, hardware) are performing well and in compliance with the requirements/specifications (Müller et al. 2011; "Types of Software Testing for Dummies" 2013).

System Testing Level is a system testing that is concerned with the complete functionality and behavior of the whole system (Müller et al. 2011). The environment where this testing level is conducted should resemble the production environment to reduce the environment-specific failures (Müller et al. 2011). System testing level "may include tests based on risks and/or on requirements specifications, business processes, use cases, or other high level text descriptions or models of system behaviour, interactions with the operating system, and system resources" (Müller et al. 2011). This testing level inspects both functional and non-functional requirements and could be conducted by an independent tester (Müller et al. 2011).

Figure 2 shows the relationship between the testing methods and the testing levels.

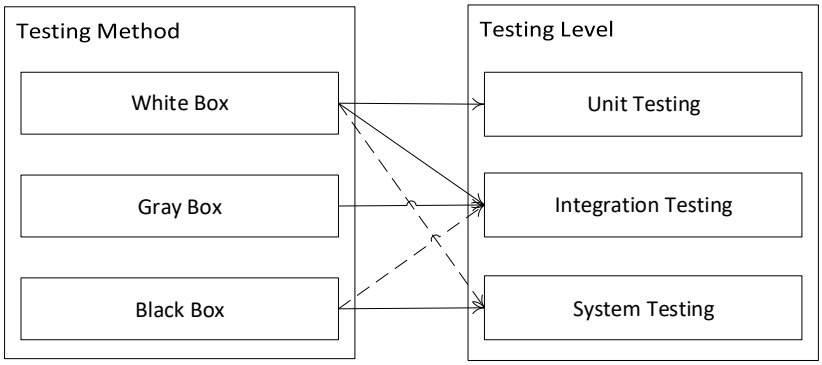

Figure 2: Testing Levels and Methods

[1] A structural or an architectural testing aims at knowing what is happening inside the system.

THE ITRACK SOFTWARE TESTING AND QUALITY ASSURANCE

Unit testing has been performed using the tools in the iTRACK development environment. The requirements for the tests were developed in a series of interviews, field research and simulation tests (Noori et al. 2017). Full documentation is available on the project website https://www.itrack-project.eu. Successive versions of the iTRACK corresponding deliverables have reported the resulted testing metrics. One of the metrics reported is the Code Coverage which is "an analysis method that determines which parts of the software have been executed (covered) by the test suite and which parts have not been executed, e.g., statement coverage, decision coverage or condition coverage." (Judy McKay et al. 2016).

In the iTRACK development environment, an Integration testing for mainly the server-side components was carried out. In a simulation exercise in April 2018, another Integration testing including the client-side components was performed in addition to a System level testing to evaluate end-to-end workflows.[2] Before the final deployment, another System-level testing is planned. After deployment other metrics like the numbers and rates of bugs and issues reported, fixes; enhancements; improvements and new features released, issues reopened, etc.(for others, please check (Data 2017; "Issues" 2018)) can be used to indicate the quality of the iTRACK system.

SOFTWARE USABILITY

Usability Testing Level (aka. Acceptance Testing) is the final testing phase prior to sending the software to the production environment in the market. This level aims at answering the question of "**did we build the right thing?**". The testing is conducted firstly in the developers' workplace by the internal developers, testers, or users employed for that reason, which is called in general Alpha testing. Then the testing is conducted at the users' place by the users to provide feedback before the system release to the market, which is called Beta testing (Müller et al. 2011; "Types of Software Testing for Dummies" 2013). "The goal in acceptance testing is to establish confidence in the system, parts of the system or specific non-functional characteristics of the system. Finding defects is not the main focus in acceptance testing" (Müller et al. 2011).

Acceptance in terms of usability is defined as "a quality attribute that assesses how easy user interfaces are to use. The word 'usability' also refers to methods for improving ease-of-use during the design process" (Nielsen 2012). Usability can be measured objectively and subjectively. Objectively by asking users to complete certain tasks and observe them. Subjectively by asking users to fill questionnaires about the usability of the software system.

USABILITY TESTING SESSIONS

Usability testing aims at observing users using the tested software under test. A set of users, preferably similar in characteristics to the end-users, should be employed and asked to fulfill goal-based tasks using the software; during these testing sessions usability problems would be observed (Corona 2014). Observations are in terms of how users use the software. Then the developers will be able to know the correct needed features and understand the issues facing the users while using the software. Accordingly, developers can make improvements based on these observations.

USABILITY EVALUATION (TESTING METRICS)

As mentioned above, the users will be given a set of tasks to complete during the testing session. The following metrics could be calculated:

- Learnability:

How easy it is for the user to learn using the system (EN_Tech_Direct 2012; Nielsen 2012). Learnability could be measured by:

$$Learnability = \frac{T_2 - T_1}{T_1}$$

Where T_1 and T_2 are the durations taken by the user to accomplish the same task for the first and the second times respectively.

[2] For a full documentation of the test results, see: https://www.itrack-project.eu/media/articles/files/iTRACK_D7.3%20–%20Results%20of%20integrated%20system%20evaluation.pdf

- Efficiency:

How quickly it is for the user to accomplish tasks after learning the system (EN_Tech_Direct 2012; Nielsen 2012). Efficiency could be measured by finding the total time saved between the first and the last times doing a certain task.

- Effectiveness:

How well the user achieves her/his goals using the system (EN_Tech_Direct 2012). Effectiveness could be measured by classifying the accomplishment level of the tasks by different users (in terms of **S** for Success, **F** for Failure or **P** for Partial **S**uccess).

e.g.:

	Task 1	**Task 2**	**Task 3**	**…**	**Task N**
User 1	F	S	S		PS
User 2	S	S	F		F
…					
User M	F	S	PS		F

- Completion Rates:

"Often called the fundamental usability metric or the gateway metric, completion rates are a simple measure of usability. It's typically recorded as a binary metric (in terms of **1** for Task Success and **0** for Task failure). If users cannot accomplish their goals, not much else matters" (Sauro 2011).

e.g.:

	Task 1	**Task 2**	**Task 3**	**…**	**Task N**
User 1	1	0	1		1
User 2	0	1	0		1
…					
User M	1	1	1		0

- Usability Problems:

This measure is about user interface problems which the users encounter during the test. The moderator/observer should "describe the problem and note both **how many** and **which users encountered it**. Knowing the probability, a user will encounter a problem at each phase of development can become a key metric for measuring usability activity impact and [return on investment] ROI. Knowing which user encountered it allows to better predict sample sizes, problem discovery rates and what problems are found by only a single user" (Sauro 2011).

Observer notes should be based on the **frequency** of the usability problem: "Is it common or rare?", the **impact** of the problem: "Will it be easy or difficult for the users to overcome?", and the **persistence** of the problem: "Is it a one-time problem that users can overcome once they know about it or will users repeatedly be bothered by the problem?" (Nielsen 1994).

- Errors:

"Record any unintended action, slip, mistake or omission a user makes while attempting a task. Record each instance of an error along with a description. For example, 'user entered last name in the first name field'" (Sauro 2011). Afterward, the moderator/observer can add severity ratings to the errors, otherwise, categorize these errors. "Errors provide excellent diagnostic information and, if possible, should be mapped to [user interface] problems. Errors are somewhat time-consuming to collect, as they usually require a moderator or someone to review recordings" (Sauro 2011). Errors are detected via the observer's notes, for example, "user entered last name in the first name field" (Sauro 2011).

- Task Time:

"**Total task duration** is the de facto measure of efficiency and productivity. Record how long it takes a user to complete a task in seconds and or minutes. **Start task times when users finish reading task scenarios and end the time when users have finished all actions** (including reviewing)" (Sauro 2011).

	Task 1	**Task 2**	**Task 3**	**…**	**Task N**
User 1	00:05:30	00:14:30	00:05:30		00:01:30
User 2	00:04:25	00:13:20	00:04:25		00:01:20
…					
User M	00:06:45	00:12:15	00:06:45		00:02:15

- Page Views/Clicks:

"For websites and web-applications, these fundamental tracking metrics might be the only thing you have access to without conducting your own studies. Clicks have been shown to correlate highly with time-on-task which is probably a better measure of efficiency. The first click can be highly indicative of a task success or failure" (Sauro 2011). Page Views/Clicks could be detected by counting the clicks and page views by the system itself.

- Expectation:

"Users have an expectation about how difficult a task should be based on subtle cues in the task-scenario. Asking users how difficult they expect a task to be and comparing it to actual task difficulty ratings (from the same or different users) can be useful in diagnosing problem areas" (Sauro 2011).

Pre-task		**1**	**2**	**3**	**4**	**5**	**6**	**7**	
How difficult you think Task M will be?	Very easy	○	○	○	○	○	○	○	Very difficult
- Please explain your choice:									

- Task Level Satisfaction:

"After users attempt a task, have them answer a few or just a single question about how difficult the task was. Task level satisfaction metrics will immediately flag a difficult task, especially when compared to a database of other tasks" (Sauro 2011). For example, was "Task M" easy to do?

Post task		**1**	**2**	**3**	**4**	**5**	**6**	**7**	
How difficult did you find Task M?	Very easy	○	○	○	○	○	○	○	Very difficult
• Please explain your choice:									

- Single Usability Metric (SUM):

"There are times when it is easier to describe the usability of a system or task by combining metrics into a single score, for example, when comparing competing products or reporting on corporate dashboards. SUM is a standardized average of measures of effectiveness, efficiency of satisfaction and is typically composed of 3 metrics: **completion rates**, **task-level satisfaction** and **task time**" (Sauro 2011).

USABILITY AND USER EXPERIENCE SUBJECTIVE EVALUATION

Over the last 30 years, several usability and user-experience subjective questionnaires have been used to assess the usability aspects as well as reliability and validity of software systems. EduTech Wiki collected many of these questionnaires. They can be used for all systems including websites and mobile apps ("Usability and user experience surveys" 2016).

According to Perlman: "Questionnaires have long been used to evaluate user interfaces … Questionnaires have also long been used in electronic form … For a handful of questionnaires specifically designed to assess aspects of usability, the validity and/or reliability have been established …" (Perlman 2015). In the following table, we enlist some of the subjective questionnaires resulted from our review.

Questionnaire title	Questionnaire type	Number of items	Sub-scales/Construct	Reference
Perceived Usefulness and Ease of Use	7-points scale	12	○ Perceived usefulness, and ○ Perceived ease of use.	(Davis 1989)
Software Usability Scale (SUS)	5-points scale	10	○ Usability and ○ Learnability.	(Borsci et al. 2009; Brooke 1996; Sauro 2015; "System usability scale" 2017)
Standardized User Experience Percentile Rank Questionnaire (SUPR-Q)	11-points scale	8	○ Usability, ○ Trust, ○ Appearance, and ○ Loyalty.	(Sauro 2015)
User Experience	7-points scale	26	○ Attractiveness,	(Laugwitz et al. 2006,

Questionnaire title	Questionnaire type	Number of items	Sub-scales/Construct	Reference
Questionnaire (UEQ)			○ Perspicuity, ○ Efficiency, ○ Dependability, ○ Stimulation, and ○ Novelty.	2008)

THE ITRACK USABILITY AND USER EXPERIENCE TESTING

The iTRACK system consists of several packages that have different roles in supporting humanitarian aid workers. Based on these roles a list of usability tasks was prepared. This list compiles the possible iTRACK system features to be tested per iTRACK system component. Each feature to be tested is supplied with a description of its test. The idea, in general, is to find if the participants will be able to fulfill the required tasks with success, partial success, or failure. One of the iTRACK system features is the "threat creation", which as the name implies, enables users to create a threat report so that other iTRACK system users can be careful. One example of a test activity description for this feature is: "create threats on the map, indicate e.g. threat types, estimated impact, etc."
The metrics mentioned previously in the review will be used whenever suitable to find our usability issues. For our select usability task example, before doing this task, the participants should answer the following question:

Before Task

How difficult you think this task will be?	Very easy	○	○	○	○	○	○	○ Very difficult
- Please explain your choice:								

After finishing the task, the participants should log the time they took to complete this task and report if the result was success, partial success, or failure. Then answer a question like the one they have answered before the task:

After Task

Task								Log
Task Time								__:__:__
Completion (Success, **F**ailure and **P**artial **S**uccess**)**								○ S ○ PS ○ F
How difficult did you find this task?	Very easy	○	○	○	○	○	○	○ Very difficult
- Please explain your choice:								

These ***Before*** and ***After Task*** questions will enable calculating most of the usability metrics mentioned in the "Usability Evaluation (Testing Metrics)" subsection of this paper.

As indicated in the review, many questionnaires could be used to subjectively measure different constructs. Usually, users' time is limited and filled with several activities. To use this limited time efficiently, our team has selected only Davis' Perceived Usefulness and Ease of Use questionnaire, and UEQ questionnaires to be administered to the users as subjective usability measures. Davis' Perceived Usefulness and Ease of Use questionnaire is short and assesses the usefulness in addition to the ease-of-use, while UEQ gives more insights into the experience of the user. These questionnaires are to be administered to users for each of the iTRACK system components individually so that users can understand the text of questionnaires within the context of each of these components.

- iTRACK Perceived Usefulness and Ease of Use

Instructions:

- Try to respond to all the items.
- For items that are not applicable, use: NA
- Add a comment about an item if needed

Perceived usefulness			**1**	**2**	**3**	**4**	**5**	**6**	**7**		**NA**
1.	Using the iTRACK system in my job would enable me to accomplish tasks more quickly	Unlikely	○	○	○	○	○	○	○	Likely	○
2.	Using the iTRACK system would improve my job performance	Unlikely	○	○	○	○	○	○	○	Likely	○
3.	Using the iTRACK system in my job would increase my productivity	Unlikely	○	○	○	○	○	○	○	Likely	○
4.	Using the iTRACK system would enhance my effectiveness on the job	Unlikely	○	○	○	○	○	○	○	Likely	○
5.	Using the iTRACK system would make it easier to do my job	Unlikely	○	○	○	○	○	○	○	Likely	○
6.	I would find the iTRACK system useful in my job	Unlikely	○	○	○	○	○	○	○	Likely	○
Perceived ease of use			**1**	**2**	**3**	**4**	**5**	**6**	**7**		**NA**
7.	Learning to operate the iTRACK system would be easy for me	Unlikely	○	○	○	○	○	○	○	Likely	○
8.	I would find it easy to get the iTRACK system to do what I want it to do	Unlikely	○	○	○	○	○	○	○	Likely	○
9.	My interaction with the iTRACK system would be clear and understandable	Unlikely	○	○	○	○	○	○	○	Likely	○
10.	I would find the iTRACK system to be flexible to interact with	Unlikely	○	○	○	○	○	○	○	Likely	○
11.	It would be easy for me to become skilful at using the iTRACK system	Unlikely	○	○	○	○	○	○	○	Likely	○
12.	I would find the iTRACK system easy to use	Unlikely	○	○	○	○	○	○	○	Likely	○

- iTRACK UEQ

Instructions: For each of the following items, mark one box that best describes the iTRACK system.

		1	**2**	**3**	**4**	**5**	**6**	**7**	
1.	annoying	○	○	○	○	○	○	○	enjoyable
2.	not understandable	○	○	○	○	○	○	○	understandable
3.	creative	○	○	○	○	○	○	○	dull
4.	easy to learn	○	○	○	○	○	○	○	difficult to learn
5.	valuable	○	○	○	○	○	○	○	inferior
6.	boring	○	○	○	○	○	○	○	exciting
7.	not interesting	○	○	○	○	○	○	○	interesting
8.	unpredictable	○	○	○	○	○	○	○	predictable
9.	fast	○	○	○	○	○	○	○	slow
10.	inventive	○	○	○	○	○	○	○	conventional
11.	obstructive	○	○	○	○	○	○	○	supportive
12.	good	○	○	○	○	○	○	○	bad
13.	complicated	○	○	○	○	○	○	○	easy
14.	unlikable	○	○	○	○	○	○	○	pleasing
15.	usual	○	○	○	○	○	○	○	leading edge
16.	unpleasant	○	○	○	○	○	○	○	pleasant
17.	secure	○	○	○	○	○	○	○	not secure
18.	motivating	○	○	○	○	○	○	○	demotivating
19.	meets expectations	○	○	○	○	○	○	○	does not meet expectations
20.	inefficient	○	○	○	○	○	○	○	efficient
21.	clear	○	○	○	○	○	○	○	confusing
22.	impractical	○	○	○	○	○	○	○	practical
23.	organized	○	○	○	○	○	○	○	cluttered
24.	attractive	○	○	○	○	○	○	○	unattractive
25.	friendly	○	○	○	○	○	○	○	unfriendly
26.	conservative	○	○	○	○	○	○	○	innovative

THE ITRACK SYSTEM USEFULNESS

System usefulness is about how the system is helping users in accomplishing their job tasks quicker, improving their job performance, productivity, effectiveness, and in general making doing their job easier, in other words, the enhancement in performance of the users doing their jobs as a result of using the system (Davis 1993). Davis found that in predicting the actual system use, system usefulness is 1.5 times more important than ease of use or usability (Davis 1993; Sauro 2011).

The iTRACK system aims to improve the security and efficiency of civilian humanitarian missions. Using the iTRACK system is expected to enhance the performance of its users. In the following subsections, we will describe the metrics that we think would be useful in assessing the performance of the iTRACK system components, the usage of these components, in addition to the performance of the individuals, teams and overall organization because of using the iTRACK system.

A humanitarian mission could be divided into three phases: 1. Planning, 2. Executing, and 3. Response and Recovery. Each of these phases has different tasks according to the mission on one hand, and the threat/attack this mission is facing on the other hand. These tasks are performed by individuals who could be part of one team or gathered from different teams. Accordingly, an indicator could be on the highest resolution scale i.e. measuring the performance of an individual working on one task. It could be scaled up to the case in which this individual is working through a full phase or a whole mission as well. The same principle applies when the indicator is scaled up from an individual to a team or an organization. Figure 3 shows indicator measurement levels granularity that we have used while composing the performance indicators in the following subsections.

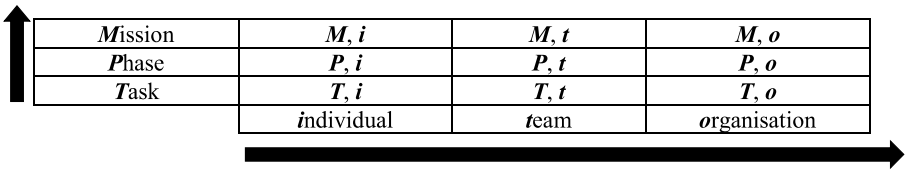

Figure 3: Indicator Measurement Levels Granularity (Arrows Go towards Higher Levels of Aggregations)

USAGE INDICATOR OF THE ITRACK SYSTEM

- Individual Usage per System Component

Usage Indicator ui_i: how many times an individual uses (open to look for or check anything) one of the iTRACK system components per time unit, therefore ui_i is measured in [times/hour].

- Team Average Usage per System Component

Usage Indicator ui_t: the average number of times of all individuals who belong to a team t use one of the iTRACK system components per time unit:

$$ui_t = \frac{\sum_{i \in t} ui_i}{|t|}$$

ui_t is measured in [times/hour], where $|t|$ is the number of all individuals who belong to the team t.

- Organization Average Usage per System Component

Usage Indicator ui_o: the average number of times of all individuals who belong to an organization o use one of the iTRACK system components per time unit:

$$ui_o = \frac{\sum_{i \in o} ui_i}{|o|}$$

ui_o is measured in [times/hour], where $|o|$ is the number of all individuals who belong to the organization o.

COORDINATION INDICATOR USING THE ITRACK SYSTEM

- Reaction Time to Messages

The iTRACK system provides users with the ability to exchange text messages. The value of this indicator is based on how long it takes a user to react because of a message she/he has received on the average. Indicators, like replying to the message or performing an action because of the message content, could be insightful. Yet, aside from being hard to measure, there are cases where a message does not need a reply or an action to be performed. For simplicity, reaction to a message could be considered as opening or reading this message (marking

it as read). For example, during the first task of the planning phase PT_1, the time passed between receiving certain message x by an individual until reading it is $\mathrm{rmt}_x^{\mathrm{PT}_1}$. Accordingly:

- For an individual, the total reaction time to all messages during this task is $\mathrm{rmt}_{total}^{\mathrm{PT}_1} = \sum_{x\in \mathrm{PT}_1} \mathrm{rmt}_x^{\mathrm{PT}_1}$ and the average is $\mathrm{rmt}_{average}^{\mathrm{PT}_1} = \frac{\sum_{x\in \mathrm{PT}_1} \mathrm{rmt}_x^{\mathrm{PT}_1}}{|\{x: x\in \mathrm{PT}_1\}|}$.
- For an individual, the total reaction time to all messages during all tasks of the whole planning phase is $\mathrm{rmt}_{total}^{P} = \sum_{x\in P} \mathrm{rmt}_x^{P}$ and the average is $\mathrm{rmt}_{average}^{P} = \frac{\sum_{x\in P} \mathrm{rmt}_x^{P}}{|\{x: x\in P\}|}$. Similarly, rmt_{total}^{E} and $\mathrm{rmt}_{average}^{E}$, and rmt_{total}^{R} and $\mathrm{rmt}_{average}^{R}$ can be calculated.
- For an individual, the total reaction time to all messages during the whole mission is $\mathrm{rmt}_{total}^{mission} = \sum_{x\in M} \mathrm{rmt}_x^{M}$ or $\mathrm{rmt}_{total}^{P} + \mathrm{rmt}_{total}^{E} + \mathrm{rmt}_{total}^{R}$, and the average is $\mathrm{rmt}_{average}^{mission} = \frac{\sum_{x\in M} \mathrm{rmt}_x^{M}}{|\{x: x\in M\}|}$.

In case the indicator is to be calculated for a team or an organization, the value can be calculated as the average of averages of all individuals who belong to that team or that organization respectively.

TIME-SAVING USING THE ITRACK SYSTEM

This indicator requires two different entities (two individuals, two teams, or two organizations) executing the same task, one of these entities uses the iTRACK system, while the other does not. Otherwise, a comparison can be conducted between the performance of the same entity in the current time and the last time this entity performed the same task, phase, or mission to measure the **learnability**. A comparison can be also conducted between the performance of the entity in the current time and the first time this entity performed the same task, phase, or mission to measure the **efficiency** (this answers questions like: how are we doing compared to the first time we have used the iTRACK system? and what is our overall trend using the iTRACK system?).

- Individual Time Saving Indicator

Let $\mathrm{ts}_i^{\mathrm{PT}_1}$ denotes the individual's time saved per task PT_1. Therefore, $\mathrm{ts}_i^{\mathrm{PT}_1}$ is the difference between the time elapsed by an individual (using the iTRACK) and the time elapsed by another individual (not using the iTRACK) –otherwise the past reading of the time elapsed by the same first individual– executing the same task PT_1. Accordingly, the individual's time saved for all tasks during the whole planning phase is $\mathrm{ts}_i^{P} = \sum_{x\in P} \mathrm{ts}_i^{x}$, similarly, we can calculate the individual's time saved during the execution phase ts_i^{E}, and the individual's time saved during the response and recovery phase ts_i^{R}. Furthermore, the individual's time saved during the whole mission is $\mathrm{ts}_i^{M} = \mathrm{ts}_i^{P} + \mathrm{ts}_i^{E} + \mathrm{ts}_i^{R}$.

- Team Average Time Saving Indicator

For the task PT_1, the average time saved across individuals who belong to a team t performing this task is $\frac{\sum_{i\in t} \mathrm{ts}_i^{\mathrm{PT}_1}}{|t|}$. The same equation can be applied for a phase (e.g. P) and a whole mission, i.e. $\frac{\sum_{i\in t} \mathrm{ts}_i^{P}}{|t|}$, and $\frac{\sum_{i\in t} \mathrm{ts}_i^{M}}{|t|}$ respectively.

- Organization Overall Average Time Saving Indicator

For an organization o, the average time saved across all individuals who belong to this organization during the task PT_1, the phase P (for example), or the whole mission can be calculated by $\frac{\sum_{i\in o} \mathrm{ts}_i^{\mathrm{PT}_1}}{|o|}$, $\frac{\sum_{i\in o} \mathrm{ts}_i^{P}}{|o|}$, and $\frac{\sum_{i\in o} \mathrm{ts}_i^{M}}{|o|}$ respectively.

In general, the time saving that is related to specific tasks like loading trucks, completing deliveries, etc. can be separately considered as independent indicators on their own.

COST-SAVING USING THE ITRACK SYSTEM

Cost could be calculated as the real cost of executing the task(s), phase(s), or mission(s) per an individual, team, or organization, which is difficult to be done quickly. Otherwise, it can be taken as the average cost per the time unit for an individual during executing task(s), phase(s), or mission(s) multiplied by her/his time elapsed executing this/these task(s), phase(s), or mission(s) respectively. The same approach can be applied to a team or an organization, by summing the cost of the individuals who belong to this team or organization respectively.

Like the time-saving indicator, this indicator requires two entities (individual/team/organization) executing the same task for comparison, one entity uses the iTRACK system, while the other does not. Otherwise, the comparisons can be conducted between the performance of the entity in the current time and the last time the

entity performed the same task, phase, or mission to measure the **learnability**. The comparisons can be also conducted between the performance of the entity in the current time and the first time this entity performed the same task, phase, or mission to measure the **efficiency**. Like the time-saving indicators, cost saving for tasks related to specific tasks like loading trucks, completing deliveries, etc. can be separately considered as independent indicators on their own.

THE ITRACK USEFULNESS SUBJECTIVE EVALUATION

Several questionnaires can subjectively assess the usefulness of the system from the users' viewpoint. For example, from the reviewed questionnaires that cover usefulness in the "Usability and User Experience Subjective Evaluation" subsection of this paper:

- Davis' Perceived Usefulness and Ease of Use,
- CSUQ/PSSUQ, and
- USE.

To subjectively measure the usefulness of the iTRACK system or one its components, as mentioned earlier, Davis' Perceived Usefulness and Ease of Use questionnaire could be used, as it has been very well accepted and used for a long time (as it is part of the Technology Acceptance Model TAM) (Müller et al. 2011). Taking into consideration the limited time of the users testing the iTRACK system, another reason to select Davis' is that it is shorter than the others.

SUMMARY

Evaluation and testing are major steps in the development of any software, but they are of particular importance if innovation is to be used in highly sensitive contexts such as humanitarian conflicts. It is a vital phase in quality assurance of the system in terms of assessing the system quality and sophistication from diverse viewpoints. Nonetheless, a comprehensive evaluation framework that combines technology, functionality and usefulness tests does not exist. The paper developed metrics that helps in measuring the quality and usefulness by using the case of the iTRACK system, a tracking and monitoring system for humanitarian conflicts.

This paper reviewed the adequate evaluation methods and measurement metrics, to compile this comprehensive evaluation framework to assist in measuring the quality and usefulness of the iTRACK system. We have indicated that the software system quality is assessed in terms of software testing. We have introduced different software testing methods and levels that are used in software testing in general. The usability of the iTRACK system is assessed separately, either via the system usability testing directly with users or via questionnaires administered to them. Moreover, for users to find the system useful, the system should solve a problem they are facing, or fill a need or offer them something. System usefulness is about helping in accomplishing job tasks quicker, improving job performance, productivity, and effectiveness, in addition to making it easier to do the job. To measure the usefulness of the iTRACK system, we have suggested several performance indicators, as well as by subjectively recognizing the users' opinion about the usefulness of the system. Figure 4 shows the pillars and details of the suggested integrated system evaluation framework.

Finally, the iTRACK integrated system evaluation framework has been reviewed by several iTRACK project partners that belong to academia, and software development and their notes were taken into consideration in the final version.

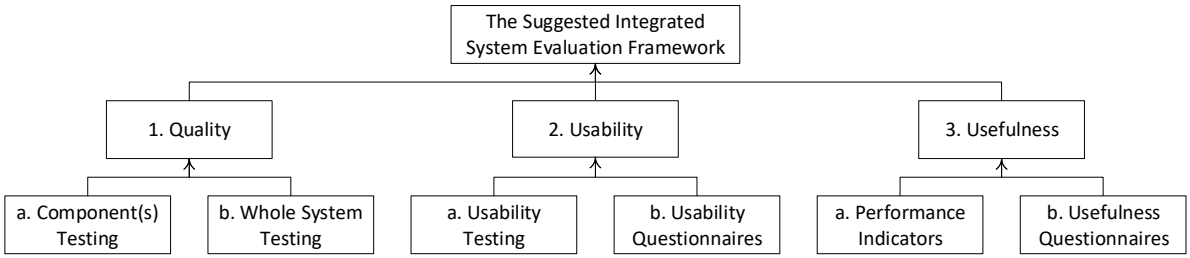

Figure 4. The Detailed Suggested Integrated System Framework

The iTRACK project conducted a simulated environment exercise in April 2018. This exercise is an example of applying the iTRACK integrated system evaluation framework, as it was the first iTRACK system testing with users. During this exercise, a set of participants tested the ready iTRACK system components. The participants were asked to complete certain tasks using the iTRACK system. The suitable usability and usefulness metrics and

questionnaires suggested in this paper were used during the exercise. As a final note, an independent reporting and evaluation software system applying these metrics for the iTRACK is under development.

ACKNOWLEDGMENTS

This work is carried out as part of the iTRACK project, funded by the European Union's Horizon 2020 research and innovation Program under grant agreement No 700510.

ABSTRACT

Providing feedback to smoke divers following their training exercises is constrained by limitations on the opportunities for observation by instructors, as the buildings are filled with smoke. Yet, sensors that can be used to track and provide data on various aspects of the smoke divers training are becoming available. This paper describes a study of how to support firefighters and their instructors with visualisations of their training performance. The study has involved the development of a training support tool, FireTracker, that visualises data from firefighters smoke diving activity, and an evaluation of FireTracker in use. FireTracker uses data from sensors such as Bluetooth Beacons and gyroscopes to detect and visualize the smoke diver's movement and work patterns during smoke diving exercises. We found that there is a training need for these visualisations, but clear limitations on the positioning data that currently can be provided.

Keywords

Smoke diver training, multimodal data, data visualisations

INTRODUCTION

Global satellite navigation systems (GNSS) have become widespread, providing positioning data from several, separate yet combinable (Zhang et al. 2013) systems for the general public, and there are a plethora of applications and systems that build on them. GNSS data are not suitable for indoor localisation, however, mainly because of the need for skywards line-of-sight to obtain data, and data disturbances caused by presence of buildings (Yassin et al. 2017). Indoor positioning technologies (IPS) are still developing. While GNSS systems work more or less the same way, IPS systems are technologically much more diverse and rapidly changing (Brena et al. 2017; Liu et al. 2007), and the ideal IPS technology depends on the purpose and use situation. This study represents an endeavor to utilise IPS enhanced by additional sensor data, to visualise indoor movement and work performed by smoke diver during training exercises, with the purpose enhancing the post-exercise evaluations.

This paper describes the development and evaluation of a tool, FireTracker, that provides data driven ICT-support for firefighter and smoke diver training. The overall goal for the study has been to develop ways of supporting training for smoke divers with data based visualisations of their smoke diving activity, with emphasis of movement, to improve training efficiency and enhance the post exercise evaluation sessions. The goal for the tool is to combine different sensor data to create visualisations of the indoor training activity of cold smoke diving. The visualisations are intended to be used by instructors and firefighters to retrospectively assess and evaluate training performances. At the current stage of the study we have developed a first working prototype of FireTracker that provides tracks of the smoke diver's movement, activeness, and time use on locations in a house during smoke diving training

*corresponding author

exercises. Firetracker has also been evaluated in use during a cold smoke diving exercise. The paper addresses the 2019 ISCRAM Advanced Technologies for First Responders workshop topics of (1) emerging mobile trends in first responder technology, and (2) multimodal data fusion, representation, and visualisation.

As a study about improving the conditions for self-reflection and learning, the underlying pedagogical rationale for development is inspired by Computer Supported Collaborative Learning (CSCL) (Koschmann 2012), a perspective on learning that emphasises the social, goal-driven and artefact-mediated nature of human activity. As an initiative to develop support for group-oriented learning and training in the workplace, our study also takes a data-driven and analytics approach to understanding learning, and is influenced by the field of Learning Analytics (LA) (Siemens 2013). In an overview of the field of LA (Misiejuk and Wasson 2017) find that there are a number of examples of using LA to understand small-group learning processes, although (Ruiz-Calleja et al. 2017) point out that there is a lack of studies taking an analytics approach to understanding learning in the workplace. For example, (Goggins et al. 2015) visualised activity analytics from student group work in order to give feedback to teachers, so they could provide support or make relevant interventions in their students work. Another example is (Martinez-Maldonado et al. 2017), who studied nurses mobility in healthcare simulations. (Worsley 2018) argues that using mobility data is an emerging trend within multi-modal learning analytics.

The approach of using sensor data visualisations to improve and enhance the training of first responders and firefighters is novel, although there are examples of using digital indoor navigation support for actual firefighting (Fischer and Gellersen 2010). Getting "lost inside" or, becoming disoriented inside a burning building is one of the most common sources of accidents and injury in firefighting (Fischer and Gellersen 2010). (Ojeda and Borenstein 2007) describe a non-GPS based navigation support system directed at walking persons, for example for first responders inside buildings. By inserting an Inertial Measurement Unit in the wearers' boots, the system uses gait to predict movement. The system feeds the data to a central control, that can build an overview, for example, of rooms that have been visited in a building. (Koch et al. 2007) have used RFID to build a system for locating humans and objects indoors, although not directly for firefighters. (Feese et al. 2013) developed a smartphone based sensing system for monitoring temporal and behavioral performance in firefighting missions. Their goal was to use the collected data to compare the performance metrics between firefighter teams participating in the same mission. They used sensors on smartphones to sample data which was stored on the smartphone and transmitted the data so it could be used for real-time monitoring.

(Fortenbacher et al. 2017) used physical and environmental sensor data to capture and understand the emotional states of firefighters in training, and how the data can be used to support self-regulatory learning. In other studies not explicitly focused on training, it has been studied how networked robots and sensors (Kumar et al. 2004) and communication networks (Wilson et al. 2007) could be utilized to expand firefighters and other first responders situational awareness. (Wang et al. 2015) describe a firefighter training system utilizing sensors embedded in the firefighters training clothes, as a way of interacting with a VR game. When nearing a fire in VR, temperature sensors increases the temperature within the clothes. (Backlund et al. 2007) and (Lebram et al. 2009) have also taken a game-based approach involving sensors and haptic feedback to firefighter training. Through the cave-based game Sidh, firefighters can train smoke diving using their own bodily movements as input, and receive feedback on surrounding screens. Evaluation of the game with firefighters highlighted the highly motivational aspect of this mode of training.

iComPAss

The study has been carried out as part of the iComPAss (inquire Competence for better Practice and Assessment) project (Netteland et al. 2016). At many workplaces training and learning is a continuous process, that includes courses, training exercises, further education, certification, and re-certification, and is often integrated with work processes. The training and learning takes place to increase the employees and the organization's competences, and is particularly relevant for firefighters who dedicate much of their workday to training and honing skills. The iComPAss project studies data (i.e., evidence) based decision making by examining how digital tools that use competence modelling, learning analytics, and visualizations can support decision making within healthcare and firefighting.

The questions that have guided the research are:

- How does FireTracker affect and support firefighter training?
- How can data from FireTracker support and enhance the evaluation of smoke diving exercises?

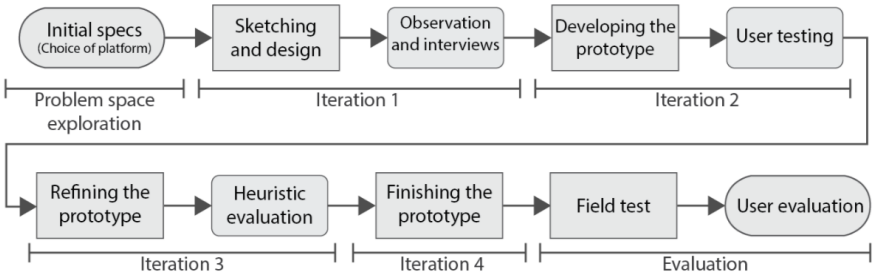

Figure 1. Overview of the development process

METHOD

The development process has been inspired by the perspectives of design science (Hevner et al. 2004), and Human Computer Interaction, and we have taken a data-driven and iterative approach to development. The approach to development is particularly inspired by the Interaction design life cycle, as described by (Preece et al. 2015), where design requirements are turned into design alternatives, which are developed into prototypes, which are then evaluated, forming the basis of new understanding of the requirements.

The research and development was carried out in collaboration with a firefighter department located in Western Norway. We interacted mainly with firefighters in three roles: smoke divers; smoke dive exercise leaders; and, departmental training officer. To understand the problem space, and the particular needs and contingencies of smoke dive training, we studied firefighter training manuals, observed and took part in smoke diving exercises and post-exercise evaluations, and interviewed exercise leaders and smoke divers about firefighter training needs in semi-structured interviews, throughout the development process. The smoke divers and exercise leaders have also given direct feedback on the different versions of the prototypes in interview sessions, following training exercises. All interviews were recorded and transcribed, and field notes were written following observations.

Early prototypes were evaluated using Nielsen's heuristics (Nielsen and Molich 1990), and we carried out our own testing of beacon precision and localisation algorithms. The development was carried out in four phases (see Figure 1), and included (1) problem domain understanding and requirements specification, (2 & 3) developing and refining the prototype, and (4) developing the currently final version.

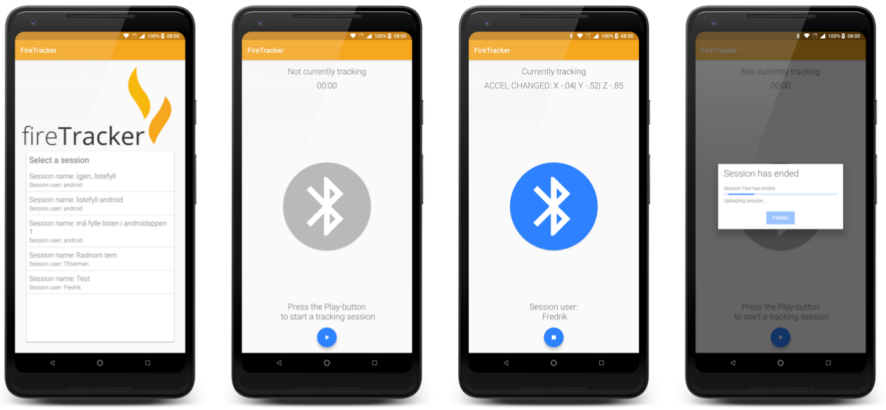
The final version was evaluated as a field trial (Brown et al. 2011) in a dedicated smoke diving exercise, where we tested different configurations of BLE beacon placement, and assessed how these affected the localisation visualisations. Two instructors and two smoke divers took part, using their regular equipment. Following the exercise, they were interviewed on usability and usefulness issues, and they also evaluated FireTracker using the System Usability Scale (Brooke 2013). One of the exercise leaders had evaluated earlier versions, while one used FireTracker for the first time. The two smoke divers used it for the first time. The results from the field trial are presented in the section "Evaluating FireTracker".

FIRETRACKER

FireTracker is a smoke diver data capture and visualisation tool, used to create data-driven improvements in training smoke diving. FireTracker has two main components: 1) an app to capture data from different sensors (Figure 2), and 2) a learning authoring tool, to be used by instructors to set up training exercises, and present the resulting visualisations during post-exercise evaluation sessions (Figure 3). The app is installed on a mobile phone attached to the smoke diver, and the authoring tool is (usually) installed on an iPad carried by the training exercise leader.

Requirements

The rationale for FireTracker is that smoke diving takes place according to a set of standards and heuristics for communication, movement pattern, order of the work, etc. The standards exist to ensure firefighter safety and efficiency in an otherwise hazardous environment. By nature, these activities are carried out in partial or total blindness for both the instructor/exercise leader and the firefighters. By creating visualisations of how these activities are carried out in practice, and making them available for inspection and discussion immediately after the exercise, we can increase smoke divers ability to understand and discuss how a particular exercise went, and better support post-reflections on the training activity.



(a) Session list (b) Tracking activity (c) Active tracking (d) Session uploading

Figure 2. The FireTracker Mobile Interface

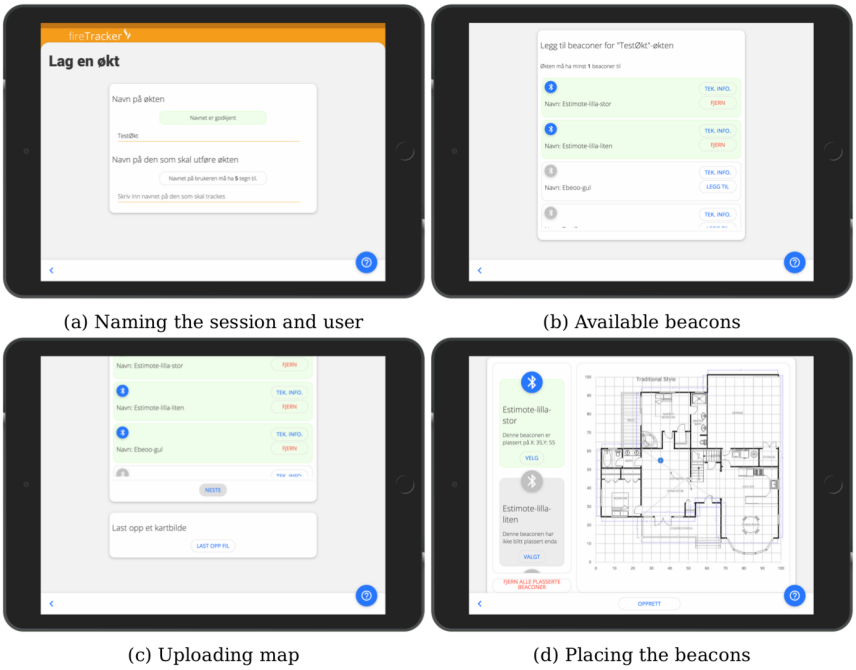
Requirements for FireTracker were developed and refined throughout the design and development iterations, in close conversation with exercise leaders, overall training leaders, and smoke divers. The most important requirements were:

- Portability: FireTracker should facilitate rapid deployment at any site, rather than be installed in a fixed location, as the firefighters avoid training cold smoke diving at any one location for too long. For the firefighters, it is an important aspect of the training to avoid becoming too familiar with the layout of a building, and that the deployment phase doesn't become routine. This requirement limited the choice of positioning technology; it is generally easier to integrate position technology in a fixed building or site (Li et al. 2014) than to rely on a portable system.
- Transportability: The physical equipment should be easy to bring along on an exercise, and not require a lot of time to set up by the exercise organisers. Any physical equipment should not restrict firefighter movement, or be in the way of the smoke divers in the building.
- Build on handheld devices: The firefighter department that took part in the study already uses handheld devices for various purposes during both their exercises, and in responding to emergencies. All their vehicles are equipped with iPads. They also carry out their post smoke dive evaluations immediately after the exercise, at the location of the exercise. To support the feedback and evaluation session, visualisations should be available for display right away, and to be passed around in a circle, rather than require a desk- or laptop computer.
- Data presentation efficiency: The data visualisation tracks should be easy to read, and provide a clear and precise picture of the smoke diver movement inside a building filled with smoke.

Infrastructure and sensors

FireTracker consists of (1) an app for tracking a set of Bluetooth Low Energy (BLE) beacons on a mobile phone to gather positioning data, and (2) a web-based administration tool on a tablet, to enable the exercise leader to set up FireTracker for the exercise, and have a suitable screen for visualising the data. BLE beacons are placed around the building that is the site for the exercise, and the mobile phone is attached to the helmet of each smoke diver.

FireTracker builds datasets from the set of BLE sensors placed around a building and the gyroscope and accelerometer sensors on the mobile phone, and the mobile phone clock. When the firefighters search through the building, the mobile phone collects data from the beacons and combines it with data from the mobile phone sensors, which are used for determining if the firefighters are moving their head or walking. During development we discovered that sometimes during exercises the smoke divers would stand still/not walk. The reasons for not walking varied, for example for sorting out confusion, or for searching for casualties. Usually, the reason for not walking carried significance to their activity, and we found to interesting to attempt to capture more aspects of non-movement. Thus we needed additional sensor data. The mobile phone accelerometer was used to detect and estimate the number of steps taken by the smoke diver. By comparing the number of steps taken in a time interval, it was possible to



(a) Naming the session and user (b) Available beacons

(c) Uploading map (d) Placing the beacons

Figure 3. The FireTracker administration tool

determine whether the smoke diver was moving or standing still at a location. The gyroscope was used to determine relative orientation of the device. By using the same method as with the accelerometer to determine movement, it was possible to compare the time interval with the gyroscope orientation values to see whether the smoke diver was rotating the device at any time. The data are visualised as a track on a map of the building indicating the path of the smoke diver during the exercise. The track is enhanced with mobility data from the gyroscope, in addition to the time use data. Steps and head movement are visualised as yes/no buttons tied to each location, and time use is visualised as a weighted dot on the track – the larger the dot, the longer the stay.

The positioning algorithm can be described as proximity positioning, based on the received signal strength of the beacon. The mobile app constantly scans a list of available beacons. It connects to the beacon with the strongest signal, from the list of available beacons specified in the administration tool before the exercise starts, and creates a location for that beacon. The beacon has a known location on a map. It calculates the time it has been connected to the current beacon, in addition to the other sensor data, as long as that beacon emits the strongest signal. When a stronger signal is received from another beacon, it creates a new location, and adds the data from the previous location to a list of locations. Different approaches to data cleaning were experimented with during the development process, to create as clear and accurate tracks as possible.

Using FireTracker

Figure 3 illustrates FireTracker administration tool in use. To set up an exercise, the exercise leader uses the administration tool to create a session (session translates to exercise) and entering his or her name (Figure 3a). Then, he or she searches for available beacons, and include them in the session (Figure 3b). Next a map of the building is uploaded (Figure 3c). The map is easily created by either taking a picture of the floor plan of the building (usually available near the floor entrances in public buildings), or creating a map of the floor plan by hand beforehand. Finally, beacons are placed throughout the building (Figure 3d), and their position is recorded by tapping on a spot on the corresponding map. Each beacon is represented by a blue dot on the map.

The sessions are selected on mobile phones, which in turn are attached to the firefighters' helmets. Figure 2, a-d illustrates a use cycle of the tracking app. Before starting the smoke dive, the app is set to start recording data on the mobile phone. During the smoke dive, the app tracks data from BLE beacons, gyroscope, accelerometer and clock. After the exercise has been completed, the data are uploaded and rendered as a track on the map of the building, which also visualises use of time and activity level at each position. The administration tool is designed to work on an iPad, to better support the physical aspect of moving around and being on your feet, which is very much a part of the exercise both for the instructors and firefighters.

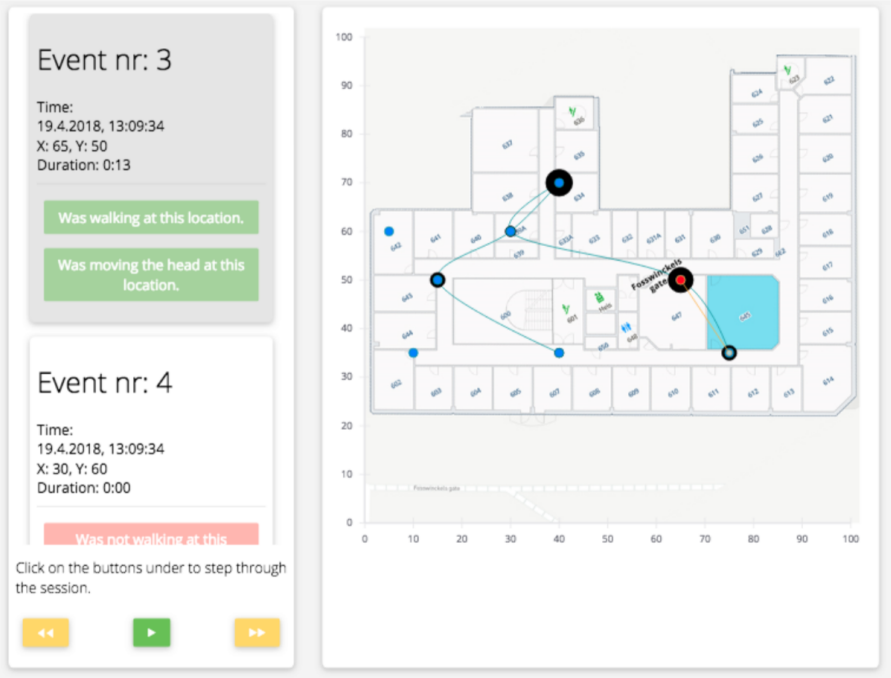


Figure 4. FireTracker Data Visualisation

The administration tool then produces a map of the activity, as can be seen in Figure 4, one for each smoke diver. The visualisation shows how the firefighters have moved in the building, illustrated as a series of locations (the circles). The blue dots represents the beacons, and if the circle is enhanced by a encompassing black circle, the location is deemed to have been visited. The movement can be replayed as a linear track, using the green "play" icon in the bottom left corner of the screen. The track can also be replayed by clicking on the list of events. Additional information is tied to each location. The size of the circle indicates for how long the location was visited – the larger the circle, the longer the stay. The red centre at one of the locations in Figure 4, represents that it is currently selected for viewing. "Playing" the track will have the red dot jump through all the locations in the order they were visited. The boxes on the left displays more information about each location, such as a time stamp, map coordinates, duration of stay, whether the firefighter was walking around or standing still at the location, and finally whether the firefighter was moving his or her head. The left boxes correspond to the red-dotted location on the map.

EVALUATING FIRETRACKER

FireTracker was evaluated in a field trial as described in the methods section. The main goal of the field trial was to understand how FireTracker affected and supported the smoke diving exercise self-evaluations, and to understand whether the data visualisations were useful for their training. In the field trial we first introduced FireTracker to the participants, and explained the purpose of the tool. One of the instructors was familiar with the tool, and had evaluated previous versions, the other three were new to FireTracker. Then we surveyed the site and building, and drew a floor plan to be used as the map by hand, as the particular building we used (an abandoned office building), didn't have a floor plan illustration available. The instructor who was previously unfamiliar with FireTracker set up the BLE beacons, and chose where to place them based on his understanding of how they worked.

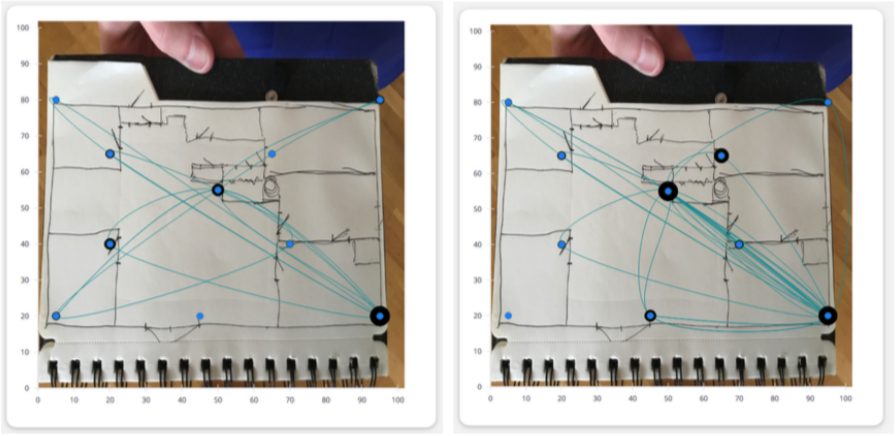
Four cycles of smoke dives augmented by FireTracker was carried out for the field trial. The cycles varied with smoke diver blinding method and equipment use, BLE beacon placement in the building, and on the roles assigned to the smoke diver (called "Smoke diver 1" and "Smoke diver 2"). Smoke diving always happens in pairs, and the tasks tied to the roles 1 and 2 are different; which smoke diver leads, which smoke diver searches rooms for missing persons whilst the other smoke diver pulls the firehose and so on. The first smoke dive was not carried out with smoke in the building, but by covering the helmet visors, which allowed the researchers to directly observe the smoke dive from within the building. The specifics of each cycle are presented in Table 1.

Results

This subsection presents the results from the field trial. The presentation of the results is divided between location tracking accuracy and value, and verbal feedback from smoke divers and instructors.

Table 1. Field trial exercise cycle

Exercise session	Equipment and blinding method	Number of participants
1	No smoke, helmet visors covered	Smoke divers: 2 Instructors: 2
2	Cold smoke, with full gear	Smoke divers: 2 Instructors: 2
3	Cold smoke, with full gear	Smoke divers: 2 Instructors: 2
4	Cold smoke, helmet only	Smoke diver: 1 Instructor: 1



(b) Smoke diver 1, exercise session 2

(c) Smoke diver 2, exercise session 2

Figure 5. Smoke dive tracks

Location tracking

As a test of the precision of the location tracks from the smoke diving, the field trial produced disappointing results. The tracks did not reflect the route chosen by the smoke divers, and made it seem like they were moving between locations to a high degree, whilst they actually were moving in a circular, clockwise pattern from right to left. The cause of the problem with the localisation was that the mobile phone intermittently picked up stronger signals from beacons that weren't the closest, producing tracks that did not reflect the path of the diver during the exercise. This happened because the location algorithm uses the beacon's known location on a map to position the user, and the user is deemed to be closest to the beacon with the strongest signal. There was also some "jumping" between beacons, resulting in a track that gave the appearance that the smoke divers walked back and to the same location.

One useful aspect of the tracking and smoke diving activity that FireTracker can be read from the tracks, can be seen in Figure 5, and can be related to the role distribution between the smoke divers. The figure shows the tracks from the second session of the exercises, for Smoke Diver 1 and 2. In the second session, both smoke divers walked the same route, but Smoke Diver 2 had the role of searching rooms, whilst Smoke Diver 1 pulled the firehose, and was more stationary when the pair was not advancing between the rooms. The track visualisations indicate more movement by Smoke Diver 2, which aligns with his role of entering and searching through each room.

Feedback from smoke divers and instructors

The smoke divers were asked questions about whether the visualizations gave them more information about the exercise and their own performance, and how it contributed to the internal evaluation of the exercise, in separate semi structured interviews. The evaluation with the smoke divers focused on wearing the mobile phone, tracking, and the resulting visualisations. The smoke divers both highlighted that FireTracker didn't require much from them, and that they concentrated on their routines during the exercise, which is in line with our goal for FireTracker to be pervasive to the exercise whilst tracking. They both gave the feedback that the tracks were too imprecise to be of value. One of the smoke divers found the presentation of the movement (as movement between the blue dots) a little confusing, and would have preferred a footpath-like track of his movement. *It (FireTracker) would have helped me appreciate more about my movement in the building. But I would have preferred a tail (visualisation). That would have made it easier for me to see where I had been. I would have understood more easily. Almost like playing*

a movie, one and one dot appearing. And preferably in two colours, one for me and one for (colleague). They both gave the feedback that the data visualisations would have been very useful if they had been more precise. The smoke divers SUS results were 67,5 and 57,5, both below the accepted score of 68.

The evaluation with the two instructors was focused on use of the administration tool, in addition to the tracking app and visualisations. They found that it was easy to use, and the instructor who had never used it before reported that "*I didn't need a manual, I figured out how to use it after a couple of minutes*". Both reported that the data would be very useful in exercise evaluation, but were currently too imprecise, and they wouldn't be able to identify errors in the smoke diver movement with the current level of granularity. One of the instructors made a similar comment to one of the smoke divers; that he would have preferred to have the localisation nodes in the visualisations appear in the same order they were visited, rather than all at once.

Regarding expectations to how they could use FireTracker, the chief training instructor responded that he sees it as a tool for inspecting or verifying the activity of the smoke divers, and as a starting poing for a discussion with the smoke divers: *It would be very good for learning about their (the smoke divers) search patterns, to see if it matches the theory. They are supposed to make a plan before entering, and with this tool you can check if they follow it. Did they follow the wall to the right, or turn around? If so, why? It would be a very useful tool for that.* He also had the idea that they could place artefacts in the house, such as training dolls and similar items, and match the track visualisation against the artefacts in the evaluation. He also thought it would be useful for the smoke divers themselves to see their own data. The other instructor commented that it would improve their basis for providing feedback to the smoke divers, and that data from one team could increase the training value to the teams that waited outside (buildings are searched sequentially by teams of two, and when one team runs out of air they exit, the next team takes over). The total SUS score for the instructors were 82,5 and 90, although they underscored that they answered under the assupmtion that the data had been precise.

Discussion

Beacon precision and track visualisation : As part of an infrastructure of a system to support indoor localisation not tied to one specific place, the beacons used in our study, in the way we have used them, currently seem to provide too imprecise data to support precision tracking. The beacon signal strength that our algorithm build on was affected by a number factors such as mobile phone make and obstruction of physical objects, resulting in unpredictable data. During development we experimented with several ways of increasing precision, such as manipulating the signal strength in digital and physical ways, and different types of placement. This finding is in line with (Fischer and Gellersen 2010), who describes the accuracy of indoor positioning systems along the two axis of precision and portability, where an increase in portability leads to less precision and vice versa. One of the main design requirements behind the development in this study, was that the localisation technology needed to work in conditions (i.e. buildings) that were unknown beforehand.

Based on their response in the interviews, our chosen way of visualising progress within the building was not intuitive to the smoke divers. Our method created a location at each placed beacon, indicated by a dot placed on the map. The algorithm was intended to create a line between all the locations/dots that were visited, which in turn could be played step-wise retrospectively. The firefighters responded that they would have preferred a caterpillar-like track that increased in length as time progressed, relative to where they were in the building. Early interviews gave us differing inputs on the requirements for actual precision, but the general opinion was that the movement visualisation only had to be somewhat accurate to be of value, as long as it was correct. Here, it is possible that the sensor errors we experienced as described above contributed to confusion in interpreting the visualisation, as there positioning data indicated movement that hadn't occurred.

Capturing non-movement: As discussed in the section on FireTracker infrastructure, the study started with the goal of capturing smoke divers indoor movement during exercises. The goal was to improve and create new opportunities for discussions between smoke divers and instructors in the post exercise evaluations, and was based on the observation that their movement and search patterns are set according to standards and competencies, yet there are limits on observation. Following observation of a full scale smoke diving exercise, and their following exercise evaluation at an early stage in the development process, we realised that there were additional important aspects of non-movement. During the evaluation session, they discussed events that had caused pauses in the search, because this was when there were situations and problems to solve. Or in other words, a search without any stops would be "everything as normal". We saw the opportunity to uncover further aspects of the smoke diving activity using the gyroscope, accelerometer and time measurements. The imagined scenario was that when a search pauses, we could provide metrics on their physical activity levels and time use, which could enhance discussions about why the momentary stop in the search took place. A large circle at a location, would for example indicate that they had stayed there for long. While the time use data is represented intuitively, the activity level data are not detailed

enough. Our current version displays these data as "yes" or "no" to walking and head movement at each location, and future versions will display these data in more detail, indicating amounts of steps and head movement.

Conclusions

The field testing of FireTracker during a training exercise revealed that both the instructors and the firefighters thought the tool was very useful. The smoke divers found the performance data on their activity interesting, and the instructors appreciated the idea behind the visualisations and found the system very easy to use, although the localisation tracks were to imprecise with our current version of FireTracker. Further development of the tool will include better quality visualisations and localisation precision, and the investigation of the use of learning analytics to identify patterns of good and bad movement so that they can be flagged to the instructors and firefighters.

ABSTRACT
Social media is used during crises and disasters by state authorities and citizens to communicate and provide, gain and analyze information. Monitoring of platforms in such cases is both a well-established practice and a research area. The question, whether people are willing to renounce privacy in social media during critical incidents, or even allow surveillance in order to contribute to public security, remains unanswered. Our survey of 1,024 German inhabitants is the first empirical study on people's views on social media monitoring and surveillance in crisis management. We find the willingness to share data during an imminent threat depends mostly on the type of data: a majority (63% and 67%, respectively) would give access to addresses and telephone numbers, whereas the willingness to share content of chats or telephone calls is significantly lower (27%). Our analysis reveals diverging opinions among participants and some effects of sociodemographic variables on the acceptance of invasions into privacy.

Keywords
Social Media, Privacy, Security, Crisis Management, Surveillance.

1 INTRODUCTION

Data in social media shared by inhabitants can be very useful for state authorities such as police, fire and rescue organizations in cases of crises and disasters, which is also shown by the fact that social media are a crucial part of ISCRAM research. Analyzing all ISCRAM papers related to social media from 2004-2018 Reuter et al. (2018), found that the papers predominantly examine social media posts in English, mostly posted on Twitter. Geographically, the analysis focused on crises in Europe and North America. Another conclusion is that in order to realize broader analyses of social media content, it will be necessary to overcome the obstacle of "even more complicated data-extraction scenarios" (Reuter et al. 2018). This obstacle is a consequence of the current increase in awareness for privacy issues and resulting changes in online behavior, as well as terms of use. Examples in point are the growing popularity of discarding Facebook's public post search feature and of the sandbox mode on Instagram. The European General Data Protection Regulation (GDPR) efficiently curbed the amount of user data that is publicly accessible for processing. Moreover, the above-mentioned debate on privacy may lead to a decrease in people's willingness to having their online behavior analyzed (Reuter et al. 2018). Notwithstanding the usefulness of data collected from social media and by surveillance measures in cases of crisis and disaster, privacy concerns have to be considered when using this data for crisis management. One part of this complex issue is the people's perception of privacy.

Therefore, this paper addresses the research question: *How far are people willing to provide their data in social media and accept surveillance to support authorities in cases of crisis and disaster?* We provide answers to the question which types of data people are more concerned to share and under what conditions they are willing to make their data available. Additionally, we ask about people's opinions on several surveillance measures aimed at increasing public security in cases of imminent threats. Some of those measures are already practiced in Germany or elsewhere, others are still broadly and controversially discussed.

Through a representative survey of 1,024 respondents, we found that German inhabitants were only partially willing to give up their privacy on social networks and, depending on the crisis context, would give specific authorities access to non-intimate but private data. Nevertheless, this disposition to (partially) waive privacy to support state authorities' crisis management goes hand in hand with the demand of holding the state accountable:

inhabitants want increased transparency of data collection as well as rights regarding the use of collected data by state authorities. We analyzed sociodemographic factors of our subjects such as gender, age and educational background and their influence on the answers given. By means of simple regression analyses we partly found correlations, partly no correlations between these criteria. Overall, there is a tendency for subjects to cooperate on certain conditions such as transparency of monitoring and selection of data transmission.

In the beginning of the paper we outline the state of research concerning social media in crisis management and users' perception of privacy in social media and surveillance (section 2). We will continue with the methodology (section 3) and the results of our analysis (section 4), followed by a conclusion and implications for further research (section 5).

2 STATE OF RESEARCH

The following section reflects the current state of research concerning social media as a tool in crisis management as well as on public perceptions of privacy concerning social media monitoring and surveillance. Moreover, it presents the research gap we aim to address.

2.1 Social Media in Crisis Management

Social media are becoming more sophisticated by the day. This is not only true for social media in day-to-day use, but also their employment in cases of emergencies (Reuter, Hughes, et al., 2018; Reuter & Kaufhold, 2018). Information technology plays a major role in context of peace and security (Reuter, 2019). The first use of social media for purposes of disaster support documented and detected by the authors took place in 2001. Since then, the use of social media has increasingly intensified, provoking a growing amount of research on the topic. It has analyzed different cases and users, practices and tools with diverging methodologies. A main goal being the support of actors involved in crises, emergencies or disasters, depending on their nature and size. The research and advancements made so far are summarized under the term of crisis informatics (Hagar, 2007; Palen et al., 2009).

Reuter & Kaufhold (2018) found studies emphasizing the role social media played in the handling of a significant majority of large emergencies in the last decade, and even in most emergencies since 2001. Although many studies initially focused on the US, research studying other continents is making up ground, thus enabling systematic comparisons across countries, regions and kinds of emergencies. Nonetheless, most studies still focus on Twitter, which is possibly due to the ease of data selection on the platform. Reuter & Kaufhold's (2018) analysis was centered on the analysis of different usage patterns, such as communication between citizens (i.e. C2C), communication from authorities to citizens (i.e. A2C), communication from citizens to authorities (i.e. C2A) and between authorities (A2A). It is important to note that the perception of social media varies across users, i.e. diverges between authorities and citizens. Although both tend to pose similar challenges, such as a lack of trust and knowledge, citizens still expect that authorities monitor social media. Thus, expectations have to be aligned in order to overcome existing problems. Due to the almost omnipresent nature of social media and its low entry and usage barriers ,"the role held by members of the public in disaster (…) is becoming more visible, active, and in possession of greater reach than ever seen before" (Palen & Liu, 2007). Each citizen can post information about an event, thereby helping the authorities and other citizens. The willingness to use voluntarily communicated information is ambiguous. Reuter & Spielhofer (2017) investigated the reasons why citizens do not use social media for crisis communication and identified them as "mistrust as well as the perceived lack of a clear purpose for using social media in emergencies" (Reuter & Spielhofer, 2017).

In addition to the positive aspects of social media collaboration between citizens and public authorities, there are also negative aspects, as illustrated by the case of the Munich rampage in the summer of 2016. While the gunman was hunting for people in the shopping center, eyewitnesses posted a number of videos on Twitter and Facebook virtually live. The police later criticized these actions on social channels, considering them to have unsettled and panicked the population. In addition, the perpetrator could have been informed about the ongoing police operation as well as countermeasures of the emergency services. A helpful communication tool such as social media can only be used effectively if actors are aware of consequences of certain courses of action (see Dobel, 2016; Schillat, 2016). In emergencies people are usually willing to help, but still do not want to be monitored.

2.2 Perception of Privacy in Social Media and Surveillance

Social media do not only pose chances, rather, looking at crisis management, there are several problems, risks and challenges (Kaufhold & Reuter, 2019). The revelations of Edward Snowden or the Cambridge Analytica affair are just two broadly discussed examples for the potential misuse of data and show the pressing relevance of privacy. One important aspect of privacy is its perception by users. The existing research on the privacy paradox suggests that people are willing to limit or even renounce their privacy for relatively small benefits, or even none

at all (Norberg et al., 2018). But further research showed that this approach is too narrow. First of all, it has to be noted that users do not necessarily understand that they are sharing personal data to be able to use "free" social networks, services and apps (Turow et al., 2015). Additionally, they lack knowledge on the consequences of sharing their data, and if so, are unable to regain control over data already shared (Acquisti & Grossklags, 2006). Therefore, users do not make an informed and deliberate choice. Even users who are aware of this, often do not see an alternative and share their data because the effort to search for and use other services is considered as to large by users, e.g. because of fast-changing terms of use (Buxmann, 2015, p. 143) As a result, they feel that they are losing control over their data (Degli-Esposti et al., 2017). One example is a value-driven approach to privacy. Buxmann focuses on the value people attach to their data. He surveyed users' opinions on data driven business models in social networks and their behavior if they disapprove of those. In 2012, 62% and in 2014 even 75% of respondents disapproved such business models – at the same time only 14%, especially older users, refused to use those services (Buxmann, 2015).Simultaneously, users appear to refuse to pay a significant amount of money for more privacy-friendly services. This can be explained with the privacy paradox, but factors such as awareness, knowledge, motivation and considered effort need to be analyzed in more detail than this concept allows.

The picture crystallizing of people's perception of surveillance is similar to the one of privacy in social media. Often people perceive surveillance as an inevitable art of the digital revolution. Even if they are aware of it, they think they need to accept it to avoid important social or economic disadvantages (Turow et al., 2015). Only a minority of people "try to avoid, evade or circumvent surveillance by adopting different strategies, from the intentional provision of inaccurate information, to the adoption of anonymization and privacy-preserving tools" (Degli-Esposti et al., 2017). Ball stresses that although people tend to do little to counter surveillance, this does not mean that surveillance is meaningless for them. It may be accepted or even approved of because providing data can satisfy individual anxieties, or patriotic or participative values. Another factor is that there is often no identifiable observer who exercises perceivable control. Furthermore, the pleasure of performative display overrides the scrutiny that comes hand-in-hand with self-revelation (Ball, 2009, p. 641).

Looking at surveillance from the privacy angle, Kasper (2005) introduces a sophisticated typology of privacy breaches, which will be introduced in further detail below, and finds that forms of intrusions are covered with different intensities in US newspapers. Thus, the public perception of privacy strongly depends on the context and on the type of invasion in it, and is subject to change: Kasper (2005) finds that – possibly due to historical events and changes in state practice – perceptions of invasions into privacy changed in the period of 1990 to 2003, for example increasing the relevance of clandestine forms of data gathering in the public debate (which she calls *stockpiling*).

2.3 Research Gap

Research on the question when and under what conditions people are willing to either, allow the state access to a well-defined set of information on them, restricted to the period of time constituted by a severe crisis or disaster, or, grant the state rights to conduct long-term surveillance efforts, in order to increase public security – remains unanswered by previous research. Reuter & Spielhofer (2017) indicate that mistrust and lack of a clear purpose are reasons for people to reject using social media in emergencies. It remains unclear under what conditions inhabitants support their use if this improves crisis management. The research of Degli-Esposti et al. (2017) shows that the "current security policies and solutions are somehow perceived as inadequate by citizens, whose demands, opinions and perceptions need to be further explored" (Pavone et al., 2017). Kokolakis demands further research in his work to "build a clearer picture of the relation between privacy attitudes and behavior" (Kokolakis, 2017). Therefore, this paper addresses these questions concerning conditions and kind of data as well as the view on surveillance measures.

3 RESARCH DESIGN AND METHODOLOGY

This paper addresses the yet unclear perception of privacy by people concerning social media monitoring and surveillance in cases of crisis. In 3.1 we outline our theory approach and the design of survey questions, 3.2 explains the survey design and conduction and 3.3 presents the respondent's characteristics.

3.1 Theory and Design of Questions

To be able to contribute to the perception of privacy we use Kasper's approach of privacy. She identified several problems with existing definitions of privacy: 1) definitions appear to be not properly specified, i.e. they are too broad or too narrow, 2) they have a strong cultural bias and 3) "tend [...] to be value-driven" (Kasper, 2005). Therefore, she developed a typology of privacy by understanding privacy "from the standpoint of its invasion" (Kasper, 2005). This typology for invasion accounts "for all possible ways in which one's privacy can be invaded and to identify distinctive characteristics associated with each type of invasion" (ibid.). Our interest expands over the typology's categories e*xtraction* and *observation*. To measure public perception of forms of *observation*, the

third question (called Q13, for the exact wording of the questions see Fig. 1-4) on different fictional laws was asked. The question addresses *observation*, because the state is granted intrusive rights to collect and store information on and metadata generated by its citizens, which comprises different forms of surveillance. Kasper (2005) defines *observation* to "mainly consist of 'watching,' [which] refer[s] to surveillance in general" (Kasper, 2005). She subclassifies *observation* into *physical observation* (i.e. "surveillance of a physical entity" (ibid.), e.g. by surveillance cameras), *communication observation* (i.e. "the interception and/or surveillance of communication in any form: telephone, mobile phone, e-mail, fax [...] and so forth" (ibid.)) and *behavioral observation* (i.e. "the explicit monitoring of a behavior" (Kasper, 2005), such as "track[ing] consumers' buying *habits*" (ibid.)). Question 13 addresses these forms of *observation* separately, by first asking whether respondents would be willing to grant the state the right to surveil them via CCTV (*physical observation*), via internet communications (*communication observation*) and lastly, all information available, which includes the former two, but adds the possibility of observing *behavioral* habits. Nonetheless, the differentiation of the categories is made difficult by the fact that both physical and communication observation include the possibility to observe individual's habits. Therefore, we will not draw any conclusions on the perception of behavioral observation as a single category, but rather as an implicit possibility taken into account by respondents when answering the questions on the first two, and particularly when considering exhaustive surveillance methods.

We will continue by considering types of information *extraction*, defined by Kasper (Kasper, 2005) as "involv[ing] a deliberate effort to obtain something from an individual or group" (Kasper, 2005). Here, opposed to observation (i.e. surveillance), data is not collected over a long period of time, but situationally and with particular effort. To measure public perception of forms of *stockpiling*, Q11 on fictional state access to private information in times of crisis was asked. The question addresses *stockpiling*, because the state is granted intrusive rights to collect and store information on its citizens, which in and of itself, is not harmful for the individuals concerned. This access however is limited in time, here to the acute crisis situation. The data is not automatically used, but stored and potentially used to ensure people's wellbeing. Though agreeing to the access to their information, people "remain largely unaware and uninformed of what happens to the information after it has been collected" (ibid.). *Appropriation/disclosure* is not covered by the questionnaire, because the state has no reason to collect potentially damaging personal information in order to disclose it later on (Kasper, 2005).

Inner-state extraction is covered by Q14, asking whether and in which cases people are willing to give up parts of their privacy in social media in order to track terrorists. The data collected is meant to provide information of the political and religious views of individuals, as well as their mental state or willingness to harm members of the public. These are not "externally knowable" (ibid.), and the judgement made on their basis decides over whether further policing steps are taken or not. Thus, the "stakes are higher than in *stockpiling*, and the purpose more specific than in *appropriation/disclosure*" (ibid.). Individuals are "usually aware of this" (ibid.), as the presence of laws allowing intrusion of this sort is known (particularly in case of the respondents who are made aware of it by the question), however (in line with Kasper's definition) it is possible that people are ignorant of the intrusion or its scope.

In her analysis of newspaper articles discussing intrusions into privacy from 1990 to 2003, Kasper (2005) finds that while data extraction is discussed most (constantly over 50% of newspaper articles), its percentage shows a declining trend. Observation however, takes increasing importance in the debate of privacy intrusions, whereas intrusion roughly stagnates (Kasper, 2005). Taking a closer look at extraction, i.e. dividing it into its subtypes, Kasper (2005) finds that while appropriation/disclosure used to be the main type discussed in the 1990s, its importance has sharply declined since. Not close to its importance in the 1990s, stockpiling is overtaking it in importance in 2003, so that the two categories roughly share the entirety of coverage on extraction in 2003. Of much smaller importance in the debate is inner-state extraction, not reaching the 10% mark of over-all privacy intrusion coverage. In the case of observation, levels of coverage are lower across categories, however physical and communication observation slightly gain importance across years (Kasper, 2005).

Kasper concludes that "[t]he instances of privacy invasion mentioned with increased relative frequency in the news are *stockpiling* extraction and *physical* observation" (Kasper, 2005). Putting this into the context of its time, i.e. 2003, we can conclude that the US' political situation of fear of terror and increasing surveillance is not unlike Germany's in 2018, although methods of surveillance have become significantly more sophisticated. Nonetheless, looking at the development of the possibilities and the debate induced by Snowden and other whistle-blowers, it can be speculated that the importance of observation in the discussion has since been increasing. Therefore, we expect to find similar, or possibly more extreme perceptions, especially regarding observation, as knowledge on security service practices of observation has increased since 2003. Kasper provides several explanations for this trend: surveillance takes place more often (ibid.), the consciousness of public has increased, therefore "people are more sensitive to such invasions" (ibid.) and the interaction of these two factors (ibid.). Concerning both types of privacy invasion (i.e. stockpiling and physical observation) people have "little knowledge and even less control" (Kasper, 2005). In addition, the already explained role of lacking awareness (Kasper, 2005) and a resignation

concerning *appropriation/disclosure extraction* and *autonomy intrusion* declined (Kasper, 2005).

3.2 Survey Design and Conduction

The study forming the basis of this paper is a representative survey of 1,024 subjects throughout Germany, adjusted according to the adult population from the age of 18 to 65 and the respective distribution of sociodemographic factors, namely gender, age, education, income, and region. It consists of an item-battery with four questions (Q11 to Q14) and lays its focus on privacy. Each question was designed to be Likert-scaled and closed-ended. The questions were developed based on a pilot study (Reuter et al., 2016). The hypotheses of this explorative study with 61 participants are tested with this quantitative approach.

The survey was conducted in German so that all participants understood the questions. The survey presented in this paper is a translation. Due to financial limitations no questions were included that checked the participants' attention or the frequency of their answers. The study was performed from 24th July to 7th August 2017.

3.3 Characteristics of Survey Subjects

The sample of survey respondents (N = 1024) was adapted to the distribution of gender, age, region, education, and income (Table 1) of the general German population by the preselection of an external survey panel provider (GapFish). In addition, solely consistent and complete answers were included. Therefore, our adapted sample consisted of 49.5% female (n = 507) and 50.5% male (n = 517) respondents. They were between 18 and 64 years old, nearly half of them being 45 and older (n = 492, 48%). Recruited participants live in all German federal states with the largest samples from North Rhine-Westphalia (n = 228, 22%) and Bavaria (n = 165, 16%). All participants are inhabitants of Germany, not necessarily German citizens. Furthermore, and important for this analysis, the subjects were classed based on their educational background: 69.2% of the subjects possess a secondary school graduation (from German Haupt- and Realschule). The other educational qualifications are distributed almost evenly over the remaining 30.8%. Only 1% (n = 9) of participants did not graduate from a school, while 15% (n = 160) held a degree from a university or college. Over two-thirds (n = 707, 69%) had an income between 1.500€ and 3.500€.

Table 1. Distribution of gender, age, education and income among participants.

Variables	Categories	Percent of respondents
Gender	Male	50.49
	Female	49.51
Age	18-24	11.82
	25-34	19.34
	35-44	20.70
	45-64	26.37
	65 and older	21.68
Education	No diploma	1
	General secondary school	33
	Intermediate secondary school	37
	High school diploma	14
	Polytechnic degree	7
	University degree	8
Income	Below 1,500	19
	1,500-2,500	29
	2,500-3,500	40
	Above 3,500	12

The responsible external survey panel provider recruited the respondents solely passively by advertising online (80%) and offline in TV commercials and newspapers (20%). There was no active recruitment via telephone or similar. The participants were chosen randomly and preselected concerning the above described criteria. They received small financial incentives between 0.5 and 2 Euros.

4 RESULTS

In the following sections, we present the results of our survey. The segmentation is based on the chronological structure of the item-battery, consisting of three questions concerning topics about the kind of personal data (potentially) accessed by state authorities, (fictional) state laws allowing surveillance and the conditions under which people would limit their privacy in social networks.

4.1 Access to Private Information by State Authorities

The first question (Q11) of the item-battery is: Which of your private data would you allow to be accessed by state authorities to combat an urgent crisis (e.g. terroristic attack or natural disaster)? The question is Likert-scaled: To each kind of private information, subjects were given different response possibilities. We included a wide range of information in order to assess peoples' general willingness to cede different private data. This allows us to roughly spot the average boundary of good will when it comes to sharing private information. Not all categories are therefore helpful to authorities in reality. A divide in the given answers is easily spotted, depending on the type of private data:

	Telephone number	Address	Location (area, city)	Location (exact position, e.g. GPS)	Account-data from Facebook, Twitter, Instagram etc.	Chat records or Phonecalls	Creditcard-/account-data
agree	37%	36%	35%	29%	17%	14%	7%
rather yes	30%	27%	31%	26%	15%	13%	6%
maybe	22%	24%	22%	25%	23%	22%	15%
rather no	6%	7%	5%	11%	20%	18%	27%
do not agree	6%	6%	6%	9%	25%	33%	45%

Figure 1: Access to Personal Information: Which of your private information would you allow to be accessed by state security services to combat an urgent crisis (terrorism, natural catastrophe) (Q11)?

The majority of the subjects would allow access to phone numbers, addresses and inaccurate GPS location data. In addition to this, accurate geolocations would be shared by most of the subjects as well. This approval of sharing private information sinks rapidly with other kinds of personal data: Access to profiles of social media accounts, contents of chats or telephone calls and financial account data would only be shared by a minority of subjects (Figure 1). Roughly 65% of the subjects agree to allow access to data like addresses, telephone numbers and geolocation-data, while only 32% would grant access to authorities to their social media profiles, 27% to contents of chats or phone calls, and only 13% would allow the mining of their financial account data (Figure 1).

4.2 Surveillance

The third (Q13) question dealt with (fictional) state laws allowing surveillance, which were discussed in German mass media. Subjects were asked to support or reject those state laws. The question was whether authorities should have the following right to establish higher public security. We included this more general question in order to account for the fact that in reality, user data is not only assessed in times of acute emergencies, but also collected and used to prevent them. Public debate in Germany has mainly focused on this type of privacy intrusion, as well as the transparency and effectiveness of the measure. Therefore, the answers to this question indicate general willingness to give up data for the more or less definite, and highly subjective goal "security" is. Figure 2 gives an overview of the response possibilities and the answers given by the subjects.

Here too, there is a differentiated view regarding authority rights and the answers given: While the majority supports video surveillance of public spaces (approx. 70%) and the statement that public security should be paramount, even if this was adverse for the government (approx. 49%), the support falls for the rest of the stated laws and rights (Figure 2).

Monitoring of the internet and global information collections are considered ambiguously by the subjects, while the collection of information about German citizens without the knowledge of those involved is rather rejected. It is also striking that more than half of the subjects reject transparency in terms of a policy of freely available information about governmental intelligence for the public.

By bringing the variables into a binary form and creating a polarized mood image Figure 5 (in the Appendix) shows such a polarized tendency concerning the heavily debated issue of video surveillance. The majority of the subjects, 707 out of 853 (approx. 83%), would support video surveillance in public spaces.

Video surveillance in Germany is a frequent subject of debate in German media and therefore shall be examined in depth in Model 1. We see that people willing to allow surveillance of all exchange of information via the internet are significantly more likely to be in favor of introducing video surveillance. People opting for transparency (and against secrecy) on parts of the state, i.e. granting access to all information the state has, are significantly less likely (on a 1% level of significance) to opt for wide-spread video surveillance. Interestingly, people with a higher net income are significantly (on 1% level) more likely to favor video surveillance than people with a lower income.

	Closed Circuit Television	Public safety should be the priority, even if it has diadvantages for the state	Monitoring of information exchanges in the internet	Comprehensive data collection of everyone, irrespective of country of residence and without their knowledge	Comprehensive data collection of everyone with Germany as country of residence and without their knowledge	All official information should be freely accessable
in any case	37%	20%	12%	12%	10%	9%
rather yes	33%	29%	22%	16%	13%	15%
neutral	17%	29%	27%	23%	21%	21%
rather no	9%	13%	23%	25%	24%	25%
absolutly not	5%	10%	16%	24%	32%	29%

Figure 2: (Fictional) Rights of Officials: Should authorities in Germany in your opinion have or have not the right to the following to ensure public security better (Q13)?

Another subject of debate in German media is internet surveillance. 34% of the subjects rather support such surveillance, the rest rejects it. To have a closer look at the trends concerned, we use an OLS model of internet surveillance (see Model 2), i.e. granting the state the right to monitor all information exchange via the internet. People willing to allow video surveillance and notably, the collection of data on all people living in Germany without their knowledge, are significantly more likely (on 1% level) to opt for internet surveillance. Contradictorily, people both in favor of more transparency and more secrecy on parts of the state concerning the data it has, are significantly (on a 5 and 1% level, respectively) more likely to be positive about data gathering on information exchange via the internet. Simultaneously, having a higher education significantly (5% level) reduces the likelihood of opting for internet surveillance.

In Model 3, we regress respondents' disposition towards comprehensive data gathering on the entire population of Germany. While the answers to questions regarding video surveillance and secrecy in the perceptional part, and education and net income in the demographic part remain insignificant, questions such as allowing internet surveillance, international data collection and transparency are all positive and highly significant.

This points in an interesting direction: On the one hand, people who are prepared to allow the state highly intrusive access to their privacy are in other questions more likely to allow comprehensive data gathering. On the other hand however, people demanding transparency from the state - i.e. wishing that the state makes accessible all data it has on the population - expressly taking into consideration the adverse effect this might have on national security, are also significantly more likely to allow non-discriminatory, Germany-wide collection of data. Thus, transparency might be a necessary condition in the eyes of many skeptics to allow data collection in Germany.

This is an interesting point, because transparency and the accessibility of all data does not make the intrusion into privacy smaller, if anything, it increases it.

In the demographic part of the regression, age is the only variable with a significant effect (on 10% level), providing evidence that older people are more likely to allow comprehensive data gathering.

Table 2. OLS models of willingness to grant authorities privacy-intrusive rights

4.3 Security and Privacy

The last question (Q14) addresses whether respondents would give up parts of their privacy in social networks if this would include tracing of terrorist organizations, and if so, under which conditions. When looking at Model 4, we observe that the respondents with a high general willingness to give up their privacy are significantly less likely to favor the necessity of a court order for access to personal data (on a 1% level of significance). This tendency of people preferring well-defined, limited access to personal data opting for court orders applies to quite some variables. Among others it applies to people willing to share their personal data with the authorities only in the case of immediate emergencies, who are also significantly more likely to prefer court orders. Similarly, people willing to share personal data only if the duration of usage is clearly defined, are significantly more likely to support the necessity of court orders for access. Equally significantly positive is the effect of pledging for self-determined usage of data by authorities.

However, this trend of people with high standards of data protection is not as consistent as it might first seem. There is no significant connection between demanding the deletion of data after usage and preferring court orders. The same is true for the demand of transparency in the states' handling of personal data and court orders. Interestingly, people with higher age and education are also more likely to favor court orders as necessity to allow for access to personal information. The effect of education is not significant in either of the other two models. Age has a significantly positive effect (on 5% level) on making the deletion of data a necessary condition for access to personal data on social media, but not on sharing data in case of an immediate emergency.

	My data will be deleted after it has been used	It will be garantied that I can track how and where my data was used	I can decide by my own wich data is accessable by the officials	A court order is necessary	Immediate terror attack/ disaster etc.	Police access to my accounts (chat reports, friends, newsfeed etc.) should have a certain duration	For compen-sation (money)	I would be willing to give up a part of my privacy in social media
yes	49%	40%	29%	26%	25%	17%	13%	12%
rather yes	22%	27%	30%	28%	32%	29%	16%	24%
I`m not sure	16%	18%	23%	27%	23%	25%	28%	29%
rather no	5%	7%	10%	11%	9%	13%	19%	14%
no	8%	8%	8%	8%	11%	16%	25%	20%

Figure 3: Conditions of Renouncing Privacy: Would you be willing to waive parts of your privacy on social media when it was used to detect terrorists and, if so, under what conditions? (Q14)

Looking at Model 5 in greater detail, we see that all other answers given to the question described above, predict the answer to sharing data in cases of immediate emergency rather well. The only significantly negative effect can be observed with wishes for self-determination of the data used. All other positive answers, be they in favor of more privacy or not, have significantly positive effects. One answer that we should highlight in this context is granting a monetary incentive for sharing personal data. This demand has no significant effect in either of the other two models. Here however, people willing to sell their data are also significantly more likely to be willing to share their data on social media. The demographic controls are all insignificant. Furthermore, all people, be they defenders of data privacy or not, are willing to share their personal data in social networks in cases of emergencies. Notably, emergencies include both natural disasters and terrorist attacks. It could be argued that this effect might be driven by the mere inclusion of terrorist attacks into the scope of 'emergencies', as the debate on political violence, particularly Islamist violence, is increasingly securitized. The control question (Q12) asked on people's willingness to share their data on social media with the authorities across different types of emergencies however, contradicts this notion.

The deletion of data after usage, as modeled in Model 6, is significantly (on a 1% level) predicted by the willingness to share data in cases of emergency, the demand for more transparency on the part of the German state, a defined duration of usage, as well as self-determination in the scope of data used. The effects of demanding a court order and a high over-all level of privacy are not significant. This implies that having a high standard of privacy, as modeled by these two variables, does not significantly predict demanding the deletion of data. Nonetheless, we find that higher age significantly (on 5% level) increases the probability of answering that deletion of data is a necessary condition for sharing personal data.

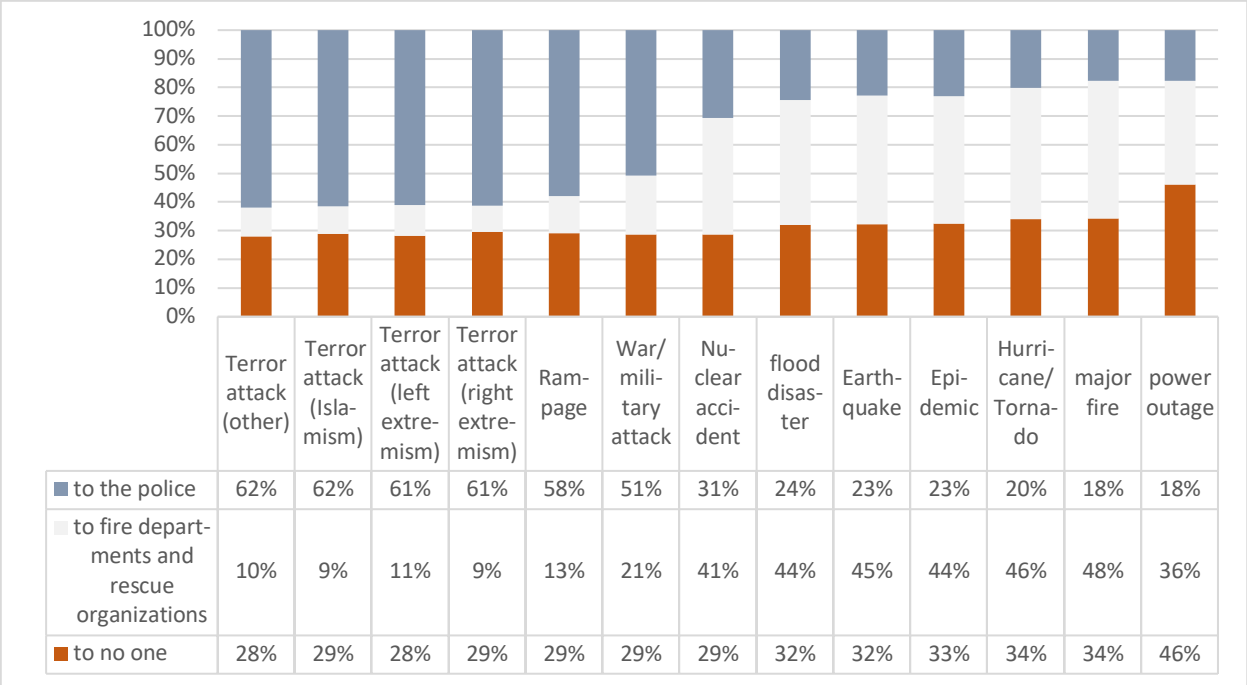

Figure 4: Situation differentiation: In the context of which acute threats would you waive parts of your privacy in social networks and to whom (e.g. by generally collecting private messages) and in which not? (To emergency response by the police, to emergency response not by the police (fire department, rescue teams), to nobody) (Q12)

5 DISCUSSION

So far, we presented the results of our work and made a first analysis of the gathered data. In the following sections we carry out a deeper examination of the findings. For this we return to our initial research questions and try to address the research gap.

5.1 Social Media in Crisis Management

Respondents are willing to cooperate with authorities and disclose information in situations of acute danger. Our models suggest that generally speaking, older and well-educated respondents are more likely to fall into the group of privacy-aware people. However, this trend is not constant and depends on the content made available to state authorities. In the case of an immediate terrorist attack, 74.5% of the subjects (when deleting neutral answers, n = 786) would give up their privacy in social media and make data accessible. Our insight on the context-sensitivity of subjects with regard to their willingness to provide information in crisis situations coincides with the findings of Ur et al. (2012). In this context, the central aspect of trust in the responsible authorities stands above all as a basis to the willingness to co-operate. This is also confirmed by Phelan et al. (2016) and Leon et al. (2015). The principle of context-dependency we have identified with regard to the information willingness of the subjects is also supported by various studies (Acquisti & Gross, 2006; Denning, 2014).

Overall, the willingness to disclose personal information in situations of acute danger (terror, war, natural disasters, etc.) is as follows: The more intimate the type of information, the lower the approval of the subjects. Telephone numbers, addresses and location information belong to the data that is not considered critically intimate and would be communicated by a large portion of subjects.

5.2 Perception of Privacy in Social Media and Surveillance

Regarding wishes and needs of citizens' concerning privacy as well as a possible monitoring of ethics by the state, we were able to obtain the following findings: More than half of the subjects approve of video surveillance of public space and regard public safety as a central task and the first and most important priority of the state (Figure 2, answer option "Security first"). Opinions in favor of video surveillance are made more likely by a generally positive view of surveillance, as approximated by consenting to internet surveillance and secrecy (as opposed to transparency), as well as a high net income. Possible causes for these views may lie in the Islamist terrorist attack by Anis Amri in Berlin in December 2016, or the various Islamist motivated attacks in Belgium, France or Great Britain since 2015. Especially the approval for video surveillance is plausible, since it has proven to be effective in relation to other crimes and their clarification. The general focus on security is also demonstrated by the fact that the subjects refuse public access to state information. Interestingly however, the relationship between opposing transparency and favoring surveillance is not constant.

Both data collection in Germany and on a global level are rejected by the subjects, especially the collection of information via internet is viewed critically by respondents. These could be impacts of the Snowden revelations, as well as general mistrust of internet surveillance measures, such as Degli-Esposti et al. (2017) describe it. But also with regard to this topic, large shares of neutral answers remain. This may be due to subjects not being sufficiently informed, simply not sure or in favor of measures for public safety but unable to oversee their consequences. Also, people endorsing transparency seem to be significantly more likely to consent to data gathering in Germany; although these two answer possibilities logically oppose each other in terms of security policy. All this makes clear that there is a need for enlightenment on measures to increase public safety. The same can be observed regarding the conditions for the abandonment of privacy: Above all, this means being aware of the nature of data potentially used by authorities. It becomes apparent, following Degli-Esposti et al. (2017), that subjects are not in need of an increased implementation of existing security measures, but rather a different implementation of existing and alternative security policies.

With regard to citizens' willingness to cooperate, we found that greater transparency and clarification by the authorities is required. Citizens are basically willing to make "superficial information", such as addresses and telephone numbers, accessible in dangerous situations. Given appropriate transparency on parts of the state, this also applies to parts of their privacy in social networks. The group opposing such measures seems to depend on the specific data to be shared. Although some models show the tendency that more educated and older people are less likely to share their data, this trend does not apply to model 3, which shows that older people are more likely to support Germany-wide surveillance. Similarly, a higher income raises the probability to support the implementation of video surveillance (model 1). A closer examination of the group in favor of privacy is necessary to make specific statements about the reasons underlying these trends. However, a non-linear effect of age on privacy attitudes might be a possible reason for what might seem at first sight to be contradictory outcomes. A first assumption can be made by relating to social media-affinity of the younger age groups and their need to express themselves on social media, while middle aged groups, not used to the openness of social media, are more likely to hide their private information. The older age groups could lack media expertise and therefore be willing

to share information (Reuter et al., 2017). Hence, the government has the obligation to provide specific education and enlightenment of its citizens, in order to increase their understanding of methods used by authorities. In this context, information transparency can be seen as a key factor to provide certain knowledge and foster a better understanding of these methods (Acquisti et al., 2015; Awad & Krishnan, 2006).

In general, a certain part of the population is prepared to give up parts of their privacy. People show a high willingness to share personal data in cases of immediate emergencies, even when demanding transparency, deletion of data, court orders, monetary incentives and self-determination about the usage of their data. At the same time, people with a low standard of privacy do not demand a law necessitating court orders for access to personal information.

Many neutral answers point out that the subjects have too little knowledge, are inhibited or simply cannot decide, respectively have concerns. In line with findings of Degli-Esposti et al. (2017; also see Kokolakis, 2017), a part of the respondents are not sufficiently informed to have an opinion. Especially the question concerning the willingness to give up parts of privacy in social media. Here, the most frequently chosen answer is "I'm unsure" (29%).

6 CONCLUSIONS AND PERCEPTIONS

In the following, we summarize the key findings of our study and focus on the most significant factors influencing the potential willingness of the subjects to cooperate. Finally, we discuss the limitations of our work, present possible perspectives for future research based on our findings and position our findings in the context of previous research.

6.1 Central Results: People Are Willing to Conditionally Give Up Privacy

The central question of our work on the willingness of the (German) population to resign parts of their privacy under certain conditions for crisis management and surveillance must be answered ambivalently. On the one hand, people are willing to do this to a certain extent. For this purpose, however, an adequate information-policy and transparency by authorities are needed. In particular, this includes self-determination in the use (about 59% consent) and confidentiality of the data, as for example the "right to be forgotten" allows (about 71% consent). Only then citizens no longer feel powerless and at the mercy of the state's surveillance activities.

A subject-related dichotomy with regard to the willingness to cooperate in social media in relation to the release of private information was identified above all by two characteristics: In particular, age and level of education have an influence on whether citizens make their private information available to the authorities. In terms of age, the regressions paint a diverse picture; age influences privacy-affinity positively in some respects and negatively in others. The educational level has a positive impact, however not constantly so: The higher it is, the more privacy-restricting authority rights are rejected (such as increased internet surveillance) and regulatory laws supported (such as court orders).

6.2 Limitations of our Work and Perspectives for Future Research

Our paper and the underlying survey have limitations concerning the methodological approach as well as the scope of the results. Because the survey was conducted online, neither an introduction nor any kind of background information were given to the participants. On the one hand, it must be stated that the respondents, although understanding the questions in general, did not necessarily understand the meaning of concepts used in the questions. On the other hand, this ensured unbiased answers of the respondents. However, in future research the used concepts should be introduced to participants to be able to get a more detailed and unambiguous insight into their mind set and opinion. Although a representation of the results and the subjects' socioeconomic properties are given, the online conducted survey only covers people who were willing to be part of this study. A bias towards internet affinity of the respondents is therefore possible. This would contradict the notion of the older participants lacking the necessary knowledge to be more critical towards surveillance. However, a general internet affinity does not necessarily imply an awareness for privacy. On the contrary, it can be assumed that people who are willing to register and share their opinion for a reward in such a panel are less concerned about their privacy than average citizens. Therefore, the analysis based on those participants is likely to underestimate skepticism towards privacy intrusions and the effect of education on it.

The sample is restricted to the German population, nonetheless our findings suggest to implicate more general correlations which may be apparent in other liberal democracies. Neither the expectations of German participants towards state authorities nor their interest in protecting their legal rights may be due to a specific German context. Furthermore, correlations between certain variables like income or education and people's attitude towards cooperation via social media may prove stable across borders as well. Nonetheless, the German historical background has to be taken into account, as it could cause a special relation to aspects of privacy and surveillance

by the state.

Our work can be elaborated with further questions regarding people's perception of privacy concerning social media and surveillance as our analyzed item-battery consisted of only three questions. Despite the meaningful results of our study, further and more in-depth questions are needed to interpret the neutral answer options. Relevant insights into the level of awareness people have concerning data exploitation and privacy intrusions in general, would encompass illuminating the reasons for people's opinions, as well as the consequences for their online behavior: The questions of why some people are more aware than others, and if higher awareness has any behavioral consequences are of central relevance. Moreover, the applied statistical methods, especially the multiple regression analyses, can be expanded. Qualitative methods should also be used to elaborate on this topic, especially to understand the neutral answers. Open questionnaires and interviews are suitable with a subsequent qualitative content analysis to cluster categories of the subjects. To get a deeper insight into the perception of privacy further research should focus on the connection between awareness for privacy and general knowledge about privacy issues, social media monitoring and surveillance measures.

6.3 Differentiation to Previous Research and Scientific Added Value

The theoretical premises of this paper are based on the work of Kasper (2005). We found that under some conditions (such as deletion after usage and transparency), a high number of people (26%) are willing to give up parts of their privacy in social media in order to detect terrorists. Thus, the threshold to allow for *inner-state* invasions (Kasper, 2005) is surprisingly low, given that the consequences (i.e. police measures against suspected terrorists) are rather severe. As shown in Model 5, in cases of emergencies even people with high standards for privacy (proxied by several conditions for state access to their data) are more likely to share their data. Keeping to forms of extraction, stockpiling, as covered by the first question (Q11), seems to be a differentially perceived form of privacy invasion. While most people are willing to share their address or telephone number, only few people are willing to share more intimate information, such as contents of chats or credit card details.

Now turning to forms of observation, a majority of respondents (70%) approves of *physical observation* as modeled by CCTV coverage of public spaces, whereas observation of *communication* and *behavior* are regarded critically by most. *Communication* was measured by granting the state access to exchanges of information via internet, which of course partly covers behavioral observation. The approval rate for this type of surveillance was 34%. An all-encompassing form of observation, i.e. gathering data on all German inhabitants without their knowledge, gained 23% positive answers. Thus, when combining several forms of *observation*, approval rates are particularly low. However, it needs to be kept in mind that with modern forms of communication and surveillance, every type of observation will reveal information belonging in either or both of the other two categories. Overall it can nonetheless be said that surveillance of communication and behavior, as well as extraction of intimate information, are particularly negatively perceived within the population. Keeping this in mind, it would be interesting to further examine people's opinions on data exploitation, as this encompasses most intimate data, but the discussion still has a very limited audience.

As Reuter & Spielhofer (2017) have shown, fundamental cooperation readiness is apparent but partly this seems to be associated with obligations of the state regarding transparency. We also considered the remarks by Degli-Esposti et al. (2017) on the unclarity of the population with respect to surveillance measures, the inherent frustration and the apathy-inducing effect on citizens.

ACKNOWLEDGEMENTS

This work was supported by the German Federal Ministry of Education and Research (BMBF) as well as by the Hessen State Ministry for Higher Education, Research and the Arts (HMWK) within CRISP as well as by the DFG within the CRC 1119 CROSSING.

We would like to thank Robin Gellert and Gordian Geilen for supporting the development of the survey items. In addition, their pilot study (Reuter et al., 2016) was a very valuable basis for this study.

ABSTRACT

Cybersecurity logs are permanently generated by network devices to describe security incidents. With modern computing technology, such logs can be exploited to counter threats in real time or before they gain a foothold. To improve these capabilities, logs are usually shared with external entities. However, since cybersecurity logs might contain sensitive data, serious privacy concerns arise, even more when critical infrastructures (CI), handling strategic data, are involved.

We propose a tool to protect privacy by anonymizing sensitive data included in cybersecurity logs. We implement anonymization mechanisms grouped through the definition of a privacy policy. We adapt said approach to the context of the EU project CIPSEC that builds a unified security framework to orchestrate security products, thus offering better protection to a group of CIs. Since this framework collects and processes security-related data from multiple devices of CIs, our work is devoted to protecting privacy by integrating our anonymization approach.

INTRODUCTION

Critical infrastructures (CIs) are either physical or virtual systems whose operation directly supports the functioning of a society. In fact, given the wide reach of critical infrastructures, even small problems on their operation could have a massive impact on a vast population (House 2013). Besides their reach, CIs are tightly coupled with sensitive areas such as health, telecommunications or economy, which are strategic for a country, so their interruption might imply severe affectation for citizens (House 2013). We are talking about the infrastructure of hospitals, transportation systems, oil and energy distribution systems, banking, environment monitoring, etc. Since these services are essential to the security, prosperity, and social welfare of the population, their corresponding CIs must not stop working and are usually managed by governments.

Given the importance of CIs, their information systems are usually strongly protected against intrusions, mainly against those coming from the Internet. Currently, the resources available for such protection involve "intelligent" cybersecurity solutions that “learn” how attackers behave and ultimately detect and stop future incidents. To do so, these solutions are fueled with so called logs, i.e., detailed information about past events, which are stored as records describing every security incident. Furthermore, logs from multiple sources are commonly shared among several devices and then aggregated so that more input information can improve the efficiency of protection . Aiming to ensure the continuity of their services, CIs have widely adopted such protection mechanisms that generate very detailed and vast information about the entities and interactions involved in security incidents.

Although more granular logs provide more intelligent security protection in CIs, inappropriate sharing of sensitive data may rise serious privacy concerns. Cybersecurity logs could include identifying attributes (IP addresses, user names, fingerprints, etc.), strategic information of companies (e.g., about vulnerabilities, software versions), and several other indicators (path names, user data) that, when disclosed, could easily be used to violate the privacy of the individuals or companies involved. The risk for privacy in this context is not only exacerbated by the increasing need of security services to aggregate shared cybersecurity data (to get improved protection mechanisms), but also by the large number of data items enclosed in cybersecurity logs.

Beyond the security they require to protect their information systems, CIs are more exposed to external attacks than conventional infrastructures due to a number of factors. First, since CIs commonly serve a large population, they are desired targets of attackers who aim at magnifying the impact of their offensive (Edwards 2018; Moyer 2010). Also, dealing with strategic processes and information, CIs are usually the target of high-level adversaries supported by powerful organizations and even governments (Swinford 2018; Woollaston 2017). These factors aggravate even more the effects of information leakage to the point that, e.g., the mere revealing of internal IP addresses or user names might imply severe risks for the integrity of such infrastructures. Interestingly then, the privacy of companies and individuals whose information is revealed in logs may have a direct impact on the security of CIs.

Our work is aimed at preserving the privacy of individuals and organizations in the context of the CIPSEC framework, and particularly in what involves the sharing of cybersecurity information. The EU project CIPSEC proposes a unified security framework to orchestrate state-of-the-art heterogeneous, diverse, security products aiming to offer high levels of cybersecurity protection. To do so, this framework is able to collect and process security-related data (logs, reports, events) so as to generate security anomaly alerts that can affect a CI health and that can have cascading effects on other CI systems. Our proposal includes a methodology and a tool (data privacy tool, DPT) for obfuscating sensitive data from cybersecurity logs to protect the privacy of the involved entities and individuals.

Namely, our DTP will modify sensitive data with the aim of *sanitizing* or cleaning it from too distinctive attributes. This involves applying several anonymization mechanisms to cybersecurity logs (suppression, generalization, pseudonymization) whose implementation will depend on the specific anonymized attributes.

THE CIPSEC FRAMEWORK

CIPSEC objectives

The main objective of the EU project CIPSEC is to create a unified security framework that orchestrates state-of-the-art heterogeneous, diverse security tools and offers high levels of cybersecurity protection in IT & OT Critical infrastructure environments. The framework is currently built to collect and process security-related data (logs, reports, events) so as to generate alerts for security incidents that can affect the integrity of a CI together with the potential cascading effect affecting other parts of the CI or event other CIs. The framework aims to be very flexible, adaptable and causing minimum interference to the normal operations of the CI, allowing for its easy updating when needed in a secure and easy manner.

The CIPSEC framework is capable of collecting events supported by different tools that monitor different aspects of the CI, such as network traffic, malware threats or wireless spectrum among others. Along with the operations for

collecting events there is also a reasoning capability based on correlation algorithms that generate alerts for the anomalies detected in the events collected. Additionally, the CIPSEC framework provides with additional services, transverse to the CI monitoring activity, which complements the activities carried out:

- vulnerability tests and recommendations, including cascading effect attacks; which allows to have a snapshot of the level of protection against cyber threats exploiting current vulnerabilities of the assets within a CI ;
- security information sharing, leveraging the report of security incidents either across the infrastructure or to the rest of the world, in order to, for instance, prevent incidents propagation;
- training services, assisting on the usage of the framework and on different characteristics of security management aspects, allowing for an easy training of security staff in the context of the CIPSEC framework;
- updating and patching mechanisms, with the purpose of having a unified view of the status of all the monitoring tools deployed in the infrastructure and giving the possibility to automatically update them, guaranteeing the timely protection against the latest security threats.

The CIPSEC framework is being validated in real environments using the infrastructure of three pilots that covers different domains: rail transportation, environmental monitoring and health sector.

CIPSEC architecture

For the sake of flexibility, the CIPSEC framework was designed to be independent from the underlying critical infrastructure (i.e., independent from the resources managed or the security requirements). The reference architecture of CIPSEC was conceived based on the flow of the data managed within a CI, or, said otherwise, was design to be infrastructure-agnostic by design. With this aim, the architecture is defined according to the life cycle of the security data (logs, events, reports) acquired, disseminated and consumed in CIs.

Data Acquisition refers to the process of collecting or storing the information (logs, events) generated by end devices devoted to secure the integrity of CIs. Thus, there are multiple sources of this data, e.g., intrusion detection systems.

Data Dissemination covers the transmission of the acquired security information to the components that will further process it. The dissemination of this data is usually performed in real-time describing the multiple processes carrying out in a CI, so that they can be monitored and controlled. In the context of CIPSEC, the information disseminated encompasses security data related to events, alarms, updates, etc.

Data Consumption concerns the processing of the acquired security information after being disseminated to the relevant consumers (e.g., incident correlators). Such information is processed and interpreted to fuel several assessment tools that enable users to make informed decisions.

Figure 1 depicts the architecture of the CIPSEC framework based on a group of layers that follow the flow of security data described above. This illustration also shows how the security data travels from the CI to a user interface so that the system admin can take appropriate decisions based in the processing activities carried out by the framework, such as enforcing mitigations or applying contingency plans.

The acquisition layer obtains a lot of information directly from the CI components dedicated such as vulnerability assessment, identity access management, integrity management, endpoint detection and response, and cryptography. The information collected is aggregated and processed by a component called anomaly detection reasoner that triggers security alerts depending on the patterns devised in security data.

The *data processing* layer is on top of the acquisition layer and involves two main components: the DPT and the forensics service. While the forensics filters and analyzes indicators potentially useful for forensic analysis, the DPT aims at preserving privacy in the security data coming from the CI and at storing such sanitized data in a different database for sharing purposes. This component is the one whose implementation we present in this paper.

The *presentation layer* aggregates the information produced by the underlying layers through a dashboard that offers a user interface where statistics and evolution indicators are presented to illustrate the security status of the whole CI. Such interface provides with an aggregated and uniform view of this status to the user in order to facilitate decision-making processes.

Finally, other complementary services are also provided by the architecture in order to guarantee the support to end users, the compliance with the CIPSEC framework, and the continuity of the services.

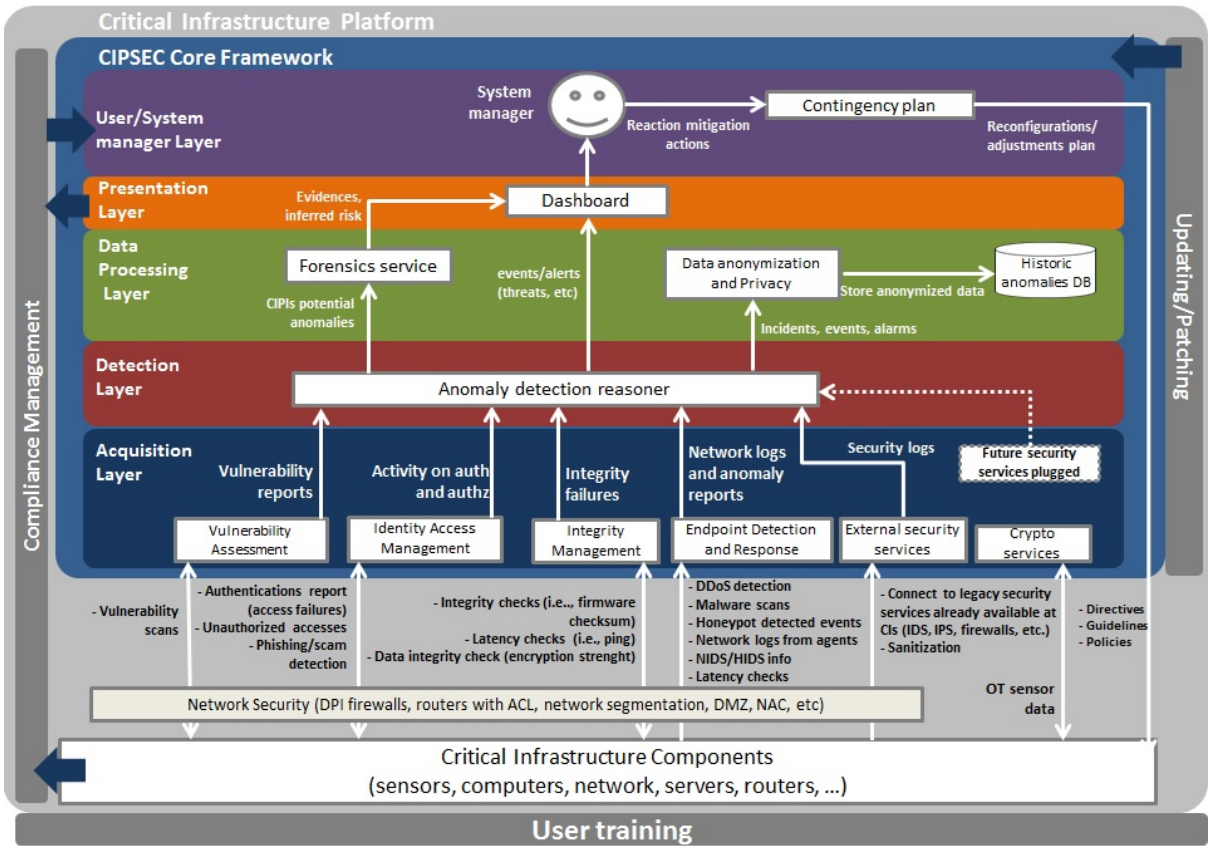

Figure 1. CIPSEC Reference Architecture for protecting of critical infrastructures.

DATA PRIVACY TOOL

Background on cybersecurity logs and privacy protection mechanisms

Logs are pieces of information that sequentially register the events affecting a system; therefore, when seen aggregated, they constitute evidence of the system behavior. Said diagnosis is fundamental to scrutinize and then fix a given issue, even more in the cybersecurity realm where thousands of attackers are permanently generating incidents that threaten the integrity of critical systems connected to the Internet.

Usually, logs contain a lot of granular information on the related event, starting with a time stamp. Cybersecurity logs may include, e.g., IP addresses, process IDs, hardware information and event descriptions.This information is stored in text files formatted to guarantee its agile reading and processing. For instance, two formats extensively used to store logs are XML and JSON. Both have interesting features based on labels to present information as name-value pairs, e.g., "ID: 123456" or "Alarm type: critical". Namely, the attributes or information elements of a log are organized using a name (or label) of the attribute and its corresponding value (the raw data). This way of representing information in logs significantly facilitates further selection and replacement (transform) of sensitive attributes.

Roughly speaking, protecting said information against privacy threats builds on these two operations: *selection* of sensitive attributes in the logs and *transformation* of corresponding values to a more private version. This is more deeply described in this document, where our proposal is presented. Although the definition of said operations depend on the context (sharing policies, organization concerns, etc.), the modern ways to structure logs are decreasing the complexity of performing these operations of selection (search) and transform (replace).

First, to protect privacy, sensitive attributes (the target) must be defined and then detected in logs. In practice, this task consists in searching for specific information in plain text. Given the vast log data that cybersecurity systems could generate, such searching for specific items might be daunting if it is expected to be done manually by a human operator. Fortunately, technology can now be used to automatize the detection of this type of attributes. Moreover, the most common logging formats are based on labeling every single piece of information contained in the log. Thus, once the sensitive attribute (or its label) is defined, it is not difficult to retrieve it from the logs along with its value. If the data within logs were not appropriately formatted, sensitive information should be located by looking

for specific syntax patterns that such information present in logs. For instance, if IP addresses were considered as sensitive information, the privacy protecting approach could start detecting IP addresses in logs by resorting to its unambiguous syntax. Then, searching for a pattern of four numbers separated by dots would eventually lead the system to find said IP addresses. Regular expressions are powerful constructions that can be used to represent and search such patterns.

After finding the attribute in cybersecurity logs, it has to be protected to preserve the privacy of involved companies or individuals. This implies modifying or transforming the value of the attribute to obfuscate any sensitive information there contained. This task is also referred to as *sanitization* in the sense that it "cleans" data from too distinctive attributes. To do so, some anonymization or sanitization mechanisms are commonly implemented. These mechanisms are described in the following lines.

Suppression is the simplest strategy to protect privacy in this context. It consists in completely eliminating sensitive information, which can be interpreted as replacing it for a blank or any meaningless string. This implies that no trace of said sensitive data is left which may directly affect the utility of the logs.

Generalization is rather a less destructive anonymization approach. It builds on replacing sensitive information with more general but still meaningful data. For instance, if the sensitive piece of data is the IP address 192.168.1.1, a generalized version would be 192.168.0.0. In contrast with suppression, generalization could keep some utility from the data in log records, depending on the deep of generalization attained.

Pseudonymization is a mechanism that consists in replacing identifying information by artificial identifiers, also called pseudonymous. Since said pseudonymous would be used instead of the original identifier, each time the latter appears, it is possible in practice to recover the original information from its pseudonymized version. Also, if such identifiers are only used for identifying purposes, pseudonymizing them would not affect the utility of information.

As briefly described, the resulting utility of cybersecurity logs may be more or less affected depending on the anonymization mechanism used to protect privacy.

Privacy risks from disclosing cybersecurity logs

In general, logs contain a lot of information since they are aimed at describing the state of a system at a given point in time. Further, an aggregated set of logs should enable an administrator to have a general view of the performance of said system. In particular, the specific amount of data items (we will call them attributes) present in a log record will depend on the level of granularity set in the logging service. Interestingly, some equipment, e.g., networking devices, allow to be configured with such high levels of granularity that manufacturers explicitly warn about the risk of saturating storage or processing resources. Thus, logs could become extremely detailed pieces of data describing a system where companies and individuals are involved.

Cybersecurity logs might include very sensitive data since they are commonly associated with vulnerabilities and security threats. If that information fell into the wrong hands, it could cause severe damage to the data owners. Besides, the level of granularity of security logs is usually higher to afterwards enable the detection of security breaches (which use to be provoked by undercover interactions), so more and more attributes are included in logs to improve protection to the same extent. As a consequence, the potential leakage of this information implies serious privacy risks for the entities involved, not only due to the weaknesses that such logs could reveal to attackers, but also due to the increased detail of the information.

Ironically, the risk of leaking this information does not necessarily come from deliberate attacker intrusions to steal it, but from the voluntary release of such logs when sharing them to other partners. In fact, sharing cybersecurity logs has become a common practice among organizations as a collaboration mechanism to enhance the effectiveness in detecting and preventing security threats. The attributes characterizing a security incident in a system, e.g., IP addresses, file names, sizes, can be shared with system administrators with the aim to help other systems detect or prevent related threats. More specifically, information sharing enables sharing partners to enhance their defensive capabilities, i.e., detecting, responding, and recovering from cybersecurity incidents. As a matter of fact, the collective aggregation of shared security logs is currently the main input fueling powerful antivirus and network security devices.

Despite the great benefits that sharing cybersecurity logs may bring, some challenges still remain. One of said challenges is safeguarding sensitive information that might be included in these logs, i.e., protecting the privacy of the entities whose information is shared. The violation of privacy in this context (e.g., due to the disclosure of personally identifiable information) may have serious consequences, particularly for companies, such as the ones listed below:

Table 1. Some attributes whose disclosure in cybersecurity logs might jeopardize privacy.

Attribute	Privacy risk
IP address	May enable identification of users and organizations.
e-mail address	May enable identification of users and organizations.
path names	Could disclose user names, directory hierarchies.
patching information	Could reveal software updating calendars, thus when
software versions	Along with other attributes, could enable fingerprinting and identification of users.
incident description	When associated with an origanization, could unveil its vulnerabilities.
organization name	May allow attackers to identify an organization.

- financial loss,
- legal action,
- loss of reputation,
- exposure to protection capabilities.

As explained above, the nature of cybersecurity information contained in logs is inherently sensitive since it includes several attributes and also some very punctual data items that may reveal strategic operations of systems regarding their security. Virtually every computing device and application are enabled to generate this type information, especially if they engage networking or Web interactions. Some examples of sensitive information that could be included in cybersecurity logs are described next.

Timestamp. A time stamp is fundamental to determine the moment when an security incident occurred. The exact date and time of the incident allow to correlate other events that could contribute on the investigation of the threat. However, if coupled, e.g., with individuals, temporal data could also help attackers perform the same correlation to unveil patterns (a person's sleep time, a company's patching calendar) to violate privacy.

IP address. IP addresses individuate devices so that security issues can be associated with the entity where the incident has been generated. Nevertheless, in the same line, IP addresses are key information for privacy attackers to identify the individuals and companies involved. In fact, an IP address could unequivocally represent an individual or a family, so the security logs related to their interactions would reveal such tight association. The mere availability of this information enables further security attacks (denial of service, fingerprinting) to companies, which could reveal even more indicators about potential victims (privacy violations).

IP addresses are not the only data items with this individuating capability. Other attributes that may appear in security logs such as user names, host names and MAC addresses have similar identification capabilities, although their presence is not as common as IP addresses. There are also apparently innocuous indicators that are contained in cybersecurity logs that can serve as identifying parameters when combined, e.g., software version and patch level information, hardware information, system event, file access, etc. Interestingly, the resulting combination of said attributes can be seen as a fingerprint of the associated entity and could be used as an identifier by itself.

Any indicator or attribute included in logs could reveal further sensitive information. The specific privacy risk, however, depends on the context, i.e., on the background information available for the attacker, and his objective, but also on the particular status of the potential victim. For example, path names could disclose information about the work a user might be performing, or operating system and patches names may reveal the preferences of a company regarding their network or software implementation (which it had been keeping secret). Disclosing such information in logs that will be shared may represent a privacy violation for users or the company whether or not the parameters included are critical for each entity.

Besides identifying attributes or other complementary indicators, the information included in cybersecurity logs may be very specific when generated by specialized devices such as routers, antivirus servers, intrusion protection systems, forensic toolkits, SIEMs (security information and event management systems), etc. Moreover, these logs contain very critical information since it is commonly derived from assessment routines, i.e., contemplates "refined data" (which in practical terms implies more and more valuable data). This information might span vulnerability alerts, system artifacts, attack alerts, or summary reports, whose disclosure is a direct threat for the privacy of the entities involved.

The risk to privacy when sharing cybersecurity logs is seriously exacerbated when CIs are involved since the corresponding entities and their workers are more exposed given the strategic role they are playing. In Table 1, we describe some attributes whose disclosure in cybersecurity logs may imply serious privacy risks.

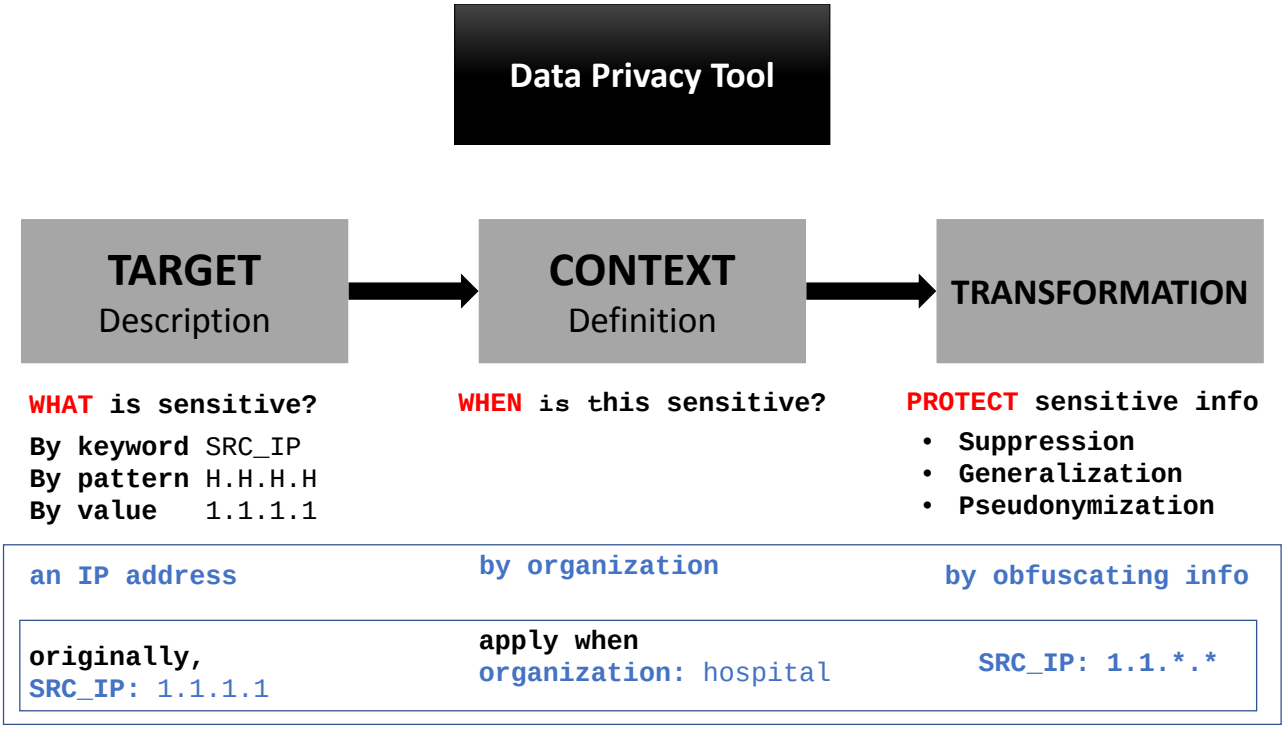

Figure 2. Architecture of the data privacy tool.

Architecture of the data privacy tool

The objective of our DPT is offering privacy for individuals and institutions in a context where cybersecurity logs have to be shared among different partners. While disclosing and aggregating such data may improve the capabilities of security solutions in CIs, the high granularity of logs and the sensitive attributes there contained may jeopardize privacy. Thus, we devise a tool to protect this sensitive data by anonymizing it. This tool encompasses the components described below.

Target description

The first step in protecting privacy in cybersecurity logs is determining the set of sensitive attributes that will have to be sanitized. Said otherwise, the specific target of the anonymization mechanisms has to be defined since logs use to hold a lot of information.

The level of sensitivity, however, depends on the specific context in which users and companies perform (their interests, needs, worries, adversaries, etc.). Moreover, although some attributes might be defined as sensitive by default (e.g., identity numbers), or automatic mechanisms could be created to "recognize" them, the operators of the DPT should always have the last word when deciding what attributes to protect by defining a privacy policy.

Evidently then, to locate sensitive attributes and their values within the data provided by logs, some language might be necessary for the user to describe the corresponding targets. If logs were generated by CIs without any visible structure, patterns should be found to detect the sensitive attribute, e.g., looking for quartets of decimal numbers separated by commas to find IP addresses (which the operator would have defined as sensitive). Fortunately, to facilitate its exploitation and analysis, logs are commonly generated in structured formats, sometimes even in hierarchical trees, such that the information be organized according to certain logic and that every attribute value is labeled.

As logs are presented through standard approaches and attribute values are indexed through labels, it is straightforward to refer to such attributes to then retrieve their values. For instance, let us suppose that the operator is interested in preventing individuation of his company in the logs generated by their devices. Thus, he might have to detect identifying data in logs, such as IP addresses, to anonymize them and protect privacy. There may be different approaches to search for IP addresses in a log, as described below.

- **By keyword.** Within cybersecurity logs, IP addresses are usually labeled with a keyword such as SRC_IP (source IP) or DST_IP (destination IP) or any other. Knowing such keyword, it is pretty easy to obtain the sensitive value associated in the corresponding log.

```
{'AlarmEvent': {
'USERNAME': '', 'SRC_IP': '188.112.63.117', 'BACKLOG_ID':
'839301cfd5b54179847535ffa3e29adc', 'DATE': '2018-07-17
09:00:16',

```

Figure 3. Sample of logs generated by the CIPSEC framework.

- **By pattern.** If the sensitive data to be anonymized is not systematically associated with an index or label, a pattern could be used to look for such data. In the IP address example, e.g., we could look for any group of four numbers from 0 to 255 separated by dots, which could be symbolically represented as X.X.X.X.
- **By value.** Still in the case when no specific keyword is available, the value of the sensitive attribute could be directly searched in the logs. The drawback of this approach is evidently that this search spans a single value while the firs two may encompass a wider spectrum of values.

Since the first step to protect privacy in cybersecurity logs involves searching for a string (keyword, pattern or value) in a piece of text, it is worth noting that, at an implementation level, the use of regular expressions is highly recommended for such tasks. See Figure 2 where this component of target description of our DPT is depicted as it would work with the other two components described in the next subsections.

Context definition

As stated in the previous section, the sensitivity of some data item is subject to the context where its owner performs. In the same line, the privacy protection mechanism required will vary according to the specific needs and characteristics of the subjects involved. The context-definition component then enables the user of our DPT to set any restriction or condition on the application of the privacy protection strategy.

While a lot of restrictions could be integrated, there is one in which we are interested for the CIPSEC framework. Since three different pilots or organizations are sharing their cybersecurity logs, the user of the DPT could opt for anonymization or not depending on the organization he belongs to. For instance, air quality monitoring might not involve sensitive attributes for the organization generating such data so could decide not anonymizing their data. Other more complex scenarios may be characterized, e.g., by a company having very specific needs on anonymizing attributes that in other contexts might not be critical to protect. In brief, the scope in which our DTP is used may also define the operation of the DPT.

In Figure 2, we illustrate this component within the whole architecture of this tool.

Transformation

Once sensitive information and context are defined, sensitive data has to be transformed in order to protect privacy. Said transformation implies perturbing attribute values so that, e.g., identifiers no longer serve to identify individuals, or that sensitive values provide less specific information regarding individuals or companies.

The transformation component in the architecture of our DPT is implemented through the anonymization mechanisms described in Section 3.1. As explained above, such mechanisms will replace the original sensitive value with another (at least less specific) string. Figure 2 shows how this component is integrated in the architecture of our DPT.

It is worth noting that when transformation has to be done dynamically (i.e., when replacing according to a a predefined pattern), regular expressions are also very useful as with target description.

```
"SRCIP":{
      "ORGANIZATION":"all",
      "ACTION":"generalization",
      "TYPE":"ip_address",
      "KRE":"^SRC_IP$",
      "VRE":"",
      "SRE":""
},
"USERDATA":{
         "ORGANIZATION":"all",
         "ACTION":"suppression",
         "KRE":"^USERDATA*",
          "VRE":"",
         "SRE":""
},
```

```
"ORG":{

      "ACTION":"pseudonymization",
      "TYPE":"organization",
       "KRE":"^ORGANIZATION$",
      "VRE":"",
      "SRE":""
 }
```

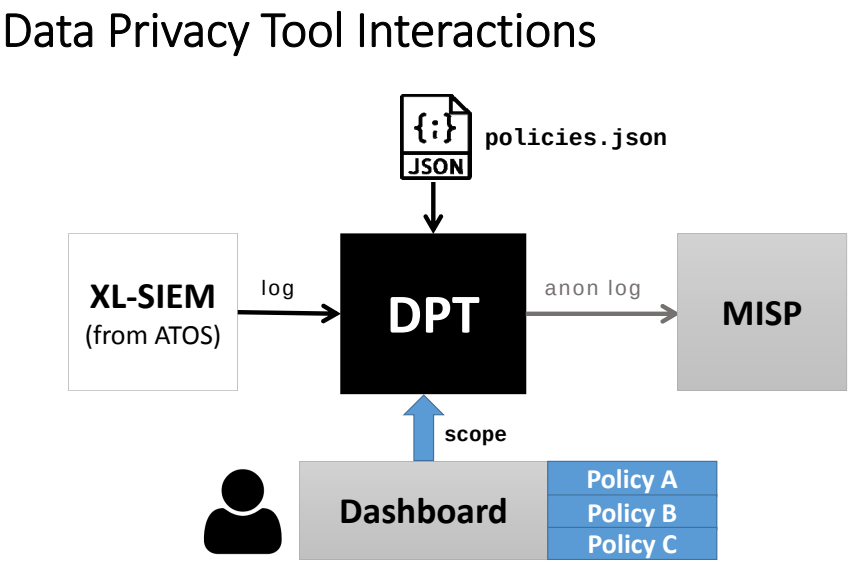

Figure 5. Interactions of the DPT with different components of the CIPSEC framework.

Privacy policies

In order to enable users to set the context of their privacy protection, a privacy policy has to be defined. A privacy policy is essentially a list of named rules that include the parameters that characterize the anonymization of sensitive information, i.e., the description of the specific attribute to be anonymized, the transformation mechanism to use, and any other criterion (e.g., the organization whose logs will be anonymized).

IMPLEMENTATION AND INTEGRATION IN THE CIPSEC FRAMEWORK

As explained throughout this article, cybersecurity logs enable the intelligent protection provided by the CIPSEC framework. Meanwhile, our DPT aims at preserving the privacy of individuals and organizations involved in such logs when shared among different partners. All the logs generated by several security devices in the CIPSEC infrastructure are aggregated and formatted in standard JSON format in real time to then be stored in a security information and event management server (XL-SIEM). Figure 3 depicts a sample of these logs that are further available for sharing in a Malware Information Sharing Platform (MISP).

As mentioned in Section 3, our DPT has three main inputs that guide the anonymization process: the cybersecurity logs that are fueled by the XL-SIEM; a privacy policy, also as a file formatted in JSON (an example is depicted in Figure 4); and a scope that indicates the organization that is executing the anonymization process. The latter

argument enables the user to anonymize only the logs that belong to his organization. After logs are anonymized, they are sent to the MISP for sharing purposes.

Finally, for the sake of usability, the control of the execution of the DPT and the selection of the privacy policy is delegated to a graphical user interface integrated in the dashboard of the CIPSEC framework. Figure 5 illustrates the components mentioned in this section and their corresponding interactions, while Figure 6 shows how a single anonymized log record would look. As a side note, our DPT is implemented using Python.

Related work

The concerns on the privacy risks from cybersecurity data are not new. The Government Accountability Office (GAO) of the USA already reports in (*High risk series: An update. Ensuring the security of federal information systems and cyber critical infrastructure and protecting the privacy of personally identifiable information* 2015) how the advances in technology have given rise to important challenges to ensure the privacy of personally identifiable information. The GAO recommends implementing privacy practices to protect personal identifying information, especially when managed in critical infrastructures. But in a wider scope, severe regulation is currently been applied in the USA and Europe (*General Data Protection Regulation (GDPR)* 2016) to protect privacy at every context, essentially by given users great control over their data. Though these documents acknowledge the increasing need to protect privacy, they are regulatory approaches that require implementation according to the specific domain.

Several approaches can be found in the literature that describe privacy preserving mechanisms on unstructured data (e.g., any type of log data). Those mechanisms are based on sanitization (through suppression, generalization, or any kind of perturbation) of such data. Some works address related mechanisms (Sánchez and Batet 2015), not only focused on protecting privacy but also on preserving the utility of sanitized data (Sánchez, Batet, and Viejo 2014). Interestingly, some of such approaches even consider the semantics of the text to be sanitized to get more efficient mechanisms (Sánchez, Batet, and Viejo 2013; Chakaravarthy et al. 2008). Unlike those works, our approach focuses on privacy preserving within cybersecurity data in the particular context of the CIPSEC framework.

With regards to the exchange of threat information several initiatives are exploiting their possibilities. For example, the DiSIEM project [1] uses it to empower Security Information and Event Management systems by exporting and importing data about incidents detected, allowing for the update of detection rules according to the information imported. DiSIEM also uses MISP as platform for the exchange of information although the privacy considerations are something not considered so far. Also, in 5G networks it is considered the usage of Threat Intelligence Exchange capabilities to import and export incident information across the network slices considered in 5G infrastructures [2].

CONCLUSIONS

Cybersecurity data generated in the form of logs is very prone to including sensitive information about individuals and organizations, even more so when such logs belong to CIs. The strategic importance of such data, then, makes those individuals and organizations common targets of privacy adversaries. The EU project CIPSEC integrates the cybersecurity information systems of three CIs to improve their threat detection and reaction capabilities. However, since this integration involves sharing such cybersecurity data, there are privacy risks that must be tackled.

The solution we propose addresses this issue by pre-processing logs to anonymize sensitive attributes according to a privacy policy that defines a particular context. Enabling users to set privacy policies is definitely the most important and complicated task since many factors have to be considered to define not only what data to anonymize, but also when and how. Fortunately, the logs generated by information systems are currently represented using more structured and flexible formats (e.g., JSON), which, along with the power of regular expressions to define context, significantly facilitate matching and dynamically perturbing string-based attributes.

As a work in progress, there are several avenues to enhance our privacy tool. Perhaps the most important pending work has to do with assessing the impact of the anonymization mechanisms on the practical utility of cybersecurity logs. Undoubtedly, data perturbing strategies reduce the quality of of the information involved so a balance must be reached to protect privacy while minimizing utility loss. Moreover, standardization of the definition of privacy policies is necessary to simplify the configuration of the anonymization mechanisms. This could be a daunting task so automating it according to the requirements of users and organizations might certainly help. Furthermore, a challenge in data sanitization is the reidentification risk posed by inferences based on several attributes exploited simultaneously. Finally, in the same line, more usable (probably graphical) interfaces could be developed to enable end users to provide the parameters of a personalized context in order to better guide the anonymization process of cybersecurity logs.

ABSTRACT

While accepted as part of critical infrastructure (CI) resilience, no consensus exists on how to measure the exact minimum level of service or the rapidity of rapidly restoring services. The H2020 European project IMPROVER (Improved risk evaluation and implementation of resilience concepts to critical infrastructure) suggests to use the public's declared tolerance levels for both minimum level of service and rapidity of service restoration as criteria with which to evaluate if the resilience of a given CI is resilient enough. This paper demonstrates the development of a questionnaire-based methodology to determine public tolerance levels. It then tests this methodology via a pilot case study at IMPROVER's Hungarian Highway Living Lab. The paper argues that public tolerance levels are a reasonable choice for resilience evaluation criteria and demonstrates that the questionnaire-based methodology permits one to evaluate public perception in such a way as to compare it to technical resilience analyses.

Keywords

Critical infrastructure, resilience, questionnaires, tolerance triangle.

INTRODUCTION

Critical infrastructure (CI) resilience is defined by the H2020 European project IMPROVER (Improved risk evaluation and implementation of resilience concepts to critical infrastructure) as: "the ability of a CI system exposed to hazards to resist, absorb, accommodate to and recover from the effects of a hazard in a timely and efficient manner, for the preservation and restoration of essential societal services," which is adopted from the UNISDR (United Nations International Strategy for Disaster Reduction) definition. Thus, key parameters associated with CI resilience are both the ability to maintain a minimum acceptable level of service and the ability to rapidly restore full service in relation to a crisis event on the CI system. However, no consensus currently exists on how to measure these elements. Furthermore, once measured, how does one know if one's CI is resilient enough?

To answer these questions, IMPROVER has designed a framework: IMPROVER Critical Infrastructure Resilience Framework (ICI-REF), which proposes a relationship between CI resilience and CI risk assessment (Figure 1) (Lange et al., 2017). ICI-REF maps resilience management onto common risk management frameworks (such as ISO 31000). Within this framework, *resilience assessment* is made up of both *resilience analysis*, where the given level of resilience which a CI has (in response to an identified threat and within a given resilience domain if appropriate) is identified, and then *resilience evaluation* whereby the results of the *resilience analysis* are compared with some criteria to determine if the resilience is adequate or if further action is required to improve it.

The IMPROVER project has suggested to use the public's declared coping capacity as criteria for *resilience evaluation*. Indeed, previous work within the IMPROVER project has found that the general public, end users of CI services, appear to have reasonable expectations of CI operators in crisis times (Petersen et al., 2017a; Petersen et al., 2017b; Petersen et al., 2018a). The public's reputation for having too high of expectations appears unmerited; they are willing to cope in times of crisis. Further, this better aligns the idea of resilience to the purpose of CI, namely to deliver services to society. As an added bonus for CI operators, going beyond meeting needs to meeting expectations helps maintain reputation during a crisis (Barker, 2013).

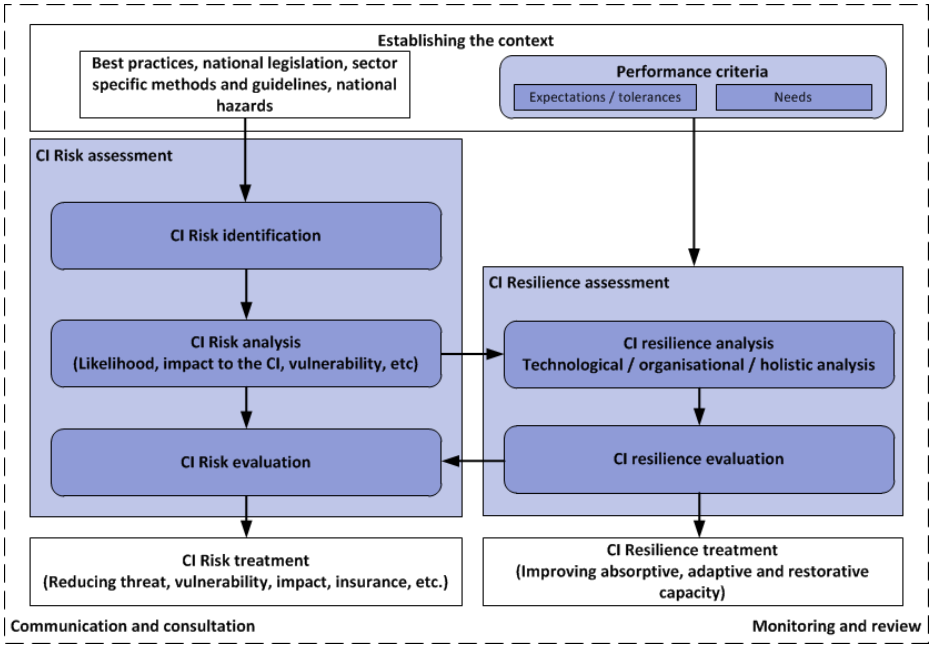

Figure 1 IMPROVER ICI-REF. CI operator risk and resilience management process (note that 'Communication and consultation' and 'Monitoring and review' are continuous processes which should interact with all other processes)

We propose to use a questionnaire survey in order to determine the public's perception of their own coping capacity in crisis times. Previous research has shown that people are good judges of their ability to deal with disturbance and change (Nguyen & James, 2013). The idea of people being able to accurately judge themselves has been used successfully in psychology, well-being and subjective resilience domains (Jones & Tanner, 2015). Furthermore, previous research into customer preferences and satisfaction has also used questionnaires to establish coping capacity in times of reduced service (OECD, 2001; Centre for Transport & Society, 2015; Transport Focus, 2017). The goal of the questionnaire then is to have a comprehensive understanding of the local population's expectations and tolerance levels. It is important to remember that it is the public's own views that are of interest here. While, as seen in Figure 1, within ICI-REF understanding the tolerances of the population falls under *establishing the context*, it is necessary that the questionnaire is designed in such a way that the results will be comparable to the results of the *resilience analysis* during the *resilience evaluation* part of the framework.

Within the IMPROVER project, a pilot test of such a questionnaire for a highway infrastructure was carried out. Similar work was carried out for a municipal freshwater network (Petersen et al., 2018b).

Public expectations for highways in crisis times

The relative importance of transportation infrastructure in ensuring emergency response, providing accessibility to other critical infrastructures for their recovery and in the day-to-day lives of citizens explains the high expectations for transportation infrastructure during and after a disaster (Petersen et al., 2017b). There is an expectation that a minimum level of mobility can be achieved, even if that requires a change in means of getting around (Petersen et al., 2018). Previous research has shown that the public is willing to tolerate reduced transportation service in terms of reduced capacity or frequency, diversion or alternative means for a period of months (Petersen et al., 2018). Recent research into public tolerance levels to a change in service of the Oresund Crossing due to the refugee crisis in 2016 using both questionnaires and a case study found that the public was willing to tolerate service disruption in times of crisis (Petersen et al., 2017a). Another recent study of the Oresund Crossing asked users "do you have a plan B?" in the case of service disruption and found that respondents felt capable of coping with short, medium, and long-term disruption scenarios (Dahlberg, 2017). When highways are

no longer operable due to a crisis, the public appear to expect an offer of public transporation to be made available based on survey results from victims of both the 2011 Great East Japan Earthquake and the 2010-11 Queensland Floods (Regional Australia Institute, 2013; Nakanishi et al., 2014).

However most previous research into public expectations/tolerances/satisfaction of transportation infrastructure does not investigate crisis times but instead "normal" times or planned works. Much research in this area has focused on user satisfaction with roadways by evaluating travel time, reliability of travel time, and delays in travel time (OECD, 2001). Unsurprisingly, the greater the delay experienced by the user, the worse the impact is on user satisfaction (Centre for Transport & Society, 2015). However, satisfaction surveys also demonstrate that the cause of the delay affects expectations, whereby accidents and "unexplained incidents" are mainly accepted by users as unforeseen events (Transport Focus, 2017), further demonstrating that people are willing to adapt after a crisis. Lastly, once a delay is communicated to the users, users are willing to accept it as part of their normal mobility, meaning that there is not a reduction in satisfaction due to the stated delay (Centre for Transport & Society, 2015; Transport Focus, 2017).

Hungarian M1 Highway Living Lab

The IMPROVER project uses Living Labs in order to study various aspects of CI resilience. Living Labs are a research concept that create an open-innovation ecosystem and use a systematic user co-creation process. This means the actors of a Living Lab are not simply subjects but also active participants in the research process. Thus, qualitative methods such as semi-structured interviews are carried out with the actors of the Living Lab. Living Labs have been the focal point of the scientific work carried out within IMPROVER and have been used to test various project methodologies, including the creation and implementation of tolerance questionnaires.

The M1 Highway is one of the most important highways in Hungary, serving the north-west part of the country (Figure 2). It is a transport infrastructure of importance at both national and European scale as it provides passenger and freight transport between the country's capital, Budapest, and two neighbouring capital cities: Vienna in Austria and Bratislava in Slovakia. The M1 highway is operated and maintained by Magyar Közút Nonprofit Zrt. (Hungarian Public Road Non-Profit Plc. - Közút). They were established in 2005, starting in 2014 were owned by the Ministry of National Development and since 2018 are owned by the Ministry for Innovation and Technology.

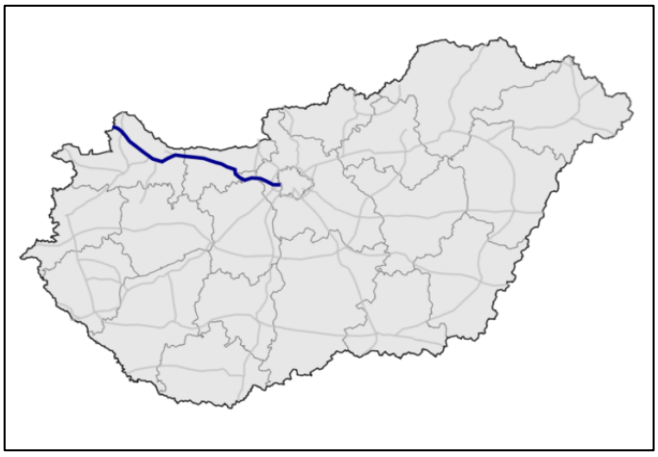

Figure 2 The IMPROVER Living Lab of the M1 Hungarian Highway shown in blue on the map

Several hazards may influence the highway network, including snowstorm, earthquake, flooding and collision leading to serious damage of bridges. A recent snowstorm that impacted travel on the M1 highway occurred on March 14, 2013 leading to a 3-day closure, where trucks were stuck, traffic was diverted to Road 1, the army had to intervene and evacuate cars, and which affected a total of 17,000 people. The effects of the crisis were heightened due to the combination of the storm occurring the day before a major Hungarian holiday, leading to an already increased rate of road traffic, and a swift change from spring-like weather to a winter storm. Another recent crisis event occurred on 19th May 2010 when flooding led to a 2-day closure of the M1 Highway, causing major traffic disruption, including cross-border traffic to and from Austria. The tender for restoration amounted to a total of 100 million HUF (ca. 437.000 USD at the time of the incident). (Honfi et al., 2018)

METHODOLOGY

Establishing the context

As stated in the introduction, if the results of the assessment of public expectations are incompatible with the resilience analysis, it will be difficult to use them as criteria for resilience evaluation. Thus, public perception of their own coping capacity in crisis times must be obtained in a way that is comparable to the technical performance measures of the service in question. In addition, the defined functionality and ways of measuring performance need to reflect one another. Within the IMPROVER project a resilience analysis using the IMPROVER Technical Resilience Analysis (ITRA) methodology is defined (Honfi et al., 2017). ITRA is currently being applied to the Hungarian M1 Highway Living Lab, however outside the scope of this paper. Through interviews with the living lab, it was discovered that highway performance is considered normal if, on the considered section, the highway is fully open for traffic and traffic flow is continuous without queuing. In such a case, the traffic demand is less than the actual capacity of the highway. As such, the main function of the M1 highway used for these studies was defined as being able to provide undisrupted traffic of passengers and goods, while ensuring user safety. The performance measure then to study this functionality was the travel time between selected origin destination pairs. Questions then were asked about the applicable performance measures of additional journey time and duration of additional journey time. Other factors influencing tolerance levels such as alternative routes and information provision were taken into account by inclusion in the detailed scenario (see below). In order to develop the questionnaire with a view to real world performance capabilities of operators, a combination of desk research and semi-structured interviews with the living lab operators were used.

The questionnaire was designed as an online questionnaire. The target population was adults aged 18+ who are users the M1 Highway, excluding professional users (i.e. lorry drivers). Convenience sampling was used. The questionnaire was registered with CNIL (French authority for digital privacy) and reviewed by the project's Ethics Officer. Respondents were informed of their right to withdraw from the project at any time and that the anonymised data from the questionnaire could be used in publications, presentations and reports. The questionnaire was published in English and Hungarian to best meet the linguistic needs of the user population. Unfortunately, despite the highly international character of the highway, researchers were unable to translate the questionnaire into German or Slovak. Data collection was held between 24 April 2018 and 10 June 2018.

The questionnaire began by asking respondents about their typical M1 highway usage and also investigated disaster preparedness, risk awareness and previous disaster experience of respondents. This is because expectations have been found to be influenced by these factors (Petersen et al., 2018).

Technological resilience is typically hazard dependent, having a strong link to risk analysis. Thus, in order for the results of the questionnaire to be comparable, the same hazard scenarios were considered here. Although the hazard assessment identified several potential scenarios, the two chosen for further study were a collision and a severe snow storm. These were chosen based on the interest of the operators via interviews. The collision scenario was important to Magyar Közút as they are responsible for the management of the Hungarian bridge stock, and the severe snow storm scenario was of great interest following the 2013 snowstorm crisis.

The following are the detailed scenarios that were presented individually to the respondents:

- Scenario 1: Imagine that a crash causes serious damage to a bridge on the M1 highway, leading to the closure of part of the M1 highway and prolonged delays. Users of the road will need to use deviations and will be informed ahead of time about increased travel times.
- Scenario 2: Now imagine that a heavy snow storm occurs in Budapest. Weather forecasting has predicted that there will be enough snow to impact traffic flows. Residents have been encouraged by local authorities to seek shelter and avoid traveling during the storm. Highway Operator crews have prepared the roads with salt and have used snowplows to keep the roads clear for as long as possible. However, now the M1 highway is no longer open, leading to prolonged delays.

After the presentation of a given scenario, the following two questions were asked. The first question was, "After [Scenario 1 or Scenario 2], how much additional journey time are you willing to tolerate when using a personal vehicle on the deviation route when travelling for…? Commute to work; Leisure (shopping, running errands); Holidays; Business trips." The times provided were: <20 minutes; 20 – 29 minutes; 30 – 44 minutes; 45 – 59 minutes; > 1 hour. This question aimed to capture the minimum level of acceptable service in regards to additional journey time.

The second question dealt with the duration for which an additional journey time would be tolerable. It asked, "After [Scenario 1 or Scenario 2], for how long would you be willing to put up with an additional journey time of…?" The time frames presented for the total crisis duration were different depending on the scenario. Based on the interview with Közút, the questionnaire recovery range for the collision (scenario 1) was proposed to be from less than 1 day to more than 1 month. The rather lengthy recovery time includes the reparation of the damaged bridge to allow for a full re-opening of the roadway. The recovery times of the snowstorm were based partly on

the estimates provided by Közút, who since 2013 have increased their response-ability towards snowstorm, and partly on desk research of various recent snowstorms around the world that led to highway closure. In both cases, snowstorms appear to be cleared in a matter of days, and thus the snowstorm (scenario 2) additional journey time duration was proposed as being from 1 hour to 1 week. This question aimed to capture what the public expected in terms of "rapidity" of recovery.

Lastly, the questionnaire asked about demographic information, as culture, gender, education level and socio-economic status have also been found to influence expectations (Petersen et al., 2018). Chi-squared tests were performed to explore any significant differences across responses. For some chi-squared tests, responses were grouped together in order to have enough responses.

Dissemination Plan

Dissemination was also mostly online in both English and Hungarian. Közút showcased the questionnaire on their Facebook. They also shared it with other local authorities for them to also publicise it. IMPROVER publicised the questionnaire on their Twitter, LinkedIn, website and via their email list serve, and members of the consortium were encouraged to share it with relevant people. BME (Budapest University of Technology and Economics), the Hungarian IMPROVER partner, also published it on their Facebook and Twitter.

Figure 3 Online dissemination efforts. Right, the operator's Facebook post, Top-middle, BME's Facebook post, Bottom-middle, BME's Twitter post, Left, IMPROVER's Twitter post

Sample Characteristics

There were a total of 342 clicks on the questionnaire links (combined), which led to 116 respondents participating in the questionnaire. Filtering out respondents who had never used the M1 Highway or were professional users of the highway, in total the sample size became 68 respondents.

Due to the dissemination method, this self-selected sample was not broadly representative of the Living Lab. Sample characteristics showed that 72% of participants were male and 28% female. Most were highly educated, with 72% reporting that they have a bachelor's degree or higher qualification. Both young and old people appeared to be underrepresented in the study. Respondents aged 18-24 accounted for only 13% of the total sample and only 14% identifying themselves as aged 55 years and above. An overwhelming majority of the respondents reside in Hungary (88%), whereas around 60% of the Highway users are international users (Personal interview). Income groups were more varied (Figure 4). The majority of respondents use the M1 Highway for holiday travel (Figure 5). Due to this, a typical journal time for respondents is over one hour to two hours (Figure 6).

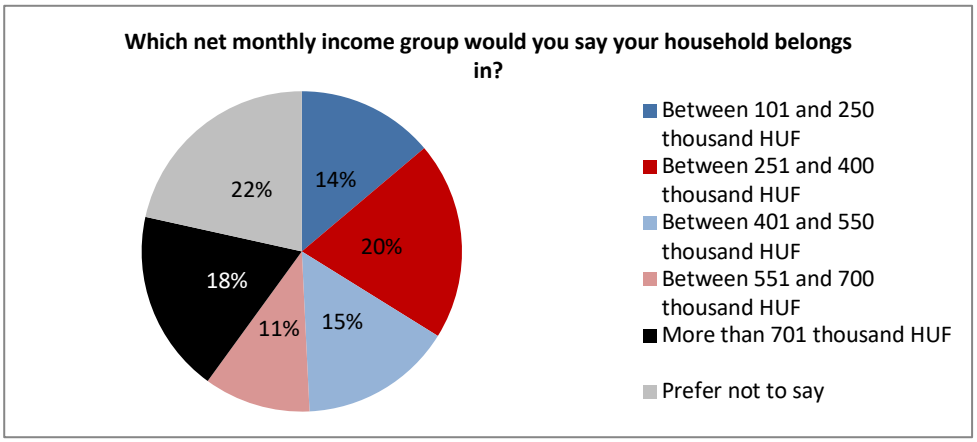

Figure 4 Monthly income group of respondents

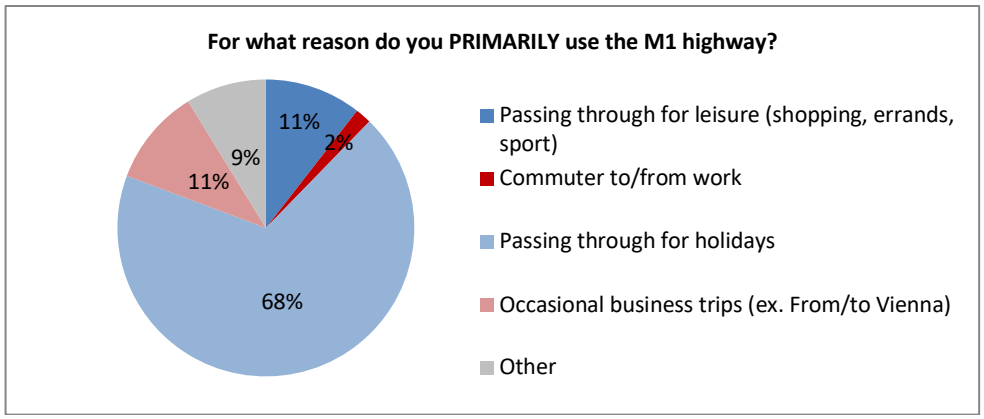

Figure 5 Respondents' primary use of the M1 Highway

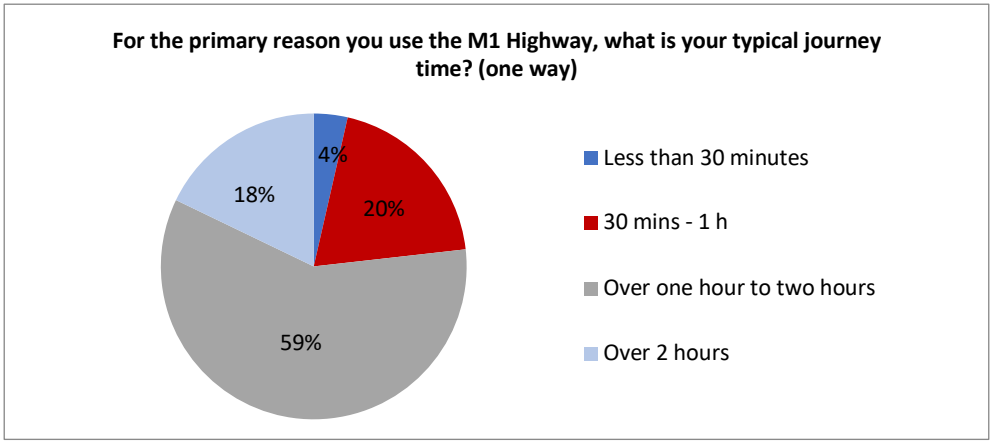

Figure 6 Respondents' typical journey time

Resilience Evaluation

As ITRA uses the idea of a resilience triangle shown schematically in Figure 7 (adapted from Bruneau et al., 2003), here we propose to transpose the results of the questionnaire into what we are calling "tolerance triangles" (Honfi et al., 2018).

Thus, a tolerance triangle is created by the accumulated percentages of respondents willing to tolerate a given service reduction for a given time frame. The next step would then be to compare the tolerance level to the resilience triangle, in order to perform the resilience evaluation and determine where public expectations are not being met (represented by the red area between the curves in Figure 7). Note that in Figure 7 the performance is plotted such that the increased positive value reflects better performance. In the case studied here we will use

"additional travel time" as an indicator of performance. Since these are intuitively plotted as a positive number the triangles that are produced will be turned upside down with positive numbers during the aftermath of the incident and normal performance reflected by a value of 0, thus no additional travel time.

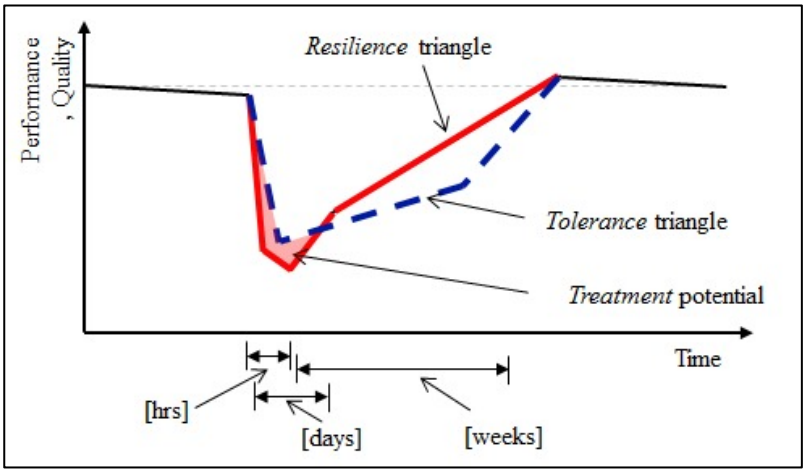

Figure 7 A schematic representation of a "resilience triangle" in red & a "tolerance triangle" in blue. From Honfi et al., 2018.

Közút's performance (the red line in Figure 7) could be evaluated using many different performance criteria. The IMPROVER project has defined the M1 hazards and their probabilities, damage states associated to these and the implications that will have on the local situation for the highway. Thereafter, traffic simulations were performed for different traffic loads and damage states. The performance measures from these simulations are chosen as (1) value of transported goods, based on data by Közút and (2) increased travel time for a specified section of the highway. It is the second of these performance measures that this paper uses to compare with public expectations.

RESULTS

The full results are available in Table 1 in the Annex. The following sections present the results in more detail.

Disaster preparedness, risk awareness and previous disaster experience

Respondents are equally split in terms of disaster preparedness regarding having emergency supplies stocked in their private vehicles (Figure 8). Respondents mostly do not think that serious damage to a bridge will occur in the next year (49%) (Figure 9). However, there is great uncertainty (21%). For the snowstorm scenario, respondents are more unsure (32%), but overall believe it is more unlikely than likely (Figure 10). Respondents are almost equally divided between those who have experienced a disaster and those who have not (49% vs. 50%, with 1% choosing I do not know). For those that have, flood and snowstorm are the most commonly experienced, both of which have recently affected the M1 Highway service in the past.

Tolerance triangles

Scenario 1

Additional journey time was asked in regards to four different possible reasons for taking the M1 Highway. Respondents using the highway for work related activities were less likely to tolerate longer delays ($X^2 = 831.39$, $df = 12$, $p < 0.001$). The related additional journey time tolerance triangles are presented in Figure 11. Duration of additional journey time was asked in regards to five different additional journey time scenarios. Unsurprisingly, shorter additional journey times are tolerated by more respondents for longer durations, however the statistical significance of this has yet to be verified ($X^2 = 1806.81$, $df = 28$, $p=0$). The related tolerance triangle is presented in Figure 12.

Scenario 2

Additional journey time was asked in regards to four different possible reasons for taking the M1 Highway. Respondents using the highway for work related activities were less likely to tolerate longer delays ($X^2 = 1341.45$, $df = 12$, $p < 0.001$). The related additional journey time tolerance triangle is presented in Figure 13.

Duration of additional journey time was asked in regards to five different additional journey time scenarios. Unsurprisingly, shorter additional journey times are tolerated by more respondents for longer durations ($X^2 = 1048.81$, $df = 20$, $p < 0.001$). The related delivery tolerance triangle is presented in Figure 14.

Resilience evaluation

Since most end-users will have unique tolerance to performance loss in infrastructure the tolerance of the public is a distribution which cannot be directly mapped onto a single curve of performance for a given scenario. The information in Figures 11-14 can shine light upon how tolerance varies among the end-users (i.e, does a minor fraction have a very low tolerance compared to the majority or are most end-users in agreement?). However, to be able to set targets one can describe the tolerance as e.g. that of the 75th percentile of the population or, as we will suggest here, as a weighted average of the whole population.

Thus, the tolerance curve for the bridge collision scenario, described as tolerable additional journey time as function of time after the incident, is the average of the different delay times shown in Figure 12 weighted by the percentage of people who stated that delay time as their maximum tolerance. The percentage of respondents that did not accept any of the proposed delay times are assumed to accept nothing but normal performance. This weighted delay time is calculated for each time after the incident.

$$\bar{t}_{Tol}(t_{incident}) = \sum_{I=1}^{X} \frac{n_i(t_{incident})}{N} \times t_{d,i},$$

where $\bar{t}_{Tol}(t_{incident})$ is the weighted average of tolerated time delay after a time $t_{incident}$ since the incident, X is the number of proposed time delays suggested in the questionnaire (the five curves in Figure 12), $n_i(t_{incident})$, is the number of respondents who stated the additional travel time $t_{d,i}$ as their maximum tolerance after time $t_{incident}$ from the incident and N is the total number of respondents. Note that this weighted average is lumped for all four different categories of travel (work commuting, leisure, …). The division between the different categories can easily be made but is not suitable for this low number of respondents.

The comparison of the weighted average tolerance in additional travel time and the estimated performance measure is shown in Figure 15 for the bridge collision. The performance curve is from Honfi et al. (2018) and is representative of a severe damage state due to a collision, a high vehicle rate of 1800 vehicles per hour and present-day resources and strategies. Figure 16 shows the equivalent data for the snowstorm scenario. The performance curve in this case is not estimated using the suggested tools for technological resilience analysis suggested in Honfi et al. (2017) but is an estimation of a realistic scenario based on the March 2013 Budapest snowstorm. Thus, it is important to keep in mind that the performance curves used here do not show the true performance of the system and are used here for illustrative purposes only.

With the tolerance curves derived here it is possible to evaluate the estimated performance for different resources available, different restoration strategies and different damage states. These evaluations will inform the decision makers on the sufficiency of the performance depending on these variables to partially guide the preventive work.

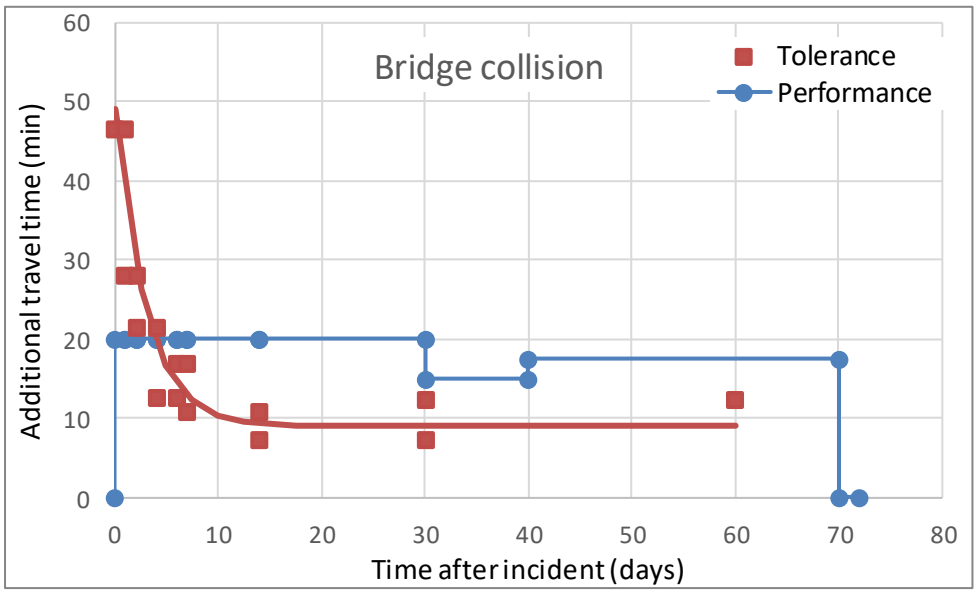

Figure 15 The performance measure of additional travel time (Honfi et al., 2018) evaluated against the tolerance curve for the bridge collision scenario. The red line is an exponential decaying representation of the tolerance data.

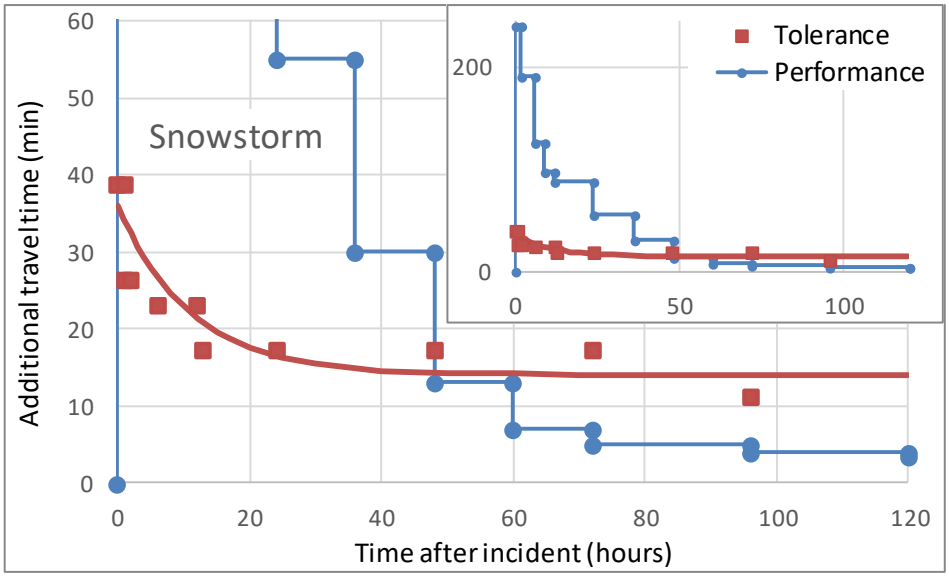

Figure 16 The performance measure of additional travel time evaluated against the tolerance curve for the bridge collision scenario. The inset shows the same data also for the period close to the incident.

DISCUSSION

Public expectations of service level and recovery time

The questionnaire results indicate that respondents are willing to tolerate service disruption in the form of additional journey times in times of crisis. For the four use-cases we presented, in both scenarios, the reason for using the highway highly affects the willingness to tolerate additional journey time. If traveling for work related reasons (commute to work & business trip), respondents were less willing to tolerate longer additional journey times. Thus, it seems that the minimum level of service expected from the public when it comes to work-related travel is between 20 and 44 minutes of additional journey time. When traveling for lesiure or holidays, respondents minimum level of service is an increased level of additional journey time then that of when travelling for work, ranging from 30 to 59 minutes. Unsurprisingly, the longer the additional journey time, the less long the respondents are willing to tolerate the new minimum level of service. For example, in Scenario 1, the majority of respondents are willing to have an additional journey time of 15 minutes for a period of 2 weeks, whereas for an additional journey time of 45 – 59 minutes, respondents choose only 3 - 4 days. The low risk awareness of

respondents indicates that both scenarios would most likely be seen as "unforeseen" events, which could help explain why highway users are so willing to have reduce service levels.

Since most travellers in our study use the M1 Highway for holiday travel, the minimum acceptable level of service recommended is 30 - 44 additional minutes of travel time (chosen by 48% of respondents for scenario 1 and 66% for scenario 2). For this additional journey time, almost half of respondents (46%) consider 5-6 days with additional travel time to fall within a "rapid" recovery for scenario 1, whereas almost half of respondents (44%) consider 13 – 24 hours with additional travel time to fall within a "rapid" recovery for scenario 2. This clearly shows the importance of the crisis scenario on expectations, as the public have demonstrated their understanding that certain disasters require a longer recovery time.

For the two cases used here the tolerance levels are both below and above the performance levels for different time durations after the incident. For scenario 1 (bridge collapse), for the first few days after the incident the expected performance for this scenario is better than the tolerances of the end-users. However, five days after the incident the end-users expect less additional travel time than what is the expected performance from the resilience analysis (for this damage state, these resources and the given strategy). Contrary to the bridge collision scenario, the estimated performance during the early stage of the snowstorm scenario (scenario 2), which is 2 days for this scenario, does not meet end-users' expectations. The very long additional travel times required just after a heavy snowfall is clearly not what the end-users expect. However, the public seem to tolerate small additions to the travel time for a longer period (> 2 days) than what is the estimated performance. While keeping in mind that these results are purely illustrative, they would permit one to advance to the next phase of ICI-REF, *resilience treatment*. For scenario 1, to better meet expectations for long-term recovery, a possible treatment could be the implementation of techniques for quick and efficient damage identification using e.g. structural health monitoring. For scenario 2, it may be beyond the capacity of the operator to meet public expectations. In this case, it is recommended to increase crisis communication during both the prevention and active crisis times. Indeed, information provision has been found to lead to more reasonable expectations of CI operators (Petersen et al., 2018; Buller, 2015).

Success of the method

Despite a low response rate, the questionnaire results demonstrate that it is possible to use this type of method in order to discern the tolerance levels of a given user population of a given CI. Indeed, starting from the same functionality and performance measures as the technical resilience analysis did not inhibit the ability of respondents to state their tolerance levels. Thanks to the use of Living Labs, the questionnaire was able to be developed with inputs from the Hungarian M1 Highway operators and study relevant crisis scenarios and realistic recovery timeframes. The operators at Közút have expressed positive feedback on the methodology and think that the results provide relevant knowledge. Of course, performing the resilience evaluation for all different damage states, recovery strategies and resource availabilities will be the true test of the method and ensure combability between the *resilience analysis* and the *establishment of the context* of the framework. This is part of ongoing work, pending the finalization of the resilience analysis. Thus, the ultimate success of the method is not yet entirely apparent. However, developing the survey in tandem with the resilience analysis parameters did not inhibit data collection and allowed the questionnaire to establish the public's tolerance levels.

As stated in the methodology, in order for the tolerance questionnaire to be comparable to the resilience analysis, the questionnaire also had to be scenario-based. This is because ITRA is dependent on undertaking a risk analysis, which in general are scenario-dependant. Thus, the results are not generalisable to all types of crisis scenarios. However, to analyse resilience of a given CI, it is not necessary to be use a scenario-based method (i.e. to use a different method during the *resilience* analysis phase than ITRA), as certain performance changes will occur regardless of the type of incident that has occurred. In this case, while it should be possible to also use a questionnaire to determine public tolerances, our results demonstrate that the type of crisis does highly affect public expectations. This shows the value of using scenarios when evaluating tolerances, to more fully understand the population. Further, as previous research has shown that nationality plays a big role in public expectations of CI operators in crisis times (Petersen et al., 2018a), it is recommended to perform a questionnaire for each CI individually.

Limitations

Survey

Questionnaires as a research method have certain limitations that maybe overcome with purposeful survey design (Jones & Tanner, 2015). Indeed, when responding to a questionnaire, people often use snap judgement and may

be influenced by emotional or contextual factors (Schwarz & Stack, 1999). For example, perhaps if the survey had been undertaken in winter, traffic delays would be more common and risk awareness for this issue would be higher. When it comes to using a questionnaire to ask about tolerances, question wording may influence responses, as research has demonstrated that when asked if they care about a given issue, people state concern for issues that do not exist (Herrmann et al., 1994). Another issue to consider is whether or not people answer in their own self-interest, claiming to tolerate less so as to not give the CI operators an excuse to perform any lower than absolutely necessary, or in a self-delusionary way, reporting that they are willing to tolerate more than they actually could handle. Another limitation to consider is that as disaster victims rarely passively wait around for someone else to take care of their needs (Quarantelli, 1998), stated tolerances may be for a level of reduced service that is higher than the actual minimum level of service that citizens are capable of tolerating. Another limitation is the sample method used does not allow for representativeness in the sample. The small sample size used here is also a limitation for the generality of the results. Further due to the dissemination method that focused heavily on Hungary, most respondents were Hungarian whereas about 60% of users of the M1 are international users according to Közút. Thus, the tolerance levels for all highway users cannot be said to be known.

Resilience evaluation

It should be mentioned that there are different ways of weighting the answers from the respondent. The method used here is to (1) average the accepted times of additional travel times for each duration after the incident. Another method could be to (2) average the duration after the incident for which the respondent will accept a certain additional travel time. For this specific case there are pros and cons to both methods. Method (1) can give non-monotonic results due to the way the precise question was presented. On the other hand, it represents all the answers better since the relative time of the largest delay time is not orders of magnitude larger than the smallest. Method (2) gives completely monotonic results but since the longest duration of time (>1 month) is so much larger than the smallest duration the final results are heavily reflecting only the answers related to the longest duration period. Both curves give similar results but method (2) cannot extend for much longer that 15 hours (for the case of bridge collapse). This could be improved in constructing a similar questionnaire in the future where the relative magnitude of the different alternatives should be spaced more evenly, or possibly that the respondent is free to write his/her own tolerance of duration without predefined alternatives.

One should also be aware of the fact that the performance measure and tolerances do not precisely reflect the same quantity. The tolerances are based on the respondent tolerance to additional travel time for their characteristic travelling (which differ in length, duration and position between the respondents). Performance is, on the other hand, defined for a fixed section of the M1 highway. Thus, 2nd order effect due to very long ques are therefore not taken into account but that could only be circumvented by performing the traffic flow analysis in a probabilistic manner having prior knowledge about the distribution of length, duration and sections of the highway used by all users… data that presently is not available.

CONCLUSION

This paper set out to establish a methodology using a questionnaire survey to determine public tolerance levels for CI service reduction in crisis times. The questionnaire was designed in such a way as to provide data that would subsequently be usable in the *resilience evaluation* step of IMPROVER ICI-REF. Using a living lab to test the methodology enabled it to ensure relevance to the CI operator. The questionnaire established that the public generally have reasonable expectations towards highway operators during both collision and snowstorm scenarios. However, the expected duration of traffic disturbance after a severe bridge collision is underestimated by the respondents. Additionally, the magnitude of the additional travel time for a short duration after a heavy snowstorm is not reflected in the tolerance of the public.

The minimum level of acceptable service was found to be dependent on the reason for travel, with work-related travel minimums being of a lesser additional journey time. In regards to rapidity of service restoration, as one would have thought, longer additional journey times were tolerated for shorter periods. These declared tolerance levels seem to fall within the response-ability of the CI operator, showcasing once again that the public have reasonable expectations of service levels in crisis times. Based on the main use case of our respondents (holiday travel), it is recommended to have a minimum service level of an additional journey time of 30 – 44 minutes and to rapidly restore normal performance would be restoring it within either 13 – 24 hours for snowstorm or 5 – 6 days for bridge collision. This pilot test then has successfully demonstrated the ability to use questionnaires as a means to discover public tolerances within the *establish the context* step of ICI-REF.

While the questionnaire results as first shown can provide a more general target, to successfully carry out a *resilience evaluation*, the results were then used to calculated the weighted average tolerance of the whole population. As such, the comparison of the tolerance criteria from *establishing the context* to the *resilience*

analysis was demonstrated. As the *resilience analysis* is still ongoing work within the IMPROVER project, the performance curves used here do not show the true performance of the system. Nevertheless, they were useful as an illustration of the resilience evaluation methodology, demonstrating the compatibility of a tolerance questionnaire with resilience analysis.

Future work includes comparing the results of this questionnaire to the plethora of results from the *resilience analysis*, thus performing the *resilience evaluation* step of the framework for different decision parameters. Followed by the development of a *resilience treatment* plan for the Hungarian M1 Highway. Future work will also build on this methodology to perform a similar questionnaire-based study of tolerances in other IMPROVER Living Labs. Lastly, the IMPROVER project will develop a guide for practitioners on how to design and implement tolerance questionnaires.

ABSTRACT

Critical Infrastructure (CI) failures are aggravated by cascading effects due to interdependencies between different infrastructure systems and with emergency management. Findings of the German, BMBF-funded research project "CIRMin" highlight needs for concrete assessments of such interdependencies. Driven by challenges of limited data and knowledge accessibility, the developed approach integrates qualitative information from expert interviews and discussions with quantitative, place-based analyses in three selected German cities and an adjacent county.

This paper particularly discusses how the mixed methods approach has been operationalized. Based on anonymized findings, it provides a comprehensive guidance to interdependency analysis, from survey and categorization of system elements and interrelations, their possible mutual impacts, to zooming into selected dependencies through GIS mapping. This facilitates reliably assessing the need for maintenance of critical functionalities in crisis situations, available resources, auxiliary powers, and optimization of response time.

Critical Infrastructure Protection, Interdependency, Resilience, Vulnerability, Cascading Effects, Emergency Management, Participatory Approach

INTRODUCTION

To build up resilience of Critical Infrastructures (CI), infrastructure operators, public crisis managers and emergency responders need to get a joint understanding of the entire system of systems. With automation, digitalization and efficiency gains, CI systems become increasingly complex, and so do their interdependencies. Preemptive risk management, as well as ad-hoc crisis response therefore need to consider this interconnectedness (Rinaldi et al., 2001; Little, 2002; O´Rourke, 2007; Lenz, 2009; Utne et al., 2011; Ouyang, 2014). As Georgios Giannopoulos of the Joint Research Centre of the European Commission puts it, „a resilience analysis requires assessing the infrastructure from a holistic point of view, enhancing coordination

and timely response throughout the interdependencies" (Giannopoulos et al., 2012, p. 38). Hence, risks can „be tackled by increasing the capacity of the dependent nodes to withstand the perturbation" (ibid.).

However, there is a general tendency among infrastructure operators to focus merely on their own systems – resulting in little exchange of information to identify the overall connectedness (Bach et al., 2013). As Grafenauer et al. (2018) have put it: "As systems become more complex, a clear overview on the consequences of a problem is harder to obtain". An insufficient understanding of the dynamics of interdependencies and of the dynamics of their interplay however may result in ineffective response and poor coordination between decision makers and disaster managers before, during and after a disaster (Baloye & Palamuleni, 2016; Faturechi & Miller-Hooks, 2015), which can lead to serious delays in emergency service delivery.

These aspects were the key motivation for performing a qualitative interdependency and impact analysis in the "Critical Infrastructures Resilience as a Minimum Supply Concept" (CIRMin) research project, running from June 2016 to May 2019. It aims at strengthening the (joint) preparedness and coping capacity of Critical Infrastructures in Germany, in order to optimize minimal supply for the population in case of CI break-downs. A reliable information basis for decision-making (Clarke, 1999; Heinecke, 2006; Weimer-Jehle 2015) was created through a thorough system analysis, involving all relevant actors and thus taking inter- and trans-sectoral dynamics of the systems' functioning into consideration (López-Silva et al., 2015; Schätter et al., 2014; Reissberg, 2012; Giannopoulos et al., 2012). It was accompanied by an open-data-based GIS spatial analysis and visualization which supported the analytical documentations of key sensitivities, weak spots and demands.

The CIRMin approach was mainly build on a personal exchange of information among experts and with the researchers. Emergency response, electricity and water supply have been selected as focal sectors, according to their relevance for civil security in Germany. Through bringing experts from those and further CI sectors together prior to hazard events, it was intended to provide them with a clearer and focused understanding of interlinkages and dependencies between their different infrastructure sectors and thus to jointly enhance resilience building.

As case studies, three municipalities (in Western Germany, Land of North Rhine-Westphalia) have been selected since this administrative level bears first responsibility for crisis management in Germany. In order to enable studies on differences and similarities, a metropole city, its neighboring, mixed rural/peri-urban district and another major city were selected.

RESEARCH GAP

The literature review related to CI interdependencies and methodological approaches included scientific publications, grey literature such as guidelines or technical reports and reports on previous or ongoing German and EU research projects. The following subchapters provide an overview of different approaches to interdependency analysis as well as a conceptual basis for the performed GIS analysis.

Methodological Approaches to Assessing CI interdependency

Most approaches of interdependency analysis attempt some kind of quantitative modelling (See e.g. Kröger, 2012; Pederson et al., 2006; Bloomfield et al., 2009; Ouyang, 2014; Dudenhoeffer & Permann, 2006; Hokstad et al., 2012). However, as Ouyang (2014) puts it in an overview, most approaches need medium to large quantities of input data with often difficult data accessibility. Also reviews from Bloomfield et al. (2009) and Pederson et al. (2006) discuss the challenges of data requirements, finding data sets and providing realistic demonstrations. It is often difficult to capture the potential sectoral and intersectoral cascading effects of supply breakdowns of critical sectors such as electricity and water in their complexity. On the other side, most purely quantitative data analyses have been limited to modeling systems in a near-realistic sense that did not sufficiently reflect the complex and often tight coupling, factors of human behavior and thus, hidden logics of CI systems (see e.g. Perrow, 1984). Also, security concerns of misuse by attackers and data sensitivity concerns are major constraints to information sharing. Bloomfield et al. (2009) therefore propose qualitative approaches that involve different stakeholder groups at least as a preliminary step.

Another challenge in research projects so far seemed to be consequently applying an intersectoral approach: Various research projects like MICIE[i], AFTER[ii], TankNotStrom[iii], MIA[iv], STREST[v], Smart Resilience[vi], NoWa II[vii], KontiKat[viii] and studies such as the TAB Report (Petermann et al., 2010) successfully tackled the above-described challenges of information exchange. But these projects so far only analyzed unidirectional

dependencies from single CI sectors, yet no holistic interdependency assessments. The projects Casceff[ix], Predict[x], DRIVER[xi], and Crisma[xii] developed practical tools with a high involvement of practitioners, to assess possible impacts of incidents to (inter)dependent systems at a higher abstraction level, i.e. systems of infrastructure sectors and their services. They thus demonstrated the importance of actively involving the practitioners from various sectors in development of interdependent infrastructure models. But still, this research mainly relied on or was limited to one or two CI systems (Barthe-Delanoë et al., 2015). Broadening the scope of application of these data bases to the entire system of systems of Critical Infrastructures and crisis management would make them hardly manageable. This "requires extensive knowledge" about a metropolitan area, "including e.g. building inventory, systems, and suitable data to characterize the employed hazard models" (Garcia-Aristizabal et al., 2015, p. 9).

Projects at the European level with an intersectoral approach (such as the Snowball[xiii] project and Fortress[xiv]) have developed computer simulations of various supply sectors. They provided a very far-reaching approach to viewing infrastructures in their vast complexity as socio-technological systems. Their developed models are user-centric by involving actively the practitioners and match demands on modern CI resilience approaches (Bach et al., 2013). But in turn, these elaborate processes rely on vast data sets about a handful of very specific impact scenarios. As an approach to identifying the key needs for action to prepare a city or region for different kinds of CI outages, they seem to be too costly and not easy to handle.

Use of GIS Analysis

The development of spatial technologies has been driven by needs for better, easier (Mansor et al., 2004) and quicker decision-making for emergency response, and for the overall resilience building (GAR, 2015). Many of the critical problems that arise with extreme events such as floods or earthquakes are inherently spatial, e.g. the extent of the disaster, on-site crises and number of people in need (Tzavella et al., 2017).

GIS are useful for emergency management by visually displaying key information before and most importantly during an emergency event (Fekete et al., 2016; Tzavella et al., 2017). In CIRMin, information about disaster impacts on a system were integrated with emergency operations capability (Petit et. al., 2015), to better understand and anticipate the consequences of an incident and to support incident management activities (cf. Petit et al., 2014). Specifically, GIS have been recognized as useful tools to determine the changes in impact on a geographic area (Robert et. al., 2015).

Scientific advances in utilizing spatial information are demanded in the areas of CI asset mapping, adding additional context information, such as technical susceptibility of system components or social vulnerability of the supplied population (Fekete, 2012a). However, such exposure assessments are not sufficient to capture effects outside of the initial damage area (such as the flood-zone), which is typical for interdependent and network type of CI services such as electricity grids (Fekete, et al. 2017). Spatially explicit interdependency assessments between CIs reaching beyond e.g. unidirectional dependencies from resources or impacts, are still lacking for Germany.

CONCEPTUAL BASIS OF THE APPROACH

Definition of CI

Critical Infrastructures are defined differently, while overlapping in stressing vital or essential infrastructure elements and processes from the viewpoint of a (mostly national) government perspective (US Government, 1996; European Commission, 2008, FMIG, 2009). In Germany, CI are defined by importance to the state if their failure can cause major damages or destabilization of public order (FMIG, 2009). For this study, this definition of Critical Infrastructures is used: "*organizational and physical structures and facilities of such vital importance to a nation's society and economy that their failure or degradation would result in sustained supply shortages, significant disruption of public safety and security, or other dramatic consequences" (*FMIG, 2009, p.3).
The CI in Germany include nine sectors and selected branches (FMIG, 2009), wherein water supply, electricity supply, and emergency response, which are the focus of the study, are listed.

Types of Interdependency

Rinaldi et al. (2001) define connections between infrastructures as unidirectional (dependency) or bidirectional (interdependency). Within the view of complex systems, many infrastructures are connected one way or

another, directly and indirectly with each other, so that it is necessary to assess the interdependency in a holistic and systemic way. Interdependent infrastructures also display a wide range of spatial, temporal, operational, and organizational characteristics, which can affect their ability to adapt to changing system conditions (Rinaldi et al., 2001).

In this paper, the dimensions of interdependency used are based on the interdependency concepts from Rinaldi et al. (2001; also: Turoff et al., 2014):

i) Physical interdependency: the state of each is dependent on the material outputs of the other
ii) Informational interdependency[1]: the state of an infrastructure depends on information transmitted through the information infrastructure
iii) Geographic interdependency**:** a local environmental event can create state changes in several infrastructures
iv) Logical interdependency: social and political processes

Conceptual Principals

The resilience of complex systems of CI can be observed using a systemic and biocybernetic lens, regarding infrastructures as dynamic and to a large degree self-steering systems. Here, Vester (1988; 1991; 2012) describes biocybernetic systems as examples for self-contained – and in a sense resilient – systems and sub-systems, which use a set of rules that make them function in an optimal way. Projecting these examples from nature on water, electricity or gas supply, transportation, ICT, emergency response and so on, helps in understanding the dynamics, the existing connections and possible interactions within and between the systems and thus the overall complexity of critical infrastructures.

For the interdependency analysis, the Vester (1991; 2012; see also Wilms, 2006) approach of system and sensitivity analysis for complex systems, as adapted by Dierich et al. (2012) (see also inter 3, 2013) to the specific context of interdependent critical infrastructure systems, has been applied. The method was advanced by integrating the concepts by Rinaldi et al. (2001) for systematic classification of interdependencies and Bagheri & Ghorbani (2008) for capturing the variability and dynamic behavior of the complex systems based on a five dimensions model framework.

METHODOLOGICAL APPROACH

The methodological activities in CIRMin took the above described state of the art into consideration to develop the mixed qualitative-quantitative approach of analyzing and mapping the interdependencies between various infrastructure sectors at manageable effort and for crisis situations in general. Employing "Fuzzy Logic" (Vester, 2012; Malik Management Zentrum, 2014) by means of reducing the information depth of the analysis of systems and their elements, the method described in the following was deemed appropriate to solve the above-mentioned handicap of purely data-based decision-support systems.

Sources for data

The basis for the study was the engagement of representatives from CI operators and other project partners from city, regional and national administration. For each case study, representatives from relevant operating companies (electricity supply grid operators, transmission grid operators, water suppliers, wastewater and flooding management and ICT operators) were involved, as well as municipal disaster management officials and emergency responders.

[1] There is a slight adjustment to the concept of Rinaldi et al. in this study, as 'informational interdependency' was used instead of 'cyber interdependency'. Rinaldi et al actually defined it in a wider sense as the dependency on information flow or exchange taking into consideration the actors involved, and as the information and communication technology used. For the study, we deemed communication and exchange of information among actors an important focus, and therefore use the widened term of 'informational interdependency' as defined above.

Qualitative and quantitative analyses have been conducted in parallel with each other. For gathering the qualitative information, semi-structured interviews and moderated focus group discussions in expert workshops served as primary data source. In total, 18 detailed (2-3 hours) interviews with in each case 1-3 participating stakeholders, as well as further telephone interviews have been conducted. Uncertainties have been minimized by comparison of expert views and their dialogic validation. Six expert workshops involving each 10-15 stakeholders and about 10 researchers took place at decisive points of each methodological step and served to discuss findings, jointly draw conclusions from them and perform key analytical steps such as the Cross-Impact-Analysis. Their structure varied from focused discussion to intense co-working. Participants slightly varied but at least the focal CI units and agencies as mentioned above were always represented - with one exception when operators from another region in Germany were brought together to evaluate the transferability of the findings of the interdependency analysis.

Quantitative analysis using GIS applications has been based mainly on available open-source (OS data) and authoritative ('official') data, and its results have been verified by the experts in an iterative process. The advantage of using OS data or even data that is produced voluntarily on-site by the people in need is that it is the most up-to-date data that the emergency responders can have at hand before and specifically during a crisis (however, always depending on the type of crisis) (Tzavella et al., 2017). For this study, before providing findings to local authorities and to the public, they needed to be screened and selected according to security and data sensitivity demands. This integrative and joint process provides new empirical and expert-verified information and at the same time further strengthens collaboration and information exchange among CI and emergency management actors.

Qualitative Interdependency Analysis Steps

Following the concepts discussed previously, the chosen approach to system analysis incorporated the identification and description of critical infrastructure elements and (inter)dependencies in a holistic picture. Different types of systemic elements have been distinguished for the analysis of the systems, together with relational processes and interdependencies. As a further step, through the sensitivity analysis according to Vester (1991; 2012), the identified system elements were aggregated - again with intensive participation of the CI stakeholders - to impact factors and juxtaposed in a cross-impact-matrix to assess their reactivity and dynamic character. The relevant stakeholders were brought together in a workshop, in order to agree on the definition of a limited number of impact factors and discuss and value their interdependencies.

Through reducing their overall complexity, a complete overview of the interwoven CI systems was to be achieved; however, zooming into them and finding accurate and reliable information about particular elements and relationships should remain possible. In both system analysis and discussion of the sensitivity of the systems, the linkages were considered more important than the singular assets, technologies, actions, etc. Therefore, structures and processes were considered in an integrated way.

Quantitative Analysis

The main idea of linking quantitative GIS analysis to the qualitative interdependency analysis was to use the capabilities of GIS in terms of i) visualizing and pinpointing focal interdependencies in a detailed manner and ii) further analyzing, verifying and complementing the gained information. In the opposite sense, the GIS analysis also examined the qualitative results for needs of further detailed analysis.

Data was processed through the Extract-Transform-Load (ETL) method[xv], also to allow for data interoperability. In order to simplify and semi-automate the processes, spatial ETL tools were used[2], for e.g.:

- Filtering attributes and merging them with other feature classes
- Using attribute values to create unique feature classes on the fly

[2] Spatial ETL tools are user-created geoprocessing tools that can transform data between different data models and different file formats. These tools are capable of a wide range of processes and data flows, from simple format translations to complex transformations, which restructure geometry and attributes. They can be used as stand-alone geoprocessing tools or run as part of a Python script tool (see https://pro.arcgis.com/en/pro-app/help/data/data-interoperability/spatial-etl-tools.htm).

- Separating data using test criteria
- Creating line features from coordinate values.

Collected data from different sources has been integrated in an ArcGIS environment. Specifically, available OS geodata have been utilized stemming from projects such as OpenStreetMap, provided and maintained by the community of Geofabrik[xvi], the city of Cologne[xvii] and the international commission of the Rhine[xviii] on actual damages, flood extent, etc. The flood extent for the area of Cologne was downloaded from the Rhine Atlas (IKSR, 2001; Rhine Atlas 2015).

After the initial spatial assessments and GIS visualisations, results and some conclusions were presented to the experts so to verify them. The quantitative research has deliberately been designed as an iterative process of building a joint knowledge basis for CI protection and emergency management. Such participatory GIS approaches have already been applied in other thematic areas (e.g. Pfeffer et al., 2011; Brennan-Horley & Gibson, 2009; Kwan & Knigge, 2006)

DATA ANALYSIS AND EXEMPLARY RESULTS

The following section shows how the interdependency analysis can be performed in four analytical steps and presents some anonymized and generalized results that are based on the actual results from the case studies[3]. For the quantitative (GIS) analysis, maps containing non-sensitive information and using open source data are presented for the city of Cologne.

The following analytical steps have been conducted:

1. identifying and categorizing key CI processes and elements;
2. analyzing interdependencies between elements within and across sectors;
3. cross-impact-analysis: clustering of elements to impact factors and valuing impacts;
4. combining the qualitative analysis results with quantitative (GIS) analysis.

Key CI Processes and Elements

Interviews and discussions with the infrastructure operators and emergency responders in the case study areas provided a thorough understanding of i) processes and elements which are important to deliver the respective services to the community, and ii) interdependency linkages with other infrastructures. Given information was questioned during the interviews with regard to possible supply outage scenarios. The following Table 1 provides a few generalized processes and associated elements - out of the hundreds identified - that applied to all four case studies.

[3] The actual results cannot be made public in detail, in order to respect confidentiality and sensitivity of the data. Selected findings have been slightly altered and thus anonymized, to be able to exemplarily show them in this paper.

Table 1: Selected examples of described processes and elements (Source: own table)

Example	Infrastructure	Process	Element(s)	Qualitative description
1	electricity supply	supply distribution	supply network and supply sub-station	network structure, supply areas, existing redundancies
2	water supply	network regulation and repair management	control center, which is linked with alert service	main point for information flow and contact with other responsible divisions as well as repair works during supply breakdowns, communication media
3	water supply	repair management	on-call duty and repairing vehicles	cooperation with external sources, capacity and repairing time
4	water supply	repair management	switching the distribution network system	network structure (redundancies), automatic or manual, estimated switching time
5	emergency response	emergency operation	operation leader	procedure in operation and decision making, cooperation with other actors

To analyze and evaluate the systems and processes graphically, elements were categorized as follows:

- actors (depicted as squares)
- technological processes and facilities (depicted as circles)
- resources (depicted as hexagons)
- measures (depicted as arrow-like hexagons)
- environmental conditions (depicted as rhombuses) and
- entire infrastructure systems (depicted as octagons).

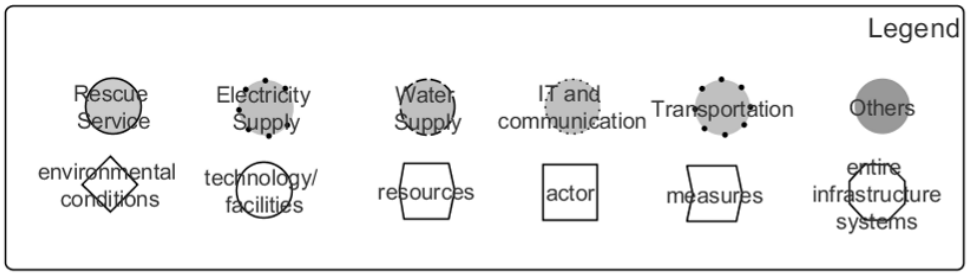

Figure 1: Categorization of elements

Interdependencies Between Elements Within and Across Sectors

As previously mentioned, the interdependencies between elements were categorized as physical, informational geographical, and logical interdependencies. Technical and informational interdependencies clearly prevailed over geographical and logical ones. Exemplary interdependencies are listed in Table 2:

Table 2: Selected interdependencies based on interdependency dimensions adapted from Rinaldi et al. (2001) (Source: own table)

Sub-process	Interdependencies			
	physical	**informational**	**geographical**	**logical**
Notification of disruption and mobilizing resources	Electricity supply of control center, electricity supply of IT system and communication media	Mobilizing resources for (manual) repairing activities Contact with fire brigade	In case of unavailable (public) ICT: distance to person/location (for e.g. courier)	Legal priority of public communication service in case of disruption
Repairing activities	Electricity supply, transportation network, fuel supply, supply with spare parts, external service firms (e.g. civil engineering)	Information exchange between control center, repairing personnel, other actors (fire brigade and police forces, crisis unit)	Accessing the affected areas, proximity to other mains, assets and supply pipes/lines	Existing contract with external service firms, prioritization
Dispatching of emergency responders and vehicles/ engines	Electricity, water, heat and food supply of fire brigade control center Fuel supply of vehicles	In case of electricity cuts: Information about their severity, information about CI (location, capacity of existing emergency power generators)	Distances, traffic, road conditions, degree and spatial extension of population/ CIs affected	Prioritization of emergency operations

As an overview, all interdependencies found in a case study have also been depicted graphically, as shown exemplarily in Figure 2.

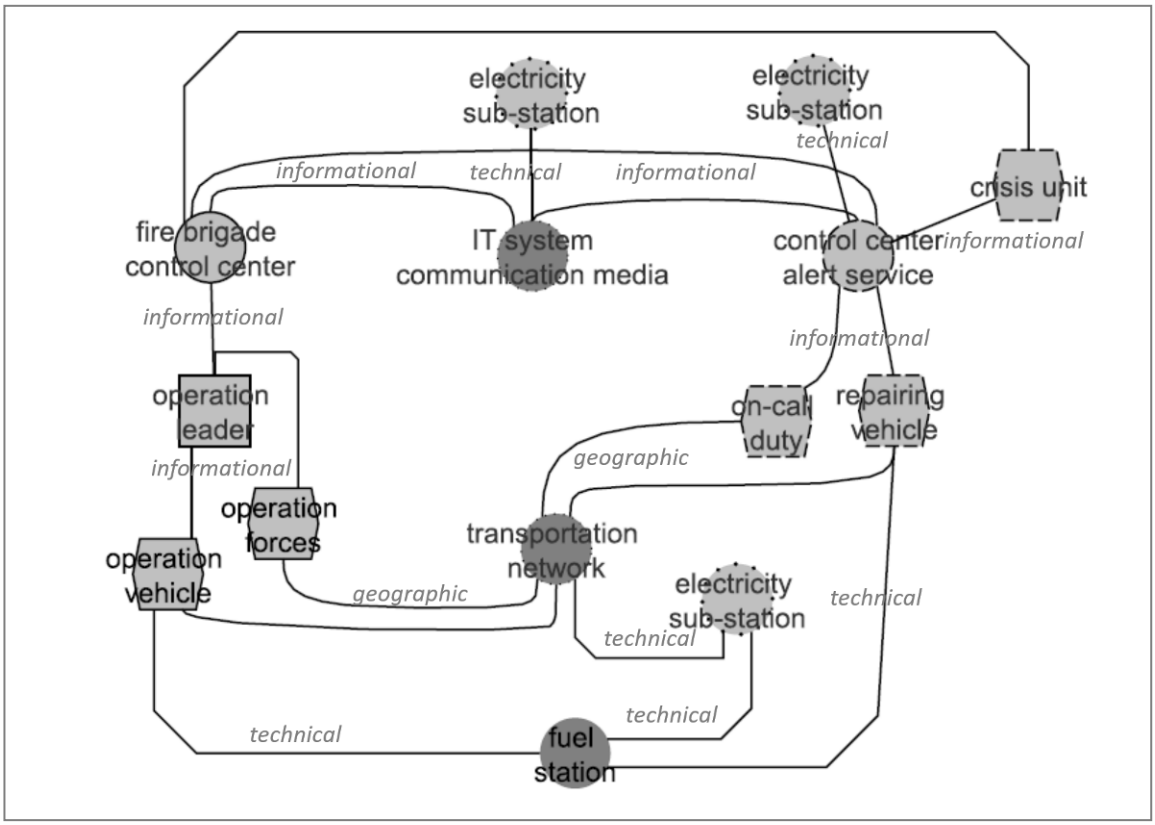

Figure 2: Visualization of the exemplary processes, elements and their interdependencies (Source: own figure)

In the simplified sub-system (Figure 2), information about any disruptions in day-to-day operation through the remote monitoring system or through notification by the customers is collected at the control center, which will in turn notify the repairing service or, in major events, the crisis management unit. The repairing service mobilizes its resources (vehicles with on-call duty) using available communication devices, and the repairing time would depend on the capacity and location of these resources, as well as on the traffic and street/road conditions (transportation network) on the way to the affected location. The service vehicles also rely on supply of fuel at petrol stations, which in turn rely on electricity. In case of a more severe supply disruption, contacts will be established, and information will be exchanged between the control center of the water supply operator and the control center of the emergency responder (fire brigade) for preparing possible operations. On the other hand, the functionalities of the control center depend on electricity supply from electricity substations (although with redundancies in the supply network and own emergency power generation capacities).

This example only shows a small part of the analysis. The whole system analysis at the end would look more complex, as exemplarily shown in Figure 3.

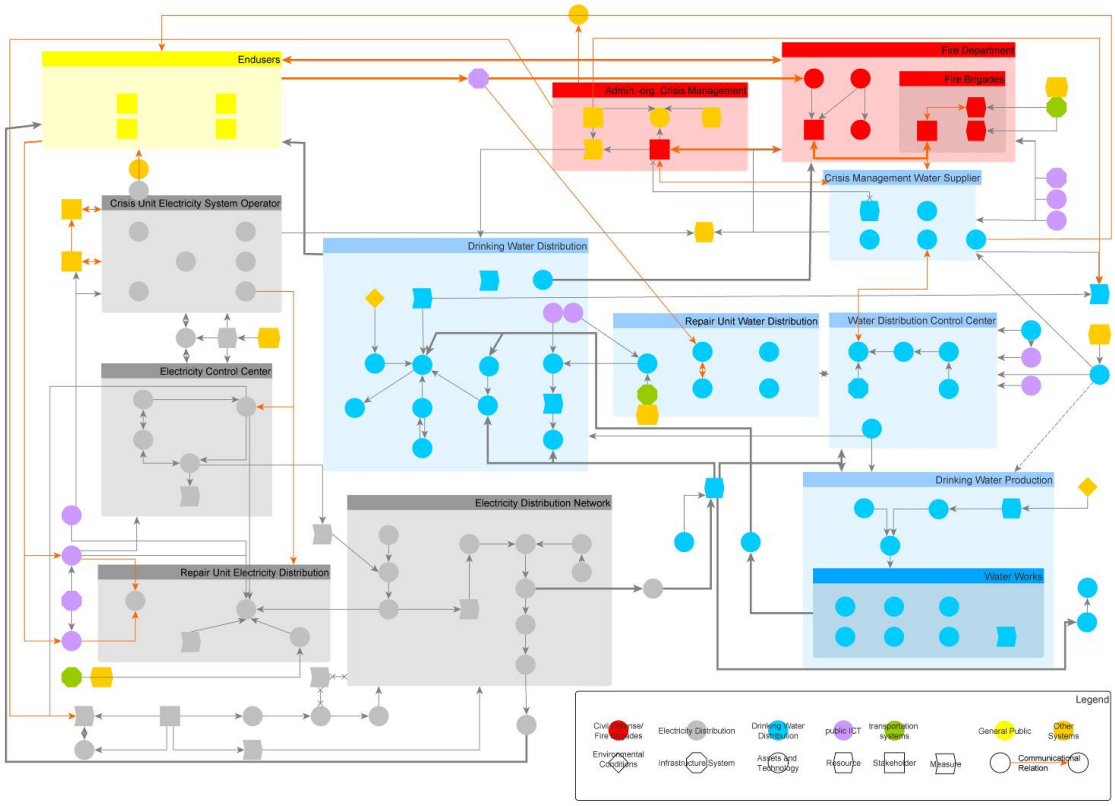

Figure 3: Schematic visualization of the processes, elements and their interdependencies in an anonymized city (Source: own figure)

Cross-Impact-Analysis: Procedure and Results

The compilation of the elements of the CI systems documents their structure and immanent processes, as well as interlinkages with each other. However, it does not help in understanding their dynamics, including their reactivity to major disturbing events and cuts in supply or information relationships. Possible cascading effects can only be assessed through a sensitivity/ cross-impact-analysis (CIA), as briefly explained above (see also (Vester, 2012; Weimer-Jehle, 2015; Heinecke, 2006). This can most practically be done by a matrix that juxtaposes system elements of the different CIs (Wilms 2006; Vester, 1991, 2012). However, as it was impossible to juxtapose each of the roughly two hundred elements (per case study) with each other, a clustering to so called "impact factors" was needed. These constitute kind of larger functional units within the systems and may embrace an entire system (such as the factors "ICT" or "flood control", see below) or even various systems (such as the factor "transportation network/ traffic"). Each of the 15 factors was defined precisely by listing up all assigned elements. This clustering allows reducing the total systemic complexity and hence gives a complete overview of the considered interdependent CI systems in the respective area/city. It visualizes the 'system of systems'.

Assessing the impacts between the factors of the different CI sectors in "Cross-Impact-Matrices" followed certain rules (see Figure 4, to the left, compare Wilms 2006; Vester, 1991, 2012):

- Both defining the factors and impact assessment was done in a workshop, involving stakeholders from the concerned CI sectors, who were divided into three groups according to the three case studies. For all three different case studies, uniform impact factors were created; however, in another context, other factors might be selected and defined.
- The assessment was done under the overarching question: "What impact does a serious disturbance of the functioning of a factor have on the other factors?" The effect partly varied according to changing focus on the different elements contained in a factor. As risk analysis needs to take into account any probabilities, these have explicitly not been assessed; unlike in the original and still vastly applied CIA

approach of Gordon, Hayward (1968), Enzer (1972) and Helmer (1983) (see also Kosow & Gaßner, 2008; Weimer-Jehle, 2015; Heinecke, 2006). However, implausible effects have been ignored.

- The assessment of impact strength was done on a scale 0 = no or very low impact/ no relation, 1 = impact underproportionate/ lower than disturbance, 2 = proportionate impact, 3 = impact overproportionate/ higher than disturbance.
- Only direct impacts were considered. For example, a problem in water extraction impacted on water distribution and this in turn on the end users.
- Participants were first asked to individually assess the impacts. The reasoning behind was then explained, discussed and documented, and each impact strength was decided in a consensual manner.

Active Side \ Passive Side	101	102	103	104	201	202	203	204	301	302	401	402	501	502	503

- 502 Administrative Organisational Crisis Management
- 503 Demands and Commitment of End Users

Figure 4: Completed Cross-Impact-Matrix for 'Anonymized City' (left) and Criticality of Impact Factors, as a Result of the Impact Assessment (right) (Source: own figure, unassigned to any concrete city)[xix]

As a result, the total criticality of the factors is manifested in its aggregated active and passive impact scores (Figure 4, to the right). Each factor was thus located in a criticality graph with the passive sum on the abscissa and the active sum on the ordinate. Factors that are particularly sensible have both high active and passive sums, highlighting particular 'critical nodes' in the system, while factors with low sums are rather slowly reacting or buffering. However, even the latter may be important in singular cases for further cascading effects. Possible second, third and fourth order cascading effects can be shown through further analytical steps of impact chain analysis.

Combination of Qualitative and Quantitative (GIS) Analysis

While the above steps helped selecting particularly sensitive or critical nodes within the entire system of systems, the performed GIS analysis was then used to a) map the selected elements and zoom into the respective

interdependencies and b) identify critical nodes and interdependencies that had been overseen in the qualitative analysis. An extreme flood scenario was chosen for GIS simulation. To show the possible impacts of the flood, the following figure visualizes selected elements of different CIs (fuel stations, emergency response and electricity distribution assets) exemplarily for the city of Cologne, using OS data and non-sensitive information (Figure 5).

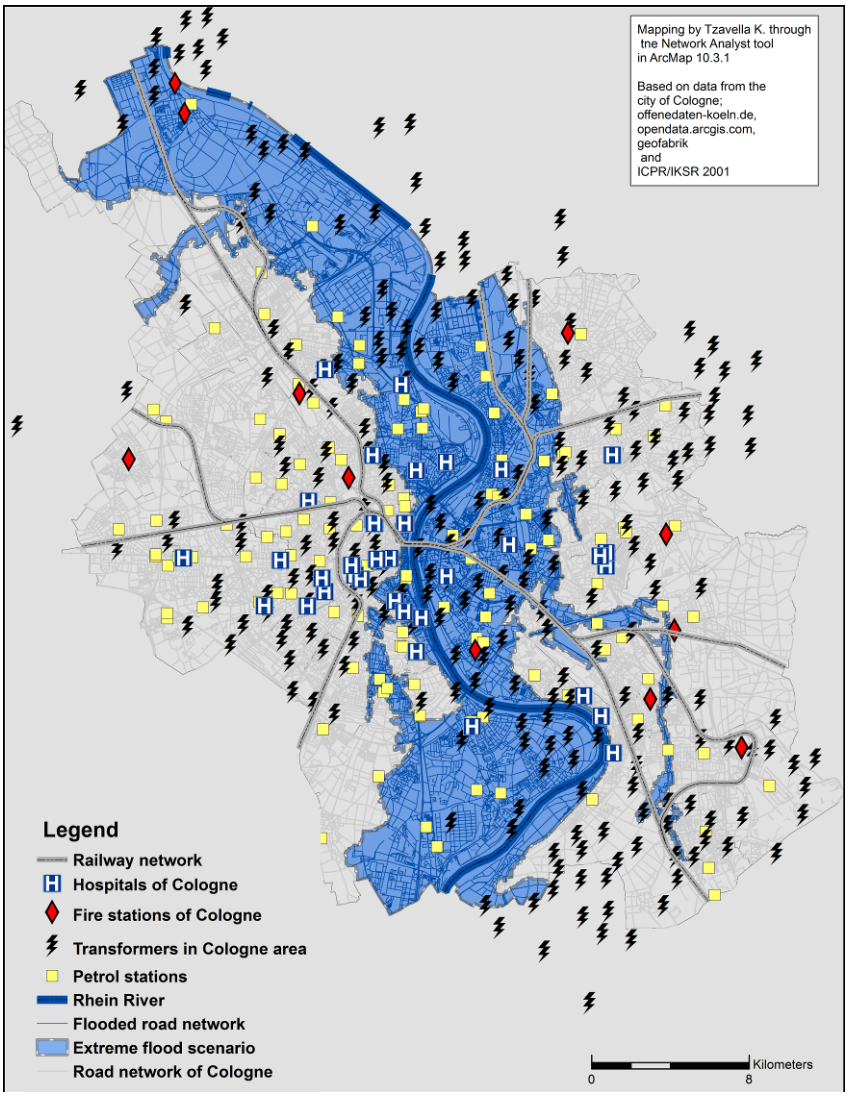

Figure 5: Different CIs of the city of Cologne affected by the extreme flood scenario (Source: own figure using open source data)

First of all, in Figure 5, the spatial exposure assessment of the different CIs to an extreme flood scenario reveals their geographical interdependency, as various CIs are exposed to flood at the same time. Furthermore, the map points to dependency of some of the above-mentioned elements (e.g. repairing activities and emergency response/firefighting) on the transportation network, fuel supply, and electricity supply. In this way, the result of the cross-impact-analysis was verified, even showing that the impact might have been underestimated given the geographical interdependency. The identification of such geographical interdependencies and their integration into an emergency response plan has been covered in detail in Tzavella et al. (2017). From the above results of the qualitative analysis steps, it was further derived that traffic is a critical impact factor and should be taken into consideration in repairing management, for operative-tactical emergency/crisis management and for flood control.

In order to test these results and get a more precise understanding of their implications for a distinct scenario, GIS data on traffic density (high road network density and high traffic lights density) was combined with the location of transformers and the flooded areas. This yielded precisely, which transformers need to be disconnected due to flooding, and thus which roads, traffic lights and intersections are most critical or – on the other hand – which ones would presumably not be as much affected as it seems from the more general qualitative analysis. Thus, effects on response and repairing time (of emergency responders and critical infrastructure repair management) can be calculated and alternative routes considered. In Figure 6, it is shown that some transformers are located in the flooded area. Emergency managers can use such information for planning repair times, considering contraints such as the driving time through flooded road networks (Fekete et al., 2016; Tzavella et al., 2017).

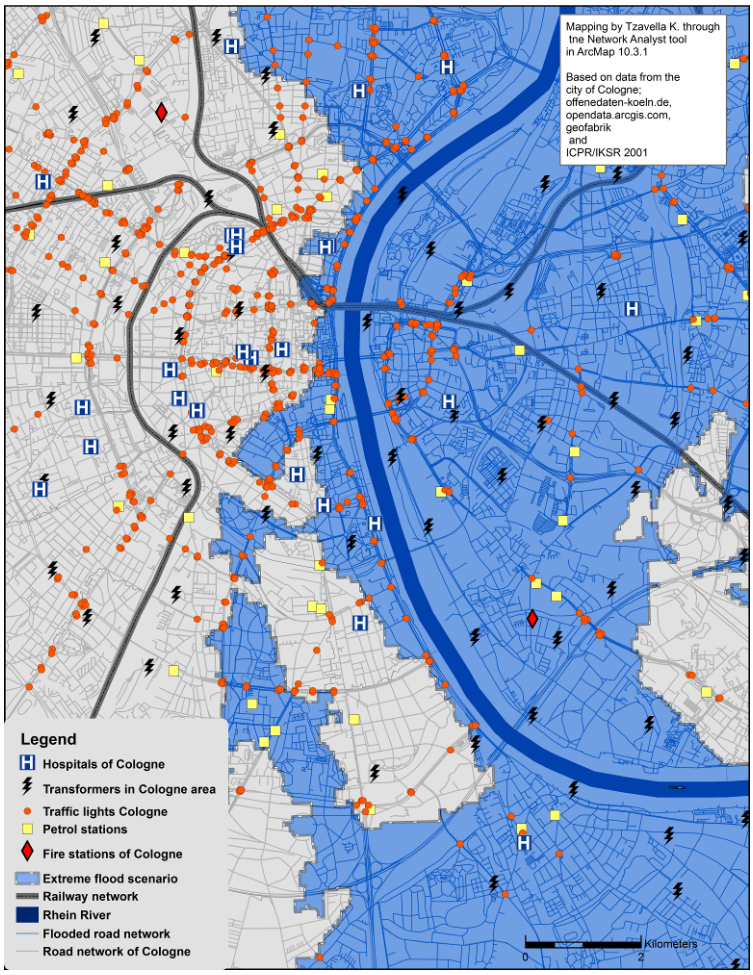

Figure 6: Critical infrastructures of Cologne affected from the flood including the traffic lights (Source: own figure using open source data)

Additionally, further **physical interdependencies** can be identified using GIS. The road and the railway networks are physically interdependent when sharing physical structure such as bridges. As observed, all the trains approaching Cologne are following railway lines that are crossing major road network segments. A bridge can also carry water lines, IT and gas lines. A failure in these areas could indicate a cascading effect of failures in the day-to-day functionality of the city.

The identification of these physical interdependencies and the information that is provided regarding the potential cascading effects mentioned above, could only be addressed through the quantitative analysis with GIS visualizations of datasets, as they had not been identified before by the stakeholders during the phase of qualitative analyses. Also, the results of GIS analysis displayed interdependencies that were implied and "hidden" in combinatory nodes between the different interdependent elements and were unidentified through the

qualitative analysis. This identification of the CI at risk adds value to the situational awareness phase of the emergency management, leading to a timely effective emergency response.

Additional information yielded by the quantitative analysis can be fed back into the cross-impact-analysis, and of course the preliminary system analysis. It can thus provide supplemental and more precise information for rethinking the sensitivities between the impact factors.

DISCUSSION: POTENTIALS AND CHALLENGES OF PARTICIPATORY QUALITATIVE-QUANTITATIVE ANALYSIS

The applied approach brings about the advantage of capturing experiences and subjective opinions of the participating stakeholders and experts, allowing them to indicate the most critical aspects and challenges they face in preparing possible supply disruptions. Compared to the existing recent methods of EU research projects discussed in the literature review, this method has a similar orientation, given its interdisciplinary and participatory character, but offers a viable solution to the challenge of data acquisition and management.

Specific Methodologic Advantages and Limitations

In comparison to preceding work, the approach disposes of three major advantages: It

i) allows for assessing the interdependencies between various systems and actors at the local level and thus serves as an iterative informational/advisory system for the decision makers,

ii) does not demand precise data sets from the participants, thus avoiding the often-insurmountable obstacle of sensitive data sharing or even costly data collection (Garcia-Aristizabal et al., 2015), and yet

iii) provides relevant information both in specific detail (combined qualitative description of key elements and analysis of their nodes and quantitative GIS analysis), as well as on a more abstract but all-embracing level (cross-impact-analysis using aggregated impact factors), thus drawing the entire picture.

The approach therefore serves as an ideal basis for further processing of information, e.g. in building reliable scenarios, or building up a systematized geo-databases (see e.g. Herrera et al., 2015). In particular, it can serve for providing an appropriate informational basis for interorganizational crisis communication and joint situation analysis tools, such as AlphaKomm (Töppel et al., 2017) or its predecessor SIMKAS-3D. However, even though the system and cross-impact, as well as geospatial analyses can be performed in detail for the interconnections between different (sub-)systems, it will only be able to serve as an important informational basis for a general understanding of the functionality of systems and their embeddedness, and for local or regional crisis-scenario-analysis. Further data-based and detailed analysis is still needed when it comes to precisely understanding technical interfaces.

The Challenge of Involving Practitioners and Exchanging Information

The chosen format of interviews and workshop discussions helped to prioritize information dialectically together with the experts. For critical system nodes and (inter)dependencies, more detailed information was gathered. Contrasting or even contradicting expert opinions could be discussed right away. On the other side, much of the subjective information gained from the experts needed to be cross-checked with other expert statements and information from existing research or other reliable sources. Concerning particularly the GIS analysis, plausibility checks through the involved experts allowed for valuable outcomes even from analyses based on lower quality open source data.

Initially, the participatory procedure faced the challenge of building trust between the involved experts and the researchers. As it demanded much time from the former to provide the needed information in workshops and interviews, they showed a certain initial skepticism. This however vanished at the point when they more clearly saw the direct benefit for themselves, namely, to exchange information about mutual dependencies and weaknesses for the first time outside of specific exercises or formal frameworks. CI operators and emergency responders recognized that they have had contrasting expectations or an incomplete understanding of service availability of the other CIs in crisis situations beforehand. They turned out to be willing to providing insights into dependencies and crisis management of their companies.

During focus group discussions, the associated partners and other potential users were repeatedly shown demonstrators of the interdependency and GIS assessments and interview results. They were asked not only to give feedback on possible improvements, but also to indicate further demands and type of documentation so they could benefit from the results. The stakeholders confirmed their usefulness e.g. in terms of i) justification of their work on security and emergency management, ii) intensifying the CIRMin-triggered knowledge exchange parallel and even after the end of the project (in bilateral collaborations) and iii) applying GIS planning instruments for emergency back-ups and resource planning.

CONCLUSION AND OUTLOOK

The interdependency analysis presented here offers several advantages, namely that it provides a way to understanding how different CI systems function i) separately (identification of system structures within each sector) and ii) in interaction (intersectoral interdependencies). Based on qualitative information and analysis, it captures not only the structure, but also the dynamic between technical, social, and communicative elements of the CI systems. This is important for being able to adopt effective resilience-building (Kröger, 2012). The combination of qualitative and GIS (quantitative) interdependency analysis yielded a comprehensive overview of what measures are needed for coping with possible disruptions and maintaining the functionalities of CI in crisis situations. It points out to indispensably needed resources for CI operation, redundancies in the supply networks and auxiliary powers, and gives hints how to optimize repairing activities, crisis management and response time. Also, in the particular research context, the documented approach helped identifying critical elements and impact factors that are relevant for providing minimal (or reduced) supply for the population. Such provision can enhance the resilience of the population to specific risks, since a thorough crisis preparation allows for a quicker bounce back to normal.

As an add-on to the documented analytical work and subject to further research, cascading effects may be visualized in the form of risk maps, showing the affected elements and their risk level to fail. This would require further spatial analyses, classifications and weighting of criticality levels, as well as a categorization of processes according to geographical relations. The resulting maps would finally provide an aggregated criticality level of the different elements per area.

Even though CI systems inside and outside of cities differ in detail, their main structures, processes and interdependencies show similarities. The presented methodological approach can hence be transferred to other areas, by some limitations: Firstly, the authors are at the same time involved as observers and participants in such a participatory approach (Fekete, 2012b). This limits their abilities to recognize certain constraints. Secondly, all case studies are located within the same region. Nonetheless, if key conditions are comparable, transferability should be possible to other German regions and even into other countries. Thirdly, readiness for co-creating knowledge is the decisive factor for applying the approach presented here.

ACKNOWLEDGEMENT

CIRMin is funded by the German Ministry of Education and Research (BMBF) from 6/2016 to 5/2019 in the context of the research program "Zivile Sicherheit – Erhöhung der Resilienz im Krisen- und Katastrophenfall".

Choosing Optimal Ways to Increase Resilience of Critical Infrastructures

Sandra König
Austrian Institute of Technology
Sandra.Koenig@ait.ac.at

ABSTRACT

Increasing resilience is a core interest in critical infrastructure (CI) protection that involves many challenges. It is necessary to agree on a common understanding of resilience and identify potential strategies to improve it. Once this is done, the question arises how to choose among these strategies. We propose to decide based on a game-theoretic framework that allows identification of optimal actions under various scenarios. This framework considers different threat scenarios as attacks to the CI and the identified strategies to improve resilience as defense strategies for the CI. Since the payoff of the game, namely the resilience of the CI, can hardly be measured with certainty we choose an extension of classical game theory that allows taking uncertainty into account and still finds provably optimal solutions. This approach is especially useful in a situation where we aim to optimize a quantity that is difficult to measure (such as resilience). The result of this analysis is two-fold: it identifies an optimal defense but also provides information about the resilience in the worst case. The approach is illustrated with a small example using a publicly available implementation.

Keywords

Resilience, critical infrastructure, optimization, game theory.

INTRODUCTION

In the context of critical infrastructures (CIs) resilience is especially important as the impact of a failure or even limited availability of a CI has a significant impact on society and economy (Boumphrey and Bruno 2015; National Infrastructure Commission 2017; Royal Academy of Engineering 2018). Several measures for resilience exist for specific sectors of CIs, e.g., for the energy domain (Panteli et al. 2017) or the water supply (Cuisong and Hao 2008), or for specific scenarios, e.g., for hurricanes (Tokgoz and Gheorghe 2013). More advanced approaches to resilience take into account viewpoints from organizations and people (Gouglidis et al. 2016) but are more time-consuming to evaluate. In this work, we use a more general formulation of resilience in the context of CIs to develop a general methodology that may be refined for specific sectors. We choose a more general measure as proposed in (König et al. 2019) that is simple but in line with a risk management process according to ISO 31000. This measure builds on the notion of risk as the product of likelihood and impact by defining the resilience against a specific scenario as the product of likelihood and a factor depending on the expected impact due to the risk scenario and the preparedness against it. It is constructed in such a way that positive values indicate that preparedness is on average higher than the expected damage and negative values indicate that preparedness is not sufficient on average.

Once agreed on a measure for resilience, the aim is to identify ways to improve it as much as possible. This involves several challenges. First, it is important to identify relevant threats and potential countermeasures. Then, the question is which of these countermeasures should be chosen to optimize resilience. Answers to the first question are manifold and may include consultation of vulnerability databases but also adversary modelling. Still, such a list of threats will always be incomplete due to the risk of unexpected events (i.e., black swans). The second question on the other hand may be threated rigorously by applying optimization techniques. As the resulting resilience depends on both the threat and the countermeasure we here apply a game-theoretic framework where an attacker causes problems that reduce the CI's resilience while the CI operator tries to maximize the resilience in the light of all possible attack. In this somewhat abstract view the attacker is not necessarily a real person but anything that threatens the CI, including nature. In this setting it is impossible to model

the adversary explicitly since we do not have any information on his intention. However, considering the worst case that the adversary's intentions are exactly opposite to the defenders ones (i.e., playing a zero-sum game) provides a lower bound to the resilience if the CI. This game theoretic optimization of resilience may benefit from existing risk management processes where for example risks have been identified and evaluated. Such information may be incorporated in the described approach.
This paper is structured as follows. After a discussion on how to measure resilience in CIs we focus on ways to improve it based on the proposed game theoretic framework. This consists of the identification of threat scenarios and strategies to improve resilience as well as estimation of the resilience for each scenario to build a game. The choice on an optimal improvement strategy is found by solving this game. An example is provided to illustrate how to apply the theoretic model. Open issues are discussed in the conclusion.

MEASURING RESILIENCE IN CRITICAL INFRASTRUCTURES

When aiming for improvement of resilience, it is necessary to have a measure of resilience so that different situations can be compared. While a general definition is hard to find, formalizations are possible for specific fields. Concerning CIs, the term resilience can be understood (analogously to the term risk) as

$$R = \sum_{s=1}^{N} \omega_s \cdot (P_s - E\,[I_s]), \qquad (*)$$

where the sum is over all scenarios s, ω_s is the likelihood of occurrence of scenario s, P_s is the preparedness against scenario s, and $E\,[I_s]$ is the expected impact on the CI in case scenario s happens (König et al. 2019). In order to compute this value, it is first necessary to agree on a set of scenarios that threaten the CI. These include both natural disasters and intentional attacks. For each of these scenarios it is then necessary to estimate the likelihood of occurrence, which is often based on historical data about similar events. Then, every single scenario needs to be investigated to answer two questions:

- What is the expected impact on the CI for this scenario?
- How well is the CI prepared for this scenario in the sense that it is able to keep its functionality to a certain level despite a realization of the scenario?

If available, simulation methods may be used to mimic a scenario and estimate its impact. Otherwise, experts may be able to provide a qualitative estimate or historical data may be available. The second question is a bit more difficult to answer as the term preparedness is not clearly defined, but needs to be taken into account (Martin and Ludek 2013). Practically, it is necessary to measure expected impact and preparedness on the same scale to be able to evaluate formula (*) above. A qualitative scale, e.g., a 5-tier scale, is recommended for experts' opinions since precise estimations are difficult to get. In that case, the term *preparedness level* is used. In the context of CI resilience, the term preparedness is understood as the maximal degree of impact that still allows smooth operation (similar to the breaking point of an estimator in statistics), i.e., a damage higher than the preparedness yields to limited functionality of the CI and reduces the overall resilience of the CI (as this scenario contributes a negative value to the sum).

When investigating resilience of a CI it is not always enough to have a single value that provides an average resilience. A deeper analysis may be concerned about the various scenarios and their severity. In particular, we aim to identify scenarios with the low resilience as these threaten the system the most. Thus, we focus on the resilience R_s for a specific scenario s,

$$R_s = \omega_s \cdot (P_s - E\,[I_s]),$$

to be able to compare the different situations. The value is also influenced by changes in the CI, in particular if different strategies for improvement are implemented. For a bunch of improvement strategies we identify those that are optimal, i.e., that reduce resilience the most.

INCREASING RESILIENCE OF A CRITICAL INFRASTRUCTURE

Evaluation of the resilience for the current situation is only the first step in an analysis that aims at improving resilience of a CI. Consider a fixed set of scenarios with known probabilities of occurrences. When applying the formulation of resilience as described above, resilience can be improved by either increasing the preparedness level or reducing the expected impact (or even both at the same time).

Potential strategies for improvement range from implementation of new protection measures (e.g., honeypots to detect malware), improving existing controls (e.g., check pumps more frequently) or training of employees to increase awareness of new threats. While a list of potential actions can be found in discussion with experts, it is

typically not possible to apply all potential actions due to limited resources. The challenge is then to decide which strategies should be chosen. In this work, we apply a game-theoretic framework that describes a threat to a CI as an attack (intentional or not) while the CI operator is in the position to defend, i.e., to protect his system. As we do not have any knowledge on the attackers intentions (especially in the case of natural disasters), we model the situation with a zero-sum game that assumes an adversary who tries to cause as much damage as possible while the defender tries to minimize the suffered damage. Analysing the situation with this approach consists of three steps:

(1) identification of threat scenarios
(2) identification of countermeasures
(3) estimating resilience for each combination of an attack and defence (a scenario)

Threat scenarios are interpreted as attack strategies where the attacker does not need to be a person but also nature, basically anything that causes harm to the CI. Similarly, countermeasures are interpreted as defence strategies since these help reducing the expected damage. Finally, the estimated resilience is the payoff that the defender cares about. He aims to maximize it while the attacker's actions aim at reducing it. In the remainder of this section we elaborate on these three steps.

Identification of Threats and Countermeasures

The identification of relevant threats to the CI and potential countermeasures to protect the system is the most difficult part of the game-theoretic analysis. A game-theoretic equilibrium identifies the worst-case attack and the best way to protect against it, but it can only be chosen from available information. The optimality of the found solution is no longer valid if attacks have not been considered or defence strategies are incomplete or cannot be applied in practice. A list of threats contains information on past incidents as well as issues identified with experts familiar with the system. Recent publications such as (Ghafir et al. 2018; Zimba et al. 2018) describe various scenarios that may harm the system.
A list of countermeasures has at least two sources of information: international standards such as ISO27001 and expert knowledge. Additional actions that may protect the system can be found when analysing past incidents or penetration testing, but also from publications such as (Walker-Roberts et al. 2018). Further, a list of threats may be available form a classical risk analysis that includes risk identification and evaluation. Despite all these different sources, the list of threats will always be incomplete (as it misses for example unexpected events). However, this is a general issues and not a weakness of the game theoretic approach. Another issue is the growth of the strategy space when combinations of attacks are considered. While this is a problem in the theoretical setting it is not such a big issue in practical applications as combination of threats (e.g., a contamination followed by an earthquake) are rather rare and arbitrary combination of protection measures may not be affordable for the CI operator.

Estimation of Resilience

Having a set of relevant attacks and feasible defence strategeis, resilience must be estimated for each scenario. For the resilience measure used here this requires estimation of the expected impact and the preparedness for a specific attack and a fixed countermeasure. The likelihood of occurrence remains the same (just as the chances of a lightning when computing the risk), but countermeasures influence the impact of a scenario (i.e., better protection prevents the house from burning down). Different strategies typically do not change the dynamics of the cascading effects but rather cause a faster or slower spreading. In case the expected impact is estimated based on simulations, different scenarios may be analysed by choosing different parameters for the simulation. In case we are not able to mimic the consequences of an attack, we need to ask experts to rate the expected damage. In both cases, we get several estimates for the same situation which yields distribution-valued payoffs. As described above, preparedness is measured through expert assessments on a qualitative scale. Also, this estimate is distributions-valued if we ask several experts for their assessment and do not aggregate their assessments.
In a classical game-theoretic setting, the estimated payoffs need to be real numbers but extensions allow payoffs to be random variables (Rass et al. 2015). This allows in particular dealing with disagreement among experts since it is not necessary to agree on a single estimate. Rather, we collect all available opinions and work with histograms instead of numbers. While this may yield pessimistic estimates (e.g., if one of the experts tends to be anxious) it is in line with a qualitative risk assessment as recommended by the German Federal office of Information Security (BSI). Further, this general approach helps to keep track of single assessments and thus increases the understanding of the decision while such information is lost if different opinions are aggregated.

Choosing Optimal Protection Strategy

In order to find an optimal protection strategy the game needs to be solved. Since our estimate of resilience contains assessments from several experts we apply the more general setting. It allows taking into account every single assessment rather than aggregating all these different opinions. Even in this generalized setting a Nash equilibrium can be computed (Rass et al. 2016) with the (generalized) fictitious play algorithm. It mimics a fixed number of game plays and records how often each strategy has been played. It can be shown that this yields an estimate of a Nash equilibrium (Rass et al. 2016) where no player has an incentive to deviate since he will not be able to improve. An implementation of the methods applied here is publicly available on CRAN (Rass and König 2018). Its use is illustrated with a small example below.
The main difference to existing approaches lies in the way how uncertainty is taken into account. Stochastic models like Bayesian games assume that a player is unsure about what type of adversary he is playing with but is certain about the payoffs in each possible case. Our point of view is different: we think it is generally very changing to exactly predict the payoffs for a given scenario which is why we replace the crisp (real-valued) payoff by a random variable.

ILLUSTRATIVE EXAMPLE

Consider a fictitious water provider that uses an industrial control system such as a SCADA (Supervisory Control and Data Acquisition) system to control its processes. The SCADA server as the central component of the SCADA network is located in a control room to allow monitoring processes in real time. Programmable Logic Controllers (PLCs) supervise processes at the treatment plant and Remote Terminal Units (RTUs) at remote sites such as pump stations.

The game-theoretic model considers the three attacks

- s_1 contamination
- s_2 earthquake
- s_3 attack on SCADA system

and the defence strategies

- d_1 more water reservoirs
- d_2 more frequent controls

Attacks on SCADA systems are manifold. We here consider the situation where data in the SCADA system are manipulated in such a way that a change at the remote site is not recognised or such that fake data provokes an act that causes damage to the system.
Increasing the amount of stored water in reservoirs aims at reducing the damage in case of a contamination. Regular controls help to detect problems with the water quality (e.g., due to a contamination) as well as a potential mismatch between the real status of a site and the data reported by the SCADA system in case of an attack that involves forged data. Countermeasures against earthquakes are complex and expensive (e.g., reconstruction of a building) and are thus not taken into account in a mid-term analysis.
In order to recognise improvements over the current state we also need to include the current situation of the CI as a defence strategy

- d_0 no change (status quo)

The likelihood of occurrence for the considered attacks are set to $\omega_1 = 0.2$, $\omega_2 = 0.2$ and $\omega_3 = 0.3$ based on reports on contamination (Brown and Darby 1988), earthquakes (Field 2015) and ICS attacks (Kovacs 2016).
We assume that estimates of the expected impact as well as the preparedness level are available either from expert knowledge or simulation. For illustration we work with the data given in Table 1, Table 2 and Table 3 where a 5-tier scale is used such that 1 corresponds to smooth operation and 5 to total failure (intermediate values correspond to limited availability, accordingly).[i] These values are artificial and solely meant to illustrate the approach. Still they should reflect the intuition that more water reservoirs (d_1) increase the preparedness against a contamination (as more pure water is available). More frequent controls (d_2) are assumed to increase preparedness against contamination and a SCADA attack (as it is discovered earlier) and to reduce the expected impact due to a contamination or a SCADA attack (as the spreading gets slower due to the controls). In practice, these values come from interviews with experts in the field that provide estimates of the preparedness and the impact. In case experts may only provide a vague prediction such as the most likely value and an assurance level, a distribution over all possible values can be estimated (König and Rass 2018). Further, simulation methods may support the impact estimation.

Table 1 Estimates for current status d_0

Scenario	Preparedness	Estimated Impact
s_1 contamination	2,3,3,3,4	3,3,4,4,4
s_2 earthquake	3,3,4,4,4	3,3,3,4,4
s_3 SCADA server attack	2,3,3,4,4	3,4,4,4,5

Table 2 Estimates for more water reservoirs d_1

Scenario	Preparedness	Estimated Impact
s_1 contamination	3,3,3,3,4	3,3,3,4,4
s_2 earthquake	3,3,4,4,4	3,3,3,4,4
s_3 SCADA server attack	2,3,3,4,4	3,4,4,4,5

Table 3 Estimates for more frequent controls d_2

Scenario	Preparedness	Estimated Impact
s_1 contamination	3,3,3,3,4	3,3,3,3,4
s_2 earthquake	3,3,4,4,4	3,3,3,4,4
s_3 SCADA server attack	3,3,3,4,4	3,3,4,4,5

These data allow computation of the resilience for each combination of a threat scenario and a defense strategy. Since we have several estimates, we use the R package HyRiM (Rass and König 2018) that is able to optimize distribution-valued payoffs. In order to apply that framework, the maximization of the resilience R needs to be translated into minimization of $-R$ and the resulting values need to be transformed such that the values are positive integers and potential gaps need to be filled by smoothing (see description of the package (Rass and König 2017) for details on how to use it). The resulting payoff matrix is shown in Figure 4.

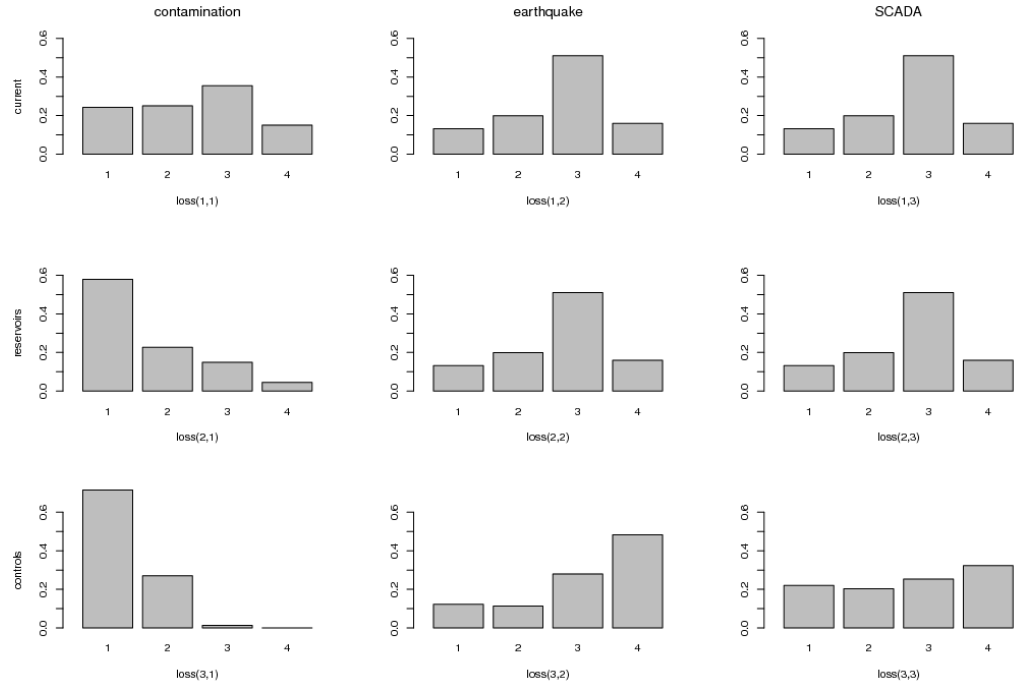

Figure 4 Payoff Matrix

Applying the generalized fictitious play algorithm to solve this game yields the Nash equilibrium (d_0, s_2), that is, the scenario that reduced resilience the most is an earthquake (s_2) and the best way to protect against it is to keep the current state (d_0). In other words, the two defense strategies d_1 and d_2 do not yield to an improvement in this setting and it is necessary to look for other strategies to improve resilience under these threat scenarios. The solution is illustrated in **Figure 5** and reads as follows: from the potential defense strategies, choose "current" $(d_0)$with probability 1 and similarly choose attack strategy "earthquake" (s_2). In case these two strategies are played the resulting distribution of the resilience is shown in the lower right corner.

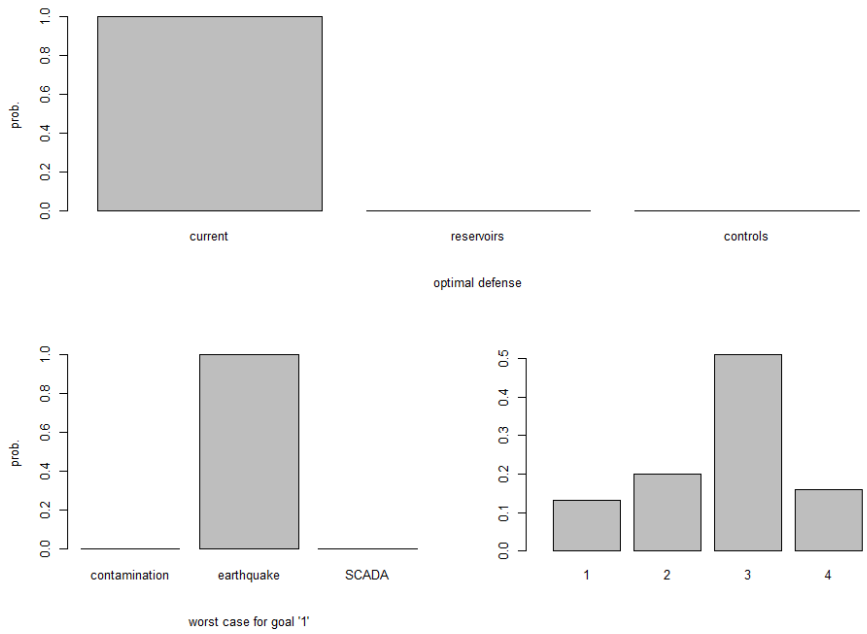

Figure 5 Optimal Strategies and Worst Case Resilience

In a more elaborated example where the list of potential defenses and threats is longer, the optimal solution may not only involve a single defense action but a combination of several actions (a mixed equilibrium). Then, the strategies with a positive likelihood need to be played with relative frequencies that match these likelihoods. For the risk scenarios that constitute the attack strategies this means that several scenarios may occur successively (with relative frequencies corresponding to the likelihoods from the resulting equilibrium). The framework allows optimizing several goals simultaneously which makes it possible to minimize implementation costs of countermeasures at the same time.

CONCLUSION

In the context of critical infrastructures several measures for resilience exist for different domains. Some of these measures allow comparison between different CIs but also for different situations a single CI may face. If it is possible to estimate the resilience for different situations, consequences of protection measures can be compared. Game-theoretic models can be applied to determine the optimal way to protect a system if a list of potential improvements is available. If various threat scenarios are considered it is further possible to determine a worst-case scenario that yields to minimal resilience and estimate the resulting resilience in this case.

While the introduced approach is general in the sense that it is applicable to a wide range of CIs, many issues are still to be investigated in more detail. A big challenge is the estimation of the preparedness level. An estimation of this value depends on many factors such as the weather conditions, so that a single value may not be enough to describe this parameter. Methods for impact estimation as well as the identification of strategies need to be examined in more depth, with different approaches for different sectors. Another issue ignored so far time that plays an important role when talking about resilience. The resilience measure used is time-independent and the game is only played once so that it optimizes the current situation.

Cascading Threats in Critical Infrastructures with Control Systems

ABSTRACT

Critical infrastructures (CIs) increase in complexity due to numerous dependencies on other CIs but also due to the ongoing digitalization in the industry sector. This yields an increased risk of failure of a single CI as the overall systems gets very fragile and sensitive to errors Failure of a single component may affect large parts of an infrastructure due to cascading effects. One way to support functionality of a CI is the use of Industrial Control Systems (ICS) that allow monitoring remote sites and controlling processes. However, this is an additional source for threats as recent cyber-attacks have shown. Further, the additional information for such cyber systems is often not efficiently combined with existing information on the physical infrastructure. We here propose a method to combine these two sources of information in order to estimate the impact of a security incident on CIs, taking into account cascading effects of threats. An implementation of the model allows simulation of the dynamics inside a CI and yields a record of the status of each asset of the CI. The way the assets change their states illustrates the consequences of an incident on the entire CI. Visualization of the results provides an overview on the situation of the entire CI at a certain point of time and a sequence of such visualization over an entire period of time illustrates the changes over time. The results from this analysis may be used to support security officers in analyzing the current (hybrid) state of their CI in case of an incident and thus increase the hybrid situational awareness.

Keywords

Cascading failures, industrial control systems, critical infrastructures, hybrid situational awareness.

INTRODUCTION AND RELATED WORK

Critical infrastructures (CIs) are growing in complexity, not to the least due to the increasing digitalization and stronger interconnections among them. In most of the CIs, Industrial Control Systems (ICSs) are used to allow monitoring physical systems and controlling processes within the infrastructure. Depending on the characteristics of the infrastructure, either Supervisory Control and Data Acquisition (SCADA) systems or Distributed Control Systems (DCSs) are used (Green et al. 2014). Critical infrastructures that span across a large area, e.g., water or electricity provider, typically use SCADA systems which are supervised in a large control center rather than several smaller decentralized centers (as in the case for DCSs). Besides such control systems, CIs typically collect information on their physical domain from video surveillance applications, access control systems, smoke detectors and other sensors. Information on the cyber domain contains data from Intrusion Detection Systems (IDSs), Security Incident and Event Management (SIEM) systems, firewalls or similar systems.

This information on the physical and cyber subsystems within a CI is not always used optimally as it is often treated independently for each of the domains. However, sophisticated attacks such as Advanced Persistent Threats (APTs), as Operation Aurora (Zetter 2010) or Stuxnet (Karnouskos 2011), often start in the cyber system and later spread to the physical system. In this context, an early step of such a sophisticated attack may be the manipulation of data collected by the SCADA system to pretend normal functionality while the actual physical process is interrupted or disrupted. Protecting a CI from these kinds of attacks requires combining information from both the physical and the cyber domain.

Several approaches exist to investigate cascading effects in CI. Petri nets have been applied (and tested) to fluid

critical infrastructures (Ghasemieh et al. 2013). An overview on failure analysis for power systems is given in (Guo et al. 2017). While most of these are domain specific, we aim for a generally applicable high-level model that needs to be refined when applied to a specific area.

More general models on cascading failures in CIs include Markov chain models (Rahnamay-Naeini and Hayat 2016; Wu and Chu 2017). Our choice of finite-state automaton (a.k.a. finite-state machines) rather than Markov chain models is due to their ability to react on external input.

A description of CIs through a network of deterministic finite-state machines is given in (Klemetti et al. 2016), who applied the model to an electric grid as well as mobile networks. The increasing uncertainty about sates over time is captured by associating a probability distribution to each automaton rather than using a probabilistic automaton.

In this paper, we propose a hybrid view that combines information from the physical and the cyber domain to support the analysis of cascading effects of an incident on the entire CI. The proposed automaton model represents the functionality of a CI's assets through different states and analyses how these states change due to the incident. The implementation of the model represents the network of interdependent physical and cyber assets as a graph and simulates the dynamics within the critical infrastructure using stochastic processes. We introduce the methodology with a focus on critical infrastructures that apply ICS to monitor their processes as an example of a cyber-physical system.

The paper is structured as follows. A hybrid situational awareness model is introduced that combines and extends existing cyber and physical situational awareness to obtain a holistic view on the CI. Further, a model for characterizing the cascading effects of an incident in the CI is described and its use for impact estimation is sketched. The approach is illustrated with a small example and the article finishes with concluding remarks.

HYBRID SITUATIONAL AWARENESS

The current state of the cyber and physical domain is conveniently described by a *cyber situational awareness (CSA)* and a *physical situational awareness (PSA)* system, respectively. The term situational awareness is generally understood as a complete description of the environment including information on potential threats. To this end, it combines several existing sources, e.g., it incorporates information from cameras or access control systems for the physical domain or technical vulnerability databases for the cyber domain. Both CSA and PSA report events that happen in the corresponding system and issue an alarm if such an event threatens the system. A cyber alarm may be a detected virus in the system (say, a malware) while a physical alarm may be a fire in a building that is part of the CI. Further, both CSA and PSA observe numerous events that do not threaten the system directly because they are legitimate activities or do not have a high criticality.

When the information from the CSA and PSA are combined, they build up a *hybrid situational awareness (HSA)* that not only contains information from both subsystems but also combines the two sources of information to obtain new insights about the current status of the CI (Schauer et al. 2019). To achieve that, the HSA links events and alarms from the cyber and physical domain and is able to identify combinations of those events that may indicate a threat to the CI. Furthermore, it also shows which cascading effects might occur within the entire infrastructure due to such an (cyber, physical or hybrid) alarm by providing a list of assets which might be affected by the incident. For example, consider the following two events: an employee leaves the area of the CI in the evening, which is monitored by the access control system at the main gate; second, his credentials are (correctly) used to log in to a computer somewhere inside the CI, which is monitored by a host-based IDS. Both events individually are not of special interest, since they are legitimate in the physical and the cyber domain, respectively, and will not trigger an alarm in the CSA or PSA. However, the combination of both events within a short period of time indicates that there might be a problem, since the same employee cannot be at two places at (roughly) the same time. Such combinations can be caught by the hybrid view of the HSA and are therefore called *hybrid threats* or *hybrid alarms* as they threaten the system but only show up in the hybrid view.

The identification of such hybrid alarms is often difficult as it depends on the context if a combination of two events represents a threat to the infrastructure or not. Therefore, such an identification can be achieved using a rule based system which either defines a set of valid (i.e., a whitelist) or invalid (i.e., a blacklist) combinations of events. However, such an automated detection of correlations between cyber and physical events may only yield candidates for hybrid alarms but expert knowledge is required to decide if this is indeed an alarm or not.

In short, the benefits of a HSA as described here include the following:

- Awareness is increased and operators gain an overview on their cyber-physical system
- Implicit and potentially unknown interdependencies become clear
- Decision making for port operators is facilitated when information about incidents can be estimated and compared

One way to identify hybrid alarms is the correlation engine introduced in (Schauer et al. 2019). The potential cascading effects on the entire CI is analyzed based on a graphical representation of the CIs assets and a stochastic model that describes the propagation through this graph. In the following section, the threat propagation engine is described in more detail.

HYBRID THREAT PROPAGATION

A formal description of a CI is often based on a graph representation where the nodes correspond to single assets of the CI (e.g., a server) and edges to dependencies between them. Our approach is also graph based and additionally, nodes are classified as either cyber or physical, depending on the system they belong to. Directed edges between two assets indicate that one depends on the other. These dependencies include the ones among the cyber and physical assets, respectively, but also interconnections between the two domains. Particularly these interconnections are often not explicitly given. Hence, when building up this asset graph, it is important to discuss with experts who are familiar with the different parts of the CI, i.e., the physical and the cyber assets, to obtain a comprehensive and in-depth description of the entire system. For example, when examining the situation of a water provider it is necessary to talk to employees who know the water distribution network and with others familiar with the SCADA system.

The graph representation is further extended such that each node (i.e., each asset) can be in one of several different states. The state of an asset changes either due to an external incident or due to a change state of an asset it depends on. In both cases, this state change is triggered from outside and does not necessarily happen in constant time intervals. Thus, we describe the dynamic of a single asset by a finite-state automaton (Paz and Rheinboldt 2014) rather than a Markov chain where changes happen at predefined points in time. The dependencies between two assets are manifold and complex as they depend on many factors such as the state of all assets they depend on (directly or indirectly) as well as external influences (such as weather). In order to capture these phenomena, we choose a probabilistic automaton that predicts the next state through a probability distribution over the set of all possible outcomes rather than a precise prediction.

Cascading effects usually have a trigger starting the process. In our case, such a trigger is an incident that causes an alarm reported by CSA, PSA or HSA that is correspondingly called cyber, physical or hybrid alarm (in the following, we will consider these alarms as a start of the cascading while keeping in mind that these are triggered by an incident or an unusual combination of events). In our approach, an alarm has attributes such as name or criticality to describe its nature. Depending on its type, an alarm may influence the dependencies between two assets (e.g., two neighboring rooms are strongly dependent in case of a fire alarm but to a lower degree in case of burglary). In order to capture this dynamic, we choose to model assets as probabilistic Mealy automaton (Paz and Rheinboldt 2014; Rabin 1963) as these also provide output after each state change. More explicitly, the inner structure of an asset looks as displayed in Figure 1.

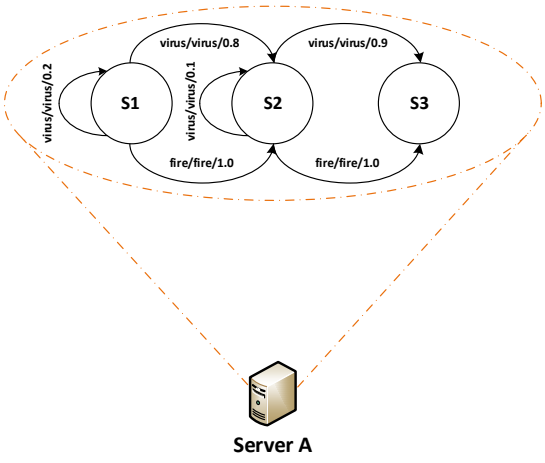

Figure 1. Representation of an asset as a probabilistic Mealy automaton

The asset can be in one of finitely many states (e.g., states s_1, s_2, s_3 as in Figure 1) and changes its state with a certain probability. This state change is due to an input and yields an output as a response to the state change. This is indicated by adding a triple of the form input/output/probability to the edges that describe potential state changes. For a Mealy automaton the output does not only depend on the current state of the asset but also on the input. This allows to forward information on an alarm from one asset to other assets depending on it. A more formal description of this model is given in (König et al. 2019), we here focus on its applicability to the security of CIs.

Dynamics inside a CI

Once the behavior of a single asset is modeled, the dynamics inside a CI can be described when the dependencies between the assets are known. Identification and modeling of dependencies inside a CI are challenging but a necessary part of risk assessment process (Schaberreiter et al. 2013). In our setting, dependencies between assets depend on static factors such as the type of an asset but also on dynamic factors such as the current state of the asset that affects the other one or the type of alarm. As an example, consider a building that is affected by a fire. The room where the fire breaks out may "inform" its neighboring rooms about the fire (i.e., the alarm) as well as how much it is affected by it (i.e., its current state). Both pieces of information influence the state change of the neighboring rooms. The effect on the entire CI due to a fire may be smaller (given that fire safety regulations are working) than, for example, in case of electricity outage where typically an entire floor, the whole building or the entire CI is affected. However, the degree of damage for a specific room also depends on the state of assets it depends on, e.g., if a small fire only affects a PC it is less likely to affect neighboring rooms than if the entire room is on fire.

Using probabilistic automaton to describe the behavior of the assets, the dynamics inside the CI become stochastic as well. This fits into the current line of research where complex systems are described through stochastic processes (König and Rass 2018; Rahnamay-Naeini and Hayat 2016; Wang et al. 2012). Such models are able to take into account the unpredictability of systems where an exact description is hardly possible due to the high complexity as well as due to unknown or non-deterministic factors. Still they provide a formal description of the system that allows an analysis of the average behavior of the system.

Implementing this stochastic model yields empirical data on the behavior of the assets that allows prediction about the future development of the CI. If enough information on the CI is available, e.g., for a specific sector such as smart grids, simulation approaches may be used as an alternative to a formal mathematical description of the dynamics (Findrik et al. 2016; Jaromin et al. 2013; Song et al. 2016). If available, testbeds may be used to simulate different scenarios (Green et al. 2016) and gain some additional insight in the dynamics of a system.

Overall State of a CI

The condition of a CI can be described through the level of functionality of its components. Clearly, if all components were in a bad state, the CI will not be able to provide the expected output while everything works fine if all components were in a good state. However, things are less clear in situations where some assets are not fully operating: Is the CI still able to provide the desired output if some components fail or only work to a certain degree? In order to answer this question, we choose a set of possible states, say "properly working", "limited functionality", and "failure" and let each asset of the CI be in exactly one of these states. For a formal analysis the states may be represented by numeric values, say 1 (properly working), 2 (limited functionality), and 3 (failure). A visualization of the states of all assets provides a basic overview on the overall state of the CI, e.g., assets colored in green (state 1), orange (state 2) and red (state 3), demonstrates where a problem affects the CI the most. The overall state of the CI may be measured by counting the number of assets in the worst state. However, not all assets are of the same importance to the CI operator, so one may only care about the output of the CI, e.g., measure the quality or quantity of the provided water.

IMPACT ESTIMATION FOR CASCADING THREATS

Based on the threat propagation model described above, it is possible to simulate the behavior of all assets of the CI (in the physical as well as in the cyber domain) after an incident. The state changes of the assets indicate the development of a threat and highlight its cascading behavior over different subsystems. The spreading process is reproduced by defining a set of states and transmission probabilities such that the probabilistic Mealy automatons simulate the behavior over time. Recording the state changes of all assets over time (yielding a time series for each asset) indicates how the spreading evolves as the states represent how strong assets are affected.. Depending on the considered scenario, it may be necessary to distinguish several alarms coming in (e.g., from different assets) which can be solved by a prioritization in terms of criticality or time. A basic implementation

can be done in a software such as MATLAB where the prioritization of alarms can be implemented as a FIFO (First In, First Out) queue.

Mimicking the cascading of threats based on the described model requires a comprehensive description of the CI. This particularly includes a list of all the relevant assets within the cyber and physical system including their interdependencies as well as the connections between these two systems. Then, the set of states of each asset needs to be defined as well as the words used for communication between the assets (i.e., the input and output alphabets of the Mealy automatons) that describe the considered alarms. This information may be collected in discussion with (risk) managers who typically have a good overview on the entire system.

After the general specification of the CI, more situation specific aspects need to be taken into account. For each pair of states, the state transitions function and output function need to be formalized. The output function assigns a deterministic output to every pair of input and state which corresponds to the message sent to the dependent asset. In the probabilistic setting, the transition function assigns a probability distribution over all possible states to each combination of an input and a state. The next state is then chosen according to this probability distribution. This more detailed information is collected in discussions with domain experts as knowledge of the processes is required to estimate transmission likelihoods or to predict the most likely next state. Asking for exact estimates of probabilities may be avoided by rather asking for the most likely value combined with an assurance and estimate a probability distribution from these inputs (König and Rass 2018).

With this general and specific information, it is possible to simulate the consequences of an alarm affecting one or more assets by implementing the random behavior of the assets. Recording the state changes over time provides empirical data that can be analyzed statistically. First, it is possible to predict the overall state of the CI by estimating how many assets fail on average (i.e., are in the worst state). Second, one can look at single assets and estimate the likelihood that it is affected or fails. This may be interesting for core assets that should be particularly protected but also provides an overview on state of the CI. To this end, the graphical representation of the infrastructure is extended such that each node is assigned a color depending on its average state, e.g., green if the likelihood of failure is low and red if it is high.

In case the analysis of the current situation has indicated problems (e.g., an important asset is likely to fail, or several assets are likely to end in a state of reduced operation), additional simulations allow testing potential countermeasures. For example, if a sensitive asset is likely to fail, the simulation may be rerun with an increased protection of the asset or a second asset in place which is organized as a backup. Moreover, if a simulation indicates that a large part of a CI is likely to be affected by an alarm additional preventive measures on an organizational level may be required to reduce the expected damage. In this sense, the proposed threat propagation method is not only a tool to analyze the impact of cascading effects on a CI but may also be used to investigate various methods to reduce the expected damage. In general, the security officers monitoring the physical and the cyber domain within a CI (e.g., within a port) will instantiate the model. Hence, it is understood as a collaborative approach with data coming from experts in their respective fields; however, the collaboration is realized in physical meetings and discussions rather than in an online tool.

EXAMPLE

Consider a water provider whose main aim is availability of water with a focus on the quality of drinking water. To reach this goal, a SCADA system is applied to ensure water production, purification and distribution. In this example, the physical domain contains assets such as pumps, wells, water plants and the water distribution system equipped with sensors and Programmable Logic Controller (PLCs). Further, the cyber domain contains assets such as laptops that allow remotely controlling pumps, the SCADA server, the communication system (including switches) and other systems. An extract of this system is displayed in Figure 2. Each component is descried through a Mealy automaton (as shown in Figure 1) but we hide the detailed description to focus on the dependencies between components.

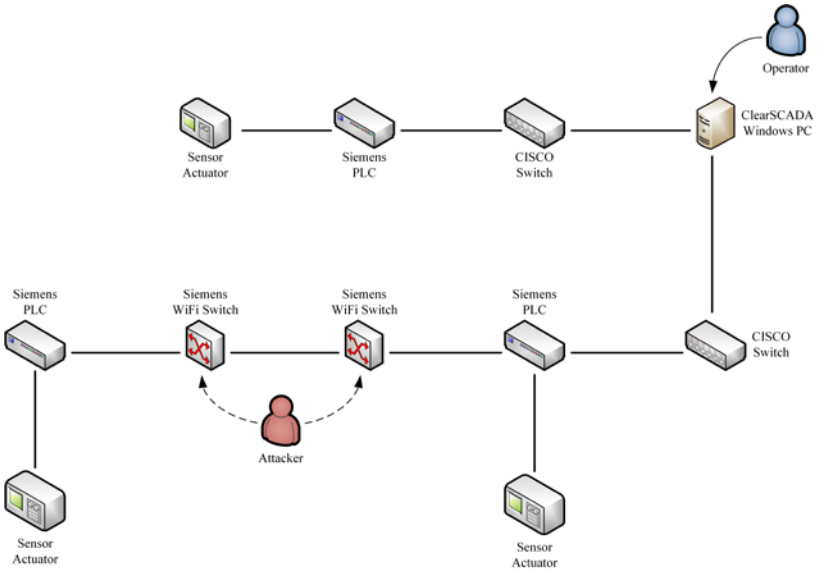

Figure 2. High-level representation of a part of a water provider (automaton details hidden)

An APT (Advanced Persistent Threat) attack on this system, as described in (Gouglidis et al. 2018), typically consist of several steps involving both the cyber and the physical system. Prior to the actual attack, information on the company is collected for a targeted attack, e.g., by social engineering. Then, a device from the cyber network connected to the WiFi network is compromised. This allows launching an attack that causes failure of some controllers (physical assets) and might further give access to the internal company network (cyber asset). Having access to a management server enables the attacker to modify controller logic to cause failure of controllers or switches in the physical network. Depending on the importance of the manipulated devices, this may cause significant damage to the CI operator.

Analyzing cascading effects in this network with our approach involves the following steps:

- Identify all important assets (physical and cyber) and specify the corresponding probabilistic automatons. In particular, define the set of potential states, the transition regimes and the notification behavior (the output function) for each asset.
- Identify all dependencies between the assets both inside the corresponding domains as well as between domains
- Identify all possible alerts (physical, cyber and hybrid) that may cause cascading effects

For the considered attack, the first two steps yield the graph model of the CI as shown in Figure 2 (the graphical representation quickly gets complex so that only a subnetwork of the CI is depicted). For each alert it is now possible to simulate the effects on the entire CI and represent the resulting states of the assets graphically.

A popular goal of such an attack is the SCADA server that allows the manipulation of switches and thus enabling denial-of-service attacks (DoS). Alternatively, technical vulnerabilities of logically connected devices such as sensors or cameras may be exploited to change their behavior or modify data such that wrong measurements or surveillance data are reported. For illustration purpose we consider an attacker who gains access to two switches through the WiFi. This may affect connected devices such as PLCs (Programmable Logic Controllers) which in turn may compromise other dependent devices. The propagation is illustrated in Figure 3 where affected devices are marked red.

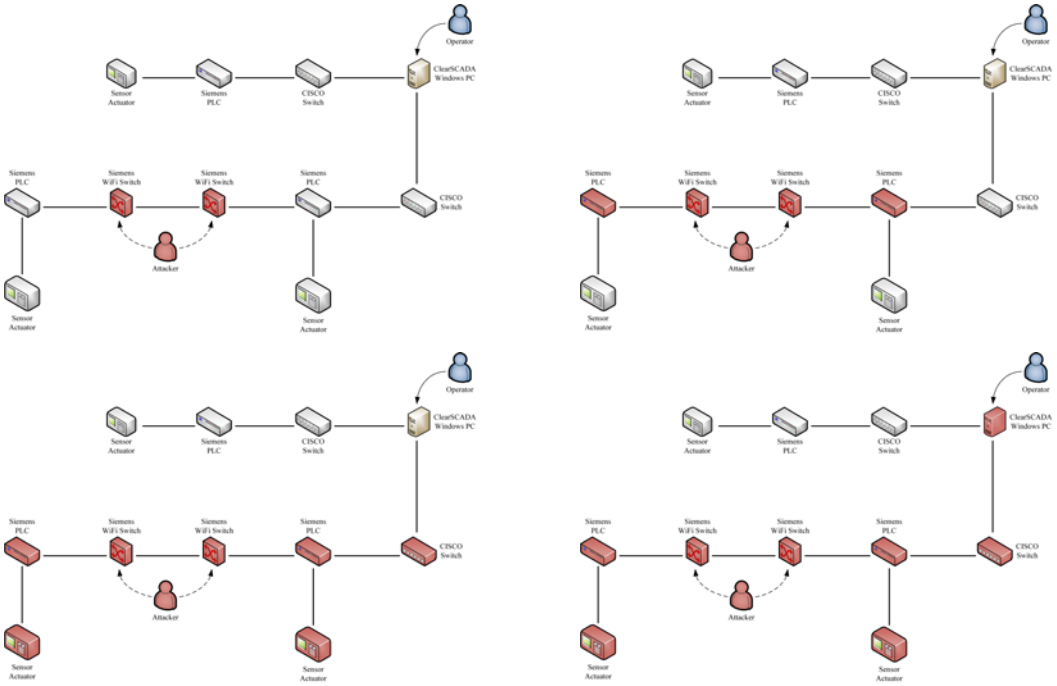

Figure 6. Cascading effects of an attack on two switches of a water provider

CONCLUSION

Investigating cascading effects of an incident within a CI requires the combination of available information on both the physical domain and a cyber domain (including control systems such as a SCADA system). A formal analysis of the CI based on a graph model where nodes are represented as probabilistic Mealy automatons allows investigating the behavior after an incident that occurs in the CI. This model considers different levels of functionality of each component while taking into account the unpredictability of complex systems. Since it combines information from CSA and PSA, the approach presented here yields a hybrid view on the infrastructure and is able to identify threats that are not recognized if the two domains are treated as independent. Simulations based on this model allow estimating the level of functionality of each component within the entire system. This provides an overview on the state of the considered CI after an incident, taking into account cascading effects.

The model described in this paper aims to find a balance between a detailed description of the CIs assets and interdependences and feasibility of implementation. The current description is limited in terms of the source of information used. Extensions may take into account social components (addressing the well-known statement that humans are the weakest link in a security chain) or more technical details. Future directions of research may also focus on the identification of hybrid threats and ways to estimate the impact for a specific type of CIs in more detail.

ACKNOWLEDGMENT

This work was supported by the European Commission's project SAURON (Scalable multidimensional situation awareness solution for protecting European ports) under the Horizon 2020 framework (Grant No. 740477).

ABSTRACT

EGCERSIS is a starting research program aiming at defining a virtual collaborative training space for crisis management. It should provide the users (first and second aid, firefighters, etc.) with a way to virtually perform operational and strategic tasks of crisis management in digital twins of critical infrastructures. The training system is structured according to four main components: (i) protocol and tools for digital twins generation, (ii) scenario editor dedicated to defining crisis use-cases within the modeled digital twins, (iii) integration with the technological crisis management platform (RIO-Suite), and (iv) monitoring component in charge of the continuous edition of dashboards (real-time and afterward). The main expected benefit of the EGCERSIS program is to create a breakthrough in the way training and exercises are performed in critical sites.

Keywords

Virtual Reality, Training, Coordination.

INTRODUCTION

Critical sites are of various types. In this article, it is considered that the word “critical” refers to the impact of a failure of a considered *system* on the capacity of the whole human *territory* to keep on performing its missions (e.g. first necessity supplying, protection, energy providing, water, health care system, etc.) as stated by some measure of performance (Stewart, 1992). The *territory* is a geographical space that covers the spatial extension of a government’s jurisdiction (Gottmann 1975). The *system* concerns a critical site that is located in the considered territory. For instance, the system may refer to a power station, a production system, a supply chain, a transport infrastructure, or a health care system (Yodo and Wang 2016).

These critical sites are legally obliged to perform training exercises to prepare for any crisis situation within the infrastructure itself. These exercises can be set up twice a year, once a year, every two years, or more or less frequently depending on the criticality of the considered system and the legislation of the considered territory.

However, setting up such an exercise is quite a complicated task, enacting the planned exercise is a difficult task too, and exploiting the results of the exercise in a productive manner is complicated as well. All these elements make crisis exercise a time and resource-consuming task with low benefits. It is a regulatory, mandatory and necessary activity which is nowadays neither effective nor efficient. The EGCERSIS research program believes that the use of virtual reality (VR) may break the barriers and reduce almost all drawbacks mentioned. This

might be a huge and significant giant leap forward in the domain of preparation (on an efficiency point of view and even on a legal point of view).

This article is structured according to the following sections: first, an overview of the context, expectations and related work is presented. Then the functional architecture of the whole virtual training system is described. Finally, the next steps are listed with perspectives as well.

CONTEXT OF THE EGCERSIS RESEARCH PROGRAM

This section aims at defining the main objectives of the EGCERSIS program. One key challenge is to identify the pros and cons of the EGCERSIS approach (based on VR) compared to the use of classical real size exercises.

The location of the EGCERSIS research program

The very classical vision of crisis management includes the following phases: *prevention*, *preparation*, *response* and *recovery* (Atlay and Green, 2016) as shown in Figure 1. The preparation phase is one critical phase for the efficiency and the effectiveness of crisis management (and especially for the efficiency and effectiveness of the response phase). If the prevention phase aims at trying to avoid the use of the response phase (by preventing the occurrence of the critical events), the prevention phase aims at supporting the response and making it as efficient and effective as possible (by setting up all the necessary resources and processes basically).

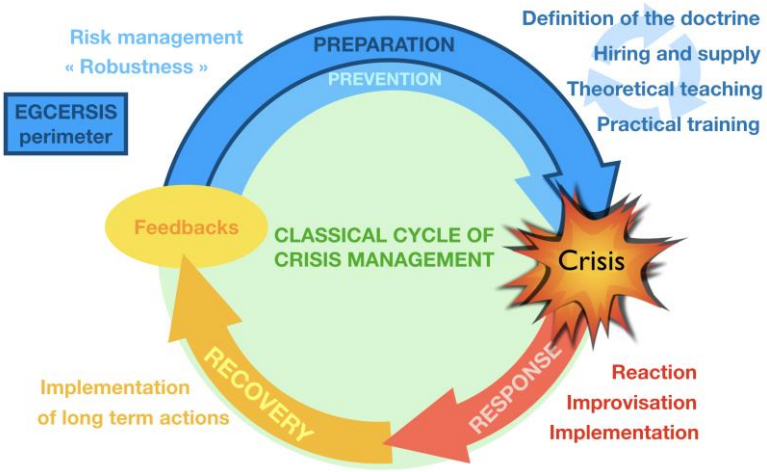

Figure 1: The location of the EGCERSIS research program in the classical cycle of crisis management

During the preparation phase, specifically in the case of critical industrial sites, there are several tasks that must be performed (**Erreur ! Source du renvoi introuvable.**). First, the doctrine must first be defined. On a practical point of view, this step concerns the definition of internal and external action plans. Then, the question of resources (human and equipment) must be considered in terms of availability and appropriateness, which concern hiring and supply. Thirdly, there is a step of theoretical training, before the fourth step of practical training. The theoretical training is more about "know" while practical training is more about "know how". In the preparation phase, the EGCERSIS program focuses on the practical training step, including exercise definition, enactment, and improvement.

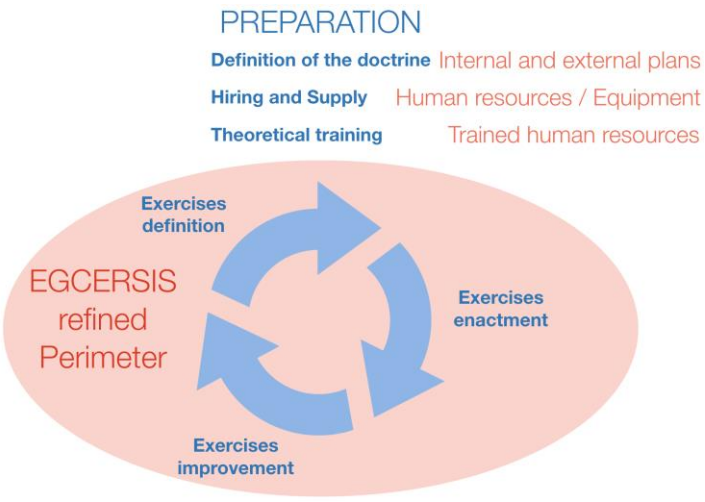

Figure 2: The refined location of the EGCERSIS research program in the Preparation phase for critical sites

The reason why the EGCERSIS research program focuses on those steps (definition, enactment, and improvement of exercises) of the Preparation phase is mainly due to the fact that these steps are the less efficient ones. This part of the preparation truly requires a concrete breakthrough to overcome the current limitation training exercises.

The limitations of training exercises

In Europe, the SEVESO[1] industrial sites are required to conform to a set of measures related to their risks. Usually, it implies to define internal plans (describing the organizational measures set up to deal with *alert*, *evacuation*, *treatment* ...) and external plans, if necessary (similar to the internal plans but dedicated to the wider impacted perimeter of the site). Besides, it is usually mandatory to run exercises dedicated to implement the internal and/or external plans and to practice the activities of first aid actors (in contact with the event), second aid (people on site trained to intervene on the event) and institutional responders (e.g. firefighters).

However, these exercises have generally a lot of drawbacks. Basically (Ardila, *et al.* 2013) summarizes the main issues: "(i) traditional training simulated-based systems are expensive and offer little flexibility (e.g. it is not possible to simply burn up a building every time a drill is carried out); (ii) real training in the field of emergency management is very expensive and complicated regarding the harmonization of procedures between agencies". More precisely, the following identifies specific drawbacks in the context of the program.

During the preparation of the EGCERSIS research program, interviews have been made of five local safety and security directors of critical industrial sites about the efficiency and effectiveness of real-size crisis management exercises in their organizations. Though there are obvious benefits and these exercises are mandatory on a legal point of view, the interviewed professional described jointly the same kind of limitations and drawbacks of the current way of managing the preparation phase of these critical sites mainly with real-size exercises. Basically, their vision can be discomposed according to the two dimensions presented in Table 1: columns represent the lifecycle of an exercise (*definition*, *enactment*, and *improvement*) while lines represents the expectations of an exercise, *i.e.* the need for participants to learn appropriate reactions and processes (*short term impact*), to remember these reactions and processes (*long term impact*), to be as many as possible to benefit from the exercise (*inclusiveness*), to be trained by the exercise on a various range of scenario (*coverage*).

Table 1. The limitations of real size exercises in critical sites

	Definition	Enactment	Improvement
Short term impact **Does the system learn something beneficial?**	• The light manpower that can be dedicated to the definition of the crisis scenario.	• The poor realism of the exercise due to the lack of special effects and real damages.	• The lack of concretely exploitable, significant, and capitalizable data except for some pictures and movies

[1] The **Seveso directive** is the generic name of a series of European directives ruling the management of industrial sites that present major accident risks (so called SEVESO sites).

	• The lack of support equipment (only maps and plans) to create relevant exercises.		(in the best case).
Long term impact **Will the system remember what has been learned?**	• The difficulty to plan an exercise with the objective of making it a long term benefit, considering that this objective may seem secondary with regards to short term impact and relevance of the scenario.	• The low frequency of these exercises due to the actual disturbing impact on the site.	• The difficulty to mobilize the workforce after the exercise considering their impression of loss of time. • The lack of concretely exploitable, significant, and capitalizable data except for some pictures and movies (in the best case).
Inclusiveness **Are all the people that should be included, actually included?**	• The difficulty to expect a large "official" mobilization of the workforce considering the actual disturbing impact of such an exercise on the site.	• The practical difficulty to explain the scenario to a lot of people and to have them commit all together in it. • The low involvement of people due to the weak sensory impact of a simulated exercise on themselves.	• The difficulty to set up a transversal feedback process to generate "lessons learned" and "significant benefits" on as much as possible sectors of the organization.
Coverage **Are all the scenarios that should be studied, actually studied?**	• The hard limits for the scenario that can be designed due to the fake aspect. • The complexity of including as many dimensions as possible in a one-shot realistic scenario.	• The low frequency of these exercises due to the actual disturbing impact on the site. • The complexity of running "live" a scenario that would include as many features as possible.	• The complexity of a fruitful analysis of the exercise with regards to all the relevant dimensions that should actually be considered.

In a nutshell: (i) mobilizing concerned actors is difficult, (ii) designing realist and fruitful scenarios is difficult to obtain, (iii) completeness, or at least a covering variety of scenarios is difficult to get, principally because of the low frequency of such exercises, (iv) implication of human beings, and the impact on them is deeply varying, and even unpredictable (Dolidon, 2018).

Related works on the use of Virtual Reality with regards to classical real size exercises

The use of Virtual Reality in crisis management has been studied a lot in the last twenty years, from its appearance to its current maturity. Basically, previous related research works have identified the pros and cons of the usage of VR:

- Identified advantage: Most authors mention the benefit of VR on a realistic point of view: "*Virtual reality is a powerful technology for creating a sense of immersion and 'intelligent' virtual characters have recently been integrated into virtual worlds for the purpose of training*" or "*the virtual environment will allow trainees users to gather all the necessary visual and auditory contextual information to make the necessary decisions*" (Dugdale, et al. 2004). The flexibility is also another positive point mentioned: "*Virtual Simulation's greatest advantage over traditional planning processes is that there is no pre-established model or hard-coded rules to follow.*" (Hendela, et al. 2006) or "*Virtual Simulation provides flexibility and ease of preparation while stimulating creative and critical thinking.*" (Hendela, et al. 2006) or "*Replicability; scalability and adaptability, testing of new technologies*" (Berndt, et al. 2018). The last main point concerns the price: "*The use of 3D virtual environments for conducting training exercises can provide numerous advantages such as flexibility, relative low cost given a midterm horizon and large scenario development capabilities.*" (Zarraonandia et al. 2014) or "*a network-based system that integrates reality and simulation will be, on the one hand, relatively cheap because all expenses that real in-site training entails (such as moving many people, vehicles) are reduced and, on the other, will facilitate the interoperability and harmonization of procedures between agencies.*" (Ardilla, et al. 2013). Finally, some authors also mention the safety aspect of using VR: "*In contrast with exercises on site, there is little if any danger to the paramedics in a VR simulation. Mistakes can be made without adverse consequences, allowing for experimentation and learning by experience. Because of safety requirements on site, some risks can be presented in an even more realistic way in VR simulations (e.g., fire, explosions, toxic gas).*" (Berndt, et al. 2018)

- Identified disadvantages: One major point concerns the lack of interactions: "*Although many virtual environments strive to offer realism in their simulations of weather, population, and incident happenings, they often fall short in terms of collaboration among simulation participants: unless participants are at the same physical location, their ability to see and interact with one and other is limited.*" (Wright, et al. 2008), or "*interactivity that is possible may not be truly synchronous*" (Wright, et al. 2008) or "*such systems […] use simplistic models of cognitive behavior and emotion to simulate intelligence, and usually only allow one user at a time to participate in the training scenario.*" (Dugdale, et al. 2004). Even if the two articles are quite old, the multi-player aspect is still an issue for deep interaction. Another point concerns the difficulty to implement such systems: "*However, the adoption of 3D virtual environments, in practice is not as widespread as might be expected due to the difficulties associated with their design and development.*" (Zarraonandia et al. 2014) or "*such systems typically require huge computational resources*" (Dugdale, et al. 2004). Finally, they are also some drawbacks regarding the completeness of the sensations "*it does not allow users to obtain the necessary tactile information (e.g. physical contact was used between trainees to reinforce a verbal message or to initiate an action)*" (Dugdale, et al. 2004) or simply the question of virtual reality sickness "*lack of the same physiological stimulation, the longstanding problem of possible simulator sickness and the lack of tactile feedback and "hands-on" experience of real-life exercises*" (Berndt, et al. 2018).

Finally, the conclusion that can be suggested, based on the previous elements, is that VR presents a lot of significant advantages (especially compared to classical exercises). Besides, most of the identified disadvantages are due to its newness. Both these statements make it a very good candidate for a tangible and meaningful innovation: a lot of good points that may contribute to a breakthrough and several bad points that should be corrected with the technological improvements.

The objectives of the EGCERSIS research program

From the two previous subsections regarding limitations of real size exercises and benefits of Virtual Reality, the EGCERSIS research program has been defined according to the following main objective: providing security managers with a framework dedicated to preparation and training for crisis management on critical industrial sites. The idea is to cross virtual reality and decision support in an uncertain environment. The virtual training environment should provide two main features:

- An immersive experience in the digital twin of the critical industrial site in order to experiment with the predefined scenario and prepare intervention teams (first aid, second aid, external responders, etc.). This will result in the creation of a twin of the site in VR, where the participants will be able to evolve thanks to VR goggles, and where they will be confronted to the predefined crisis scenario.
- Monitoring and supervision tools to support the virtual exercises and to generate useful and actionable real time and later reports to understand and capitalize on the played exercises.

These two main features will be implemented through four main components:

1. The exercise editor (dedicated to site modeling and scenario definition)
2. The virtual environment (dedicated to multi-player scenario enactment).
3. Decision support tools (dedicated to accompanying decision makers of the crisis cell).
4. Dashboard tools (dedicated to *in situ* and *a posteriori* analysis of players, exercise and plans).

These components and the provided features should tackle the limitations previously identified in Table 1, as shown in **Erreur ! Source du renvoi introuvable.**:

	Definition	Enactment	Improvement
Short term impact **Does the system learn something beneficial?**	• The light manpower that can be dedicated to the definition of the crisis scenario. • The lack of support equipment (only maps and plans) to create relevant exercises.	• The poor realism of the exercise due to the lack of special effects and real damages.	• The lack of concretely exploitable, significant, and capitalizable data except for some pictures and movies (in the best case).
Long term impact **Will the system remember what has been learned?**	• The difficulty to plan an exercise with the objective of making it a long term benefit, considering that this objective may seems secondary with regards to short term impact and relevance of the scenario.	• The low frequency of these exercises due to the actual disturbing impact on the site.	• The difficulty to mobilize the workforce after the exercise considering their impression of loss of time. • The lack of concretely exploitable, significant, and capitalizable data except for some pictures and movies (in the best case).
Inclusiveness **Are all the people that should be included, actually included?**	• The difficulty to expect a large "official" mobilization of the workforce considering the actual disturbing impact of such an exercise on the site.	• The practical difficulty to explain the scenario to a lot of people and to have them commit all together in it. • The low involvement of people due to the weak sensory impact of a simulated exercise on themselves.	• The difficulty to set up a transversal feedback process to generate "lessons learnt" and "significant benefits" on as much as possible sectors of the organization.
Coverage **Are all the scenarios that should be studied, actually studied?**	• The hard limits for the scenario that can be designed du to the fake aspect. • The complexity of including as many dimensions as possible in a one-shot realistic scenario.	• The low frequency of these exercises due to the actual disturbing impact on the site. • The complexity of running "live" a scenario that would include as many features as possible.	• The complexity of a fruitful analysis of the exercise with regards to all the relevant dimensions that should actually be considered.

Figure 3: The contributions of each of the four components on the limitations of real size exercises in critical sites

Basically, the previous figure shows that two components are more dedicated to the *definition* step (the *Exercise editor* and the *Virtual environment*), two are more dedicated to the *enactment* step (the *Virtual environment* and the *Decision support* tool), and finally one is more dedicated to the *improvement* step (the *Dashboard*).

OVERVIEW OF THE EGCERSIS RESEARCH PROGRAM

In this section, the architecture of the EGCERSIS platform is introduced more precisely.

The main scientific and technical obstacles of the EGCERSIS research program

Considering the objectives and associated components described in the previous section, the following barriers have been identified and must be considered by the EGCERSIS research program:

- Obtaining a relevant, trustable and continuously updated digital twin of the considered critical industrial site is absolutely mandatory and should be considered as an absolute requirement. Obviously, these digital twins should, in addition, be exploitable by the Virtual Reality environment (based on the Unity® framework[2]) chosen for the research program.
- Crisis management is, by essence, the world of the unexpected. More than anywhere else, instability is the norm. As a consequence, it should be possible for users, not only to define as various scenarios as they want (type of crisis, kinetics of the crisis, nature of the crisis, etc.) but also to intervene during runtime to change or update the scenario in order to optimize the training exercise. So, this is not only a question of the flexibility of the exercise editor (which is though crucial) but also a matter of dynamicity and openness of the Virtual environment.
- Moving crisis management training from the real world to the virtual world should not only include actual and current practices but also tools and technologies. As for example, if a communication, mapping or planning tool is the nowadays' reference in the world of responders (first aid, second aid or external), it must necessarily be integrated into the virtual world to optimize the training session.

[2] https://unity3d.com/

- The multi-player aspect is an unavoidable feature. It is so significant in the real world, where crisis management is foremost a collaborative issue, that it must be precisely and efficiently integrated into the virtual training platform. Besides, this collaboration aspect should cover on the one hand the human aspect (between two or more persons) and the service aspect (between two or more organizations).

Big picture of the EGCERSIS research program

To tackle the obstacles described in the previous sub-section, the EGCERSIS research program aims at performing the four main following steps as presented in Figure 4:

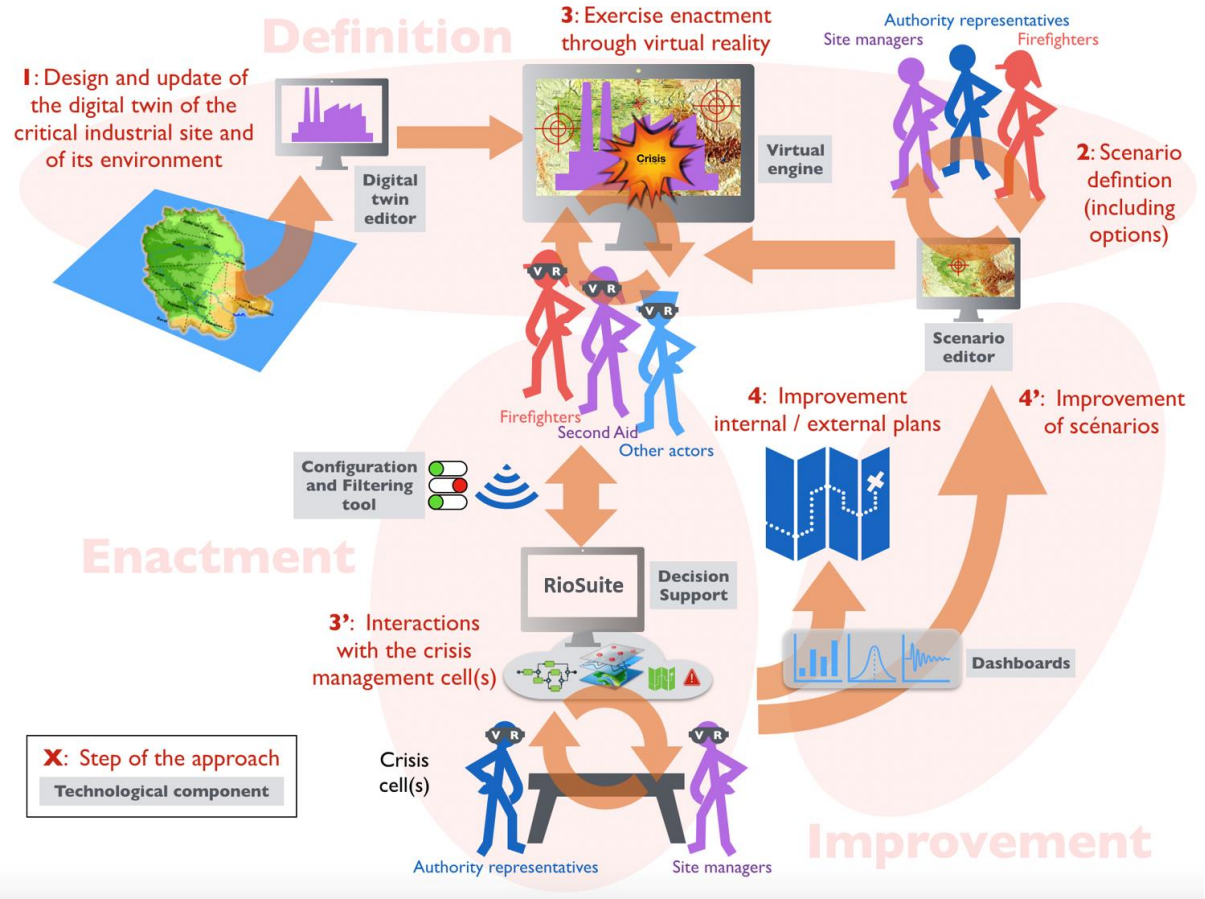

Figure 4: The big picture of the EGCERSIS outputs

1. Based on actual plans of the building (for instance the ones generally dedicated to being constantly updated in the crisis management plan of a SEVESO site) and on other inputs (crowdsourced map, private map, UVA, etc.) a 3D digital twin of the considered site should be defined within the dedicated editor.
2. The selected scenario and its characteristics (nature, timeline, kinetics, etc.) should be described in the dedicated scenario editor. This editor is to be used by authority representatives, site managers or responders. It should permit to create and implement a realist and adaptable crisis scenario. The idea would be to choose and implement a crisis scenario in a virtual reality digital twin of a chosen industrial site. One envisioned possibility is to be able to make the scenario evolve depending on the answers of the stakeholders who are solving the crisis.
3. Immersed in the virtual environment (through VR goggles), all the potential stakeholders (first aid, second aid, firefighters and other responders) do face the scenario and do experiment the exercise in a realistic environment as close as possible to the real site. Meanwhile, the crisis managers do deal with the crisis situation, using RIO-Suite as support for their decisions (RIO-Suite receive data directly from the simulation environment, filtered by a configuration panel presented in the perspective section).
4. Due to the numerical nature of the exercise, everything about the exercise and its dynamics may be

collected in real time. This is an amazingly positive point because it means that everything could be monitored and even replayed on demand to analyze, visualize and exploit the exercise. This should allow on the one hand to improve the exercise but of course, on the other hand, to improve the plan as a whole (including the skills and know-how of the people).

PERSPECTIVES OF THE EGCERSIS RESEARCH PROGRAM

From the point of view of the EGCERSIS research program, the potential results of the program would lead to a revolution in the domain of security and safety of industrial critical sites. Roughly speaking, the *frequency*, *quality*, *realism*, *coverage*, and *exploitability* of exercise could simultaneously be increased. This is definitely a very promising avenue for the improvement of (i) internal/external plans and (ii) efficiency/effectiveness of actors involved in crisis management (first and second aid as well as external responders). Such an improvement of the preparation phase of such critical industrial sites would consequently improve the resilience of the industrial system impacted. This perspective is clearly the most important of the EGCERSIS research program. Besides, it opens a full business market for Virtual Reality companies.

Another interesting avenue of the EGCERSIS research program is the possibility of having the virtual environment used for evaluating, testing, practicing not only plans and processes, but also new tools and new technologies. Actually, the virtual nature of the played exercise allows considering exploiting absolutely any type of data generated by the virtual environment. Thus, it would be of great benefit to check if the indoor geo-location of responders (which is a very trendy expectation that could completely and perfectly be simulated in the context of a virtual exercise) would help considerably or marginally crisis management. Similarly, it could also be very interesting to plug any new technological platform to the virtual environment (through a configuration and filtering tool, as presented in Figure 4, dedicated to simulating which data should actually be transmitted to the evaluated platform). For instance, within the EGCERSIS research program, it is planned to create and evaluate a new version of RIO-Suite. This version of RIO-Suite would be based on a virtual environment as well and would allow the decision makers to move in a virtual environment where the visualization and the decision-making would be easier. In this context, the configuration and filtering tool would be in charge to simulate what kind of data RIO-Suite should actually be fed with. The kind of data that RIO-Suite is able to use is presented in (Benaben et al.). The very interesting point is that all the data could entirely be obtained through the virtual environment.

The last perspective considered in this article concerns the extension to other exercises than the one in critical industrial sites. This first target is mainly due to the fact that these sites are legally obliged to run crisis management exercises and have consequently all the required material (plans, maps, scenarios, etc.) and a lot of interest for the EGCERSIS research program. However, if the process becomes seamless and effective, if the benefits are obvious and if the efficiency of preparation is clearly demonstrated, other sites could be considered: critical infrastructure (airport, train station, etc.), overcrowded site (touristic place, public building, university, etc.) and any place that potential users (responders but also homeland security stakeholders) would like to study.

CONCLUSION

The EGCERSIS research program is dedicated to creating a breakthrough in the way crisis management exercises are conducted. This domain of the *preparation* phase definitely suffers from a lack of effectiveness and efficiency. For years now, the classical yearly exercises, with simulated imaginary damages and casualties, have shown how disappointing they can be. These exercises, even if most of the time mandatory, are really far from the results they should bring. As a consequence, the *response* phase which is supposed to be a combination of a majority “implementation of the results of the preparation phase” and a minority “improvisation due to the specificity of the faced situation”, can often be considered as a majority “improvisation” and a minority “implementation”. Virtual Reality opens completely new perspectives: allowing, on the one hand, to replicate the real world to perform experiments in real size without any barriers, and on the other hand to forget about the real world in order to create completely free interfaces benefiting from the realistic physical environment but independent from the constraints of the real world. This new world of VR should be investigated with both these visions.

ABSTRACT

This paper presents a use case of mobile network data as a new source of insight for humanitarian action. Based on analysis covering the Republic of Vanuatu, we identify aggregate behavioral patterns indicating short term and medium term behavior changes as a result of a tropical cyclone, which could contribute to our understanding of the resilience of communities to natural hazards. We also find interesting behavioral insights on how the human movement network is impacted by a cyclone. Due to the detail and tractability of the data set, insights on preparation, displacement, damage and resilience could enable more agile and adaptive responses by public institutions and other actors to humanitarian emergencies. Considering the array of natural hazards that the South Pacific region faces on an annual basis, this use case contributes more evidence in favor of using anonymized mobile network data to inform humanitarian action.

Keywords

Vanuatu, mobile network data, humanitarian, disaster impact, tropical cyclones.

INTRODUCTION

This paper analyses mobile network data in the context of the Pacific island nation of Vanuatu, a Y-shaped archipelago with four main islands and 79 smaller islands (GFDRR, 2017). Vanuatu's geographical location contributes to the nation's exposure to a string of volcanoes, earthquakes and other seismic activities, as well as tsunamis, storms, tropical cyclones, coastal flooding and landslides. With such breadth and frequency of natural hazards, it is considered a country with a high degree of vulnerability. Due to the confluence of vulnerability, the availability of big data and a request for policy insights from the Government of Vanuatu, the country was selected as an appropriate context for this research.

Tropical Cyclone Donna impacted northern Vanuatu at the beginning of May 2017, with an early alert published on 3rd May. The tropical cyclone intensified to category three on 5th May, and to category five on 8th May. The

cyclone moved on from Vanuatu on 9th May. According to the UN Office for the Coordination of Humanitarian Affairs (2017) as of 8th May 2017, Vanuatu had experienced significant damage to housing and communication networks. During the tropical cyclone, the TVL mobile phone network was down in Torba Province in the north of Vanuatu. Tropical Cyclone Donna was unusual for the time of year, as May is not commonly an active month for cyclones.

The primary data source for this research project, mobile network data, is defined as the information elements contained in call detail records (CDRs) created by mobile network operators for billing purposes and summarising anonymous mobile users' activity, i.e. phone calls, text messages and data connections (UN Global Pulse, 2018), but contain no information on their content. As this data is uniquely detailed and tractable, it can capture information not easily found from other sources at a scale that would be difficult to recreate through other means (UN Global Pulse & GSMA, 2017). Once anonymized and aggregated to appropriate levels, mobile network data can provide a variety of insights with tremendous value for development and humanitarian action, including mobility, social interaction and economic activity (UN Global Pulse, 2013).

Using Tropical Cyclone Donna as a case study, we are interested in exploring how mobile network data capture aggregate behavior changes related to natural hazards, perhaps also revealing the resilience of communities to these events by the speed at which pre-disaster patterns re-emerge or the point at which new stable patterns emerge based on structural changes due to the shock. Alongside this general question, we are also interested in whether Tropical Cyclone Donna impacts the human movement network within and between islands. The use case is a tangible demonstration of how the data set can provide real value to policymakers and humanitarians by providing new insights at a higher degree of spatial granularity, at a higher frequency, in a timely manner, enabling more agile and adaptive responses by public institutions to both opportunities and challenges.

In examining aggregate behavioral patterns; we find short term and medium term behavior changes after Tropical Cyclone Donna. We identify four different classes of patterns related to behavior changes, which are increasing, decreasing, V shape, and other patterns. We also find interesting behavioral insights by processing the trajectories of anonymous mobile network users, developing our understanding of how the human movement network is impacted by a cyclone. Findings of note include the nature of inter- and intra-island human movements, both before and after Tropical Cyclone Donna, as well as the inference that the local population was taking action in anticipation of the tropical cyclone in advance of official alerts, and the observed surge in positive movement anomalies away from the Island of Ambae in Penama province on 7th May 2017, the day before the cyclone was classified as category five.

Our analysis of mobile network data complies with the Global System for Mobile communication (GSM) Association privacy guidelines for the use of mobile phone data (GSMA, 2014), originally developed in response to the Ebola outbreak in West Africa which occurred between 2013 and 2016. Specifically, the guidelines dictate that user data be anonymized, that user data not be transferred outside of the mobile network operator's systems, that all analysis take place on the mobile network operator's systems and under operator supervision, that no analysis be undertaken that singles out identifiable individuals, and that only the output of the analysis (i.e. the resulting non-sensitive data, aggregate statistics, indicators, etc.) be made available to relevant and approved aid agencies, government or research agencies that can use these inputs in their modeling and planning efforts.

RELATED WORKS

Scholars have been using various data sources and methods to understand human behaviours and movements during and after natural disasters or other types of crises. Recent developments in our understanding of these events have, in part, derived from new data sources, such as social media and Global Positioning System (GPS) records, which have enabled new insights at a finer degree of spatial and temporal granularity. Wang (2014) developed insights on human trajectories and movement patterns at high-resolution by mining Twitter data from New York City, during and for several days after Hurricane Sandy in 2012, calculating trip distance distribution, the radius of gyration of movements, and frequently visited locations. Meanwhile, Song et al. (2014) used the GPS records of 1.6 million users over one year to investigate and analyse human behavior during emergencies and their movements following the Great East Japan Earthquake and Fukushima nuclear accident.

The increasing use of mobile networks in developing countries also offers a rich source of insights for humanitarian action. Several scholars have explored the data set to meet humanitarian information needs, for example Bengtsson et al. (2011) estimated the net outflow of people from Port-au-Prince following the 2010

earthquake in Haiti by scaling insights from mobile network data via reference to the census. They also demonstrated the ability to produce rapid estimates of mobile network user movements during the Haitian cholera outbreak. Further research by Lu et al. (2012) showed that Port-au-Prince lost nearly a quarter of its residents nineteen days after the earthquake. Later research, again by Lu et al. (2016), mined mobile network data to develop insights on anomalies in communication, mobility and consumption during Cyclone Mahasen in Bangladesh. This research uses a novel approach to understanding human movements, developing time series insights on the number of mobile network users that move between the coverage areas of different cell towers, building our understanding of what the authors of this paper term a human movement network.

As highlighted in the introduction, above, mobile network data offers insights beyond human movements. De Montjoye et. al. (2016) developed an open-source toolbox for feature engineering of mobile network data, called bandicoot. The features fall into three categories: (a) anonymized individual information including the total number of calls, text response rate and others; (b) spatial information of each anonymous user such as radius of gyration, entropy of places visited; and (c) social network metrics such as clustering coefficient. For a comprehensive list and definition of these variables, please refer to the bandicoot website. Jahani et.al. (2017) and Felbo et. al. (2017) revealed that by combining bandicoot features and advanced machine learning, they are able to predict the demographic characteristics of the mobile network user population. Using similar feature engineering methods to understand behavioural changes in response to a series of earthquakes, Moumni et al. (2013) add to the literature on human movements and displacement post-disaster to examine the impact of an environmental shock on call volume, call duration and social activity. They find discernible differences in these metrics pre- and post-earthquake, although the paper analyses only two weeks of mobile network data spanning the Oaxaca Earthquake in 2012.

Gething and Tatem (2011) note that while the advantages of using mobile network data are self-evident, the limitations are weakly presented. They point out that severe natural hazards can damage mobile phone networks thus forestalling any analysis, and that when the networks are operational, the lower network coverage of sparsely populated regions makes it difficult to track displacement in rural areas. They also highlight issues connected to the representativeness of the data set, in that coverage errors and biases exist, and privacy issues regarding the mining of mobile network user data.

DATA

This paper pursues some of the research areas highlighted in the introduction and related works above, specifically insights on post-disaster aggregate behavior changes among mobile network users. In this analysis, we use anonymised call detail records generated between 1st January 2017 and 31st December 2017 and geo-located in Vanuatu. The mobile network data is accessed via a data partnership with Digicel, which holds a majority market share (TeleGeography, 2016). In 2015, Vanuatu hosted 104,000 unique mobile network users, representing approximately 40 percent of the country (GSMA, 2015); the market and the number of unique mobile network users is likely to have grown since then. By 2017, the overall mobile penetration of the population reached 80 percent of households (ITU, 2017).

There are hundreds of variables contained within one call detail record, such as transaction type, International Mobile Equipment Identity (IMEI) number, timestamp and tower ID, among others. We limit the data extraction to the variables commonly used in mobile network data analysis, namely: transaction type, transaction direction, caller id (anonymous), correspondent id (anonymous), tower id, call duration and a few others described in Table 1 below. We extract the raw data set by selecting only the specific columns of interest, highlighted in Table 1. Next, we perform data validation by selecting transactions that occur in Vanuatu, based on their antenna_id.

Mapping Tower Locations to Administrative Divisions

The call detail records are associated with cell towers; however, in some instances we require insights at different administrative levels, such as provinces or area councils. For this purpose, we conduct a reverse geolocation process for each tower, using the official shapefiles of administrative divisions from the Government of Vanuatu. In addition to this, we build a matrix of the distances between each of the towers, which is useful for analysing the human movement network. The following tables show the tower mapping information (Table 2) and sample data for the distance between towers (Table 3).

Table 1. Raw data

No	Column Name	Sample	Remark
1	caller_id	8f8ad28de134	
2	interaction	call	Call or Text
3	direction	in	In or Out

3	distance	224.81

Generating Behavioural Indicators for Each Anonymous User

We use the bandicoot toolbox (de Montjoye et al., 2016) to extract hundreds of behavioral indicators, producing a weekly time series of the average of each indicator, from the raw data. If necessary, bandicoot can also return other statistical measures such as median, maximum, minimum, skewness and kurtosis, but we retain the default settings which return mean and standard deviation. We use bandicoot because it provides a simple approach to extract diverse features from mobile phone metadata that otherwise would be complicated and time-consuming.

We aggregate all the raw transactions at a weekly level following the ISO-8601 standard (a week starts on Monday and ends on Sunday). For each week, we develop behavioural indicators for each anonymous user that made a transaction during that week. To investigate aggregate behavior changes in response to Tropical Cyclone Donna, we focus on the variables developed by the bandicoot library that provides anonymized indicators at the individual level, divided into five broad categories: basic phone use, active users behaviors, location, regularity and diversity. We take the mean, and when available the standard deviation, of each variable for all anonymous users per week, then exclude variables that have missing values or that exhibit flat figures, i.e. all ones or all zeros, for the timeframe of the analysis, for which we use data from January to December 2017.

Transforming User Trajectories into a Human Movement Network

To understand human movement patterns, we transform the raw data format into a sequence of user transactions, which gives us the trajectory of an anonymous user, see Table 4 for an example. From the transactions described in Table 4, we create new columns by shifting the transactions, using the n+1 transaction as the Next Tower ID and produce Table 5, which includes the distance between the pairs of cell towers by comparison to the cell tower distance matrix. This table can then be used to create an aggregate human movement network at different levels of spatial and temporal aggregation, we choose a daily resolution for the time series.

The human movement network does not retain the trajectories of users, instead it captures the number of users moving between the coverage areas of each origin-destination pair of cell towers within the network, based on sequential transactions by users on the mobile network. It retains the distance between the origin-destination pairs of towers as an attribute. These data processing steps have the effect of undersampling anonymous users who make few transactions, because it is not possible to calculate a trajectory from one or no data points at the resolution of the time series. In turn, this results in a bias towards active users, as only their movements would be

detected. Thus, when using the terms "human movements" and "the human movement network", we are not generalising to the entire population of Vanuatu, but referring to the movements of active Digicel mobile network users.

Table 4. User level information

No	User ID	Date	Tower ID
1	8f8ad28de134	2017-01-01	31021
2	8f8ad28de134	2017-01-01	23005
3	8f8ad28de134	2017-01-01	50003

Table 5. Distance of two towers to build administrative level data

No	User ID	Date	Tower ID	Next Tower ID	Distance
1	8f8ad28de134	2017-01-01	31021	23005	4.8
2	8f8ad28de134	2017-01-01	23005	50003	269

We process the mobile network records for the first 20 weeks of 2017, a time frame covering 2nd January to 21st May. From this data set, we extract the ten weeks running up to the week of the early alert for Tropical Cyclone Donna, a time frame covering 20th February to 30th April 2017, from which we construct the human movement network for ten 'normal' instances of each weekday. This gives us a basis for comparison when examining the human movement network during Tropical Cyclone Donna.

METHODS

We examine the impact of Tropical Cyclone Donna by detecting behavioral changes, first, as articulated by indicators drawn from mobile network data, and second, based on shifts in the human movement network within Vanuatu.

Analysing Behavioural Changes

We conduct a preliminary analysis by filtering only the numeric variables from the bandicoot software, as well as binary variables that mostly come from reporting features (TRUE/FALSE converted into 1/0). We further examine them through exploratory data analysis. The variables that demonstrate significantly different patterns after the disaster are the best candidates for tracking behavioural changes. They are subject to further analysis.

To check the robustness of the exploratory data analysis, for each variable, we develop a forecast to provide an estimation of the future short term trend assuming that the tropical cyclone did not occur. We (partially) mitigate seasonality by excluding the first week of the year from the forecast[1]. Having said this, we do not claim the behavioral differences at the aggregate level are as a direct impact of tropical cyclone. But if the actual short term trend differs from the forecast, we investigate how the pattern behaves over the longer term. If it maintains some distance or pushes away from the pre-disaster and forecast trend, we conclude that behavioral changes are more likely to have taken place.

Information from weeks two to 17 is used to forecast the point estimation, 80 percent and 95 percent confidence band of weeks 18 to 23. The *ets* package in R builds a fully automated forecast system as the default, which we use (Hyndman et al., 2008). The model is not specified, adjusting for each specific time series type. The default of the optimization criterion is log-likelihood. As an example, the simplest likelihood function of Autoregressive model of order p - called AR(p) - is defined as follows:

[1] Other potential seasonality components are not strongly identified during the first quarter of the year.

$$\ln(L) = -\left(\frac{T-p}{2}\right)\ln(2\pi) - \left(\frac{T-p}{2}\right)\ln(\sigma^2) - \left(\frac{1}{2\sigma^2}\right)\sum_{t=p+1}^{T}[\phi(L)y_t]^2$$

Figure 1 displays an example of a forecast result which assumes that the tropical cyclone did not take place, which can be used for further analysis of the trend. Comparing it with the actual trend, as in Figure 2, both figures provide useful evidence of whether behaviour changes have occurred.

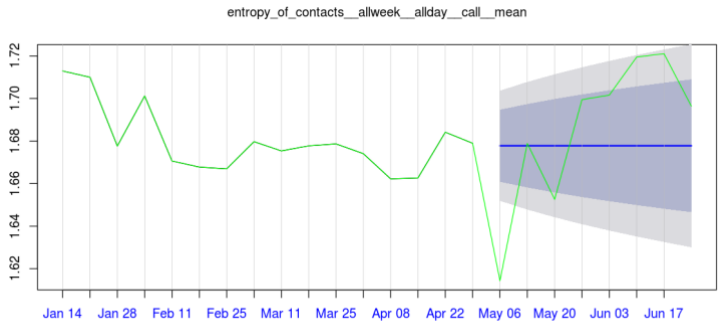

Figure 1. Example of short term forecasting. The blue line is the point estimation. Confidence bands are 80 percent (dark grey) and 95 percent (grey). Some part of the actual trend overlaps with upper limits of the 95 percent confidence band which merits further investigation.

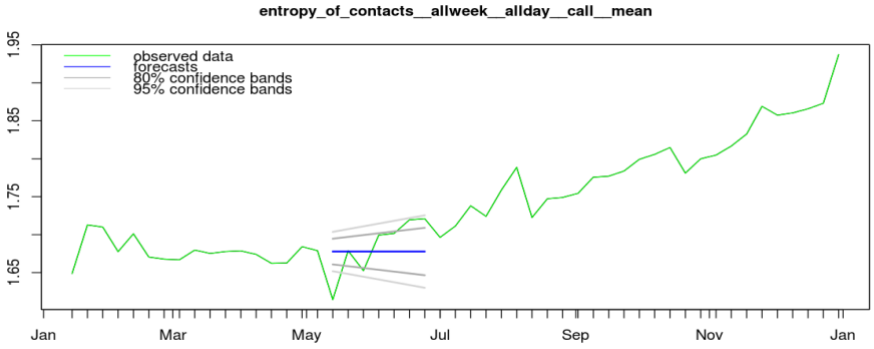

Figure 2. Example of the full year pattern in 2017. The pattern finally leaves the confidence bands, indicating evidence of longer term change in behaviour.

Analysing the Human Movement Network

As described above, we develop a human movement network for each day during the ten weeks running up to the week of the early alert for Tropical Cyclone Donna, as well as the three weeks covering Tropical Cyclone Donna and its aftermath, a time frame including 1st to 21st May 2017.

To gain a broad sense of the changes in the human movement network connected to the tropical cyclone, we multiply the directional weight associated with an origin-destination pair of cell towers (the number of users with sequential transactions connected to the origin-destination tower pair) by the distance between them and then sum at province level. Figure 7 displays the representations of the total distance traveled within each Province by the active mobile network users for a day of interest during Tropical Cyclone Donna and the ten instances of the same weekday during the ten weeks running up to the week of the early alert.

To examine changes in the human movement network at higher-resolution, we compute the z-score for the directional weight associated with an origin-destination pair of cell towers, which represents the number of standard deviations by which the value of the directional weight between a pair of cell towers on the day of interest

during Tropical Cyclone Donna is above or below the mean value of the directional weight between the same pair of cell towers for the ten instances during the ten weeks leading up to the week of the early alert for the tropical cyclone. We filter the z-score matrix for the day of interest during Cyclone Donna, to exclude z-scores between -3 and 3; z-scores above and below these values we define as anomalies. This generates a matrix of human movement network anomalies which we project onto a Map of Vanuatu for further visual analysis (see Figure 8).

FINDINGS

Patterns in Aggregate Behavioural Changes

Some variables developed from mobile network data using the bandicoot library seem to show distinctive trends after Tropical Cyclone Donna. Those trends are an initial signal of behaviour changes, but these changes are not, per se, the direct result of the tropical cyclone. Such trends should be observed more carefully, such as removing potential seasonality if there is strong evidence of its existence, and over a longer period of time to conclude that behaviour has changed as a result of the tropical cyclone.

We determine to work with 39 numeric/binary variables based on the preliminary analysis. From the method described above, we identify four major patterns of behaviour change after Tropical Cyclone Donna across 29 variables: 11 variables display an increasing trend, seven variables show a decreasing trend, eight variables demonstrate a V-shaped pattern, three variables uncover other patterns including an inverted V-shape pattern. Ten variables do not reveal significant patterns, so we exclude them from the analysis. Details of bandicoot variables used in this study are presented in Table 6-9.

There is a possibility that non-constant pre-disaster trends are affected by seasonal patterns and it might be better to only consider post-disaster patterns. Unfortunately, we do not posess data from other years to examine the seasonalities, therefore we stick to distinguishing patterns by considering pre-disaster trends as well. We focus our discussion on the average of each trend, and later on we include a small section dedicated to discussing the standard deviation.

The first pattern we discuss is the increasing trend (Figure 3, Table 6). The increasing trend is defined as showing a stable pattern prior to the tropical cyclone, then a rising pattern over time thereafter. Among the eleven variables with increasing trends, four relate to the diversity category (entropy of call contacts, call interactions per contact, variability of call interactions per contact, number of call contacts), five are related to the basic phone use category (number of outgoing call interactions, number of incoming call interactions, total number of call interactions, number of outgoing text interactions, and total number of text interactions) and two of them are reporting variables (number of records and if the records contain a call)[2].

The increasing amount of interactions, in particular outgoing calls and texts, could be a reflection of how the affected people and potentially the entire country copes with the shock. Moreover, users do not only increase the intensity of the interaction, but they also diversify their social network base by demonstrating a higher number of call contacts and higher entropy of contacts[3]. The causes of these changes in behaviours could be for information seeking or resource mobilisation. Our findings support the study on the Oaxaca earthquake by Moumni et al. (2013) where people made calls more often and carried out mobile interaction with more people around the time of the disaster. Additionally, the variability of interaction per call contact increases, which indicates that this feature is less predictable post-disaster.

We assume that the increasing trend of call diversity indicators and the basic phone use category indicators will at some point in time change, leading to two potential future outcomes: (i) a peak after which a downward trend follows, possibly after full recovery takes place, or (ii) users find a new equilibrium of higher diversity.

A decreasing trend is the second major pattern of interest (Figure 4, Table 7), where relatively constant behavior before Tropical Cyclone Donna shifts to a declining pattern post-disaster. There are seven variables displaying a

[2] More information on these metrics can be found in deMontjoye et al. (2013)

[3] For mobile network data, entropy is defined as the distribution of interaction across different contacts. Higher entropy indicates more equally balanced interactions with a large number of contacts (de Montjoye et.al., 2013).

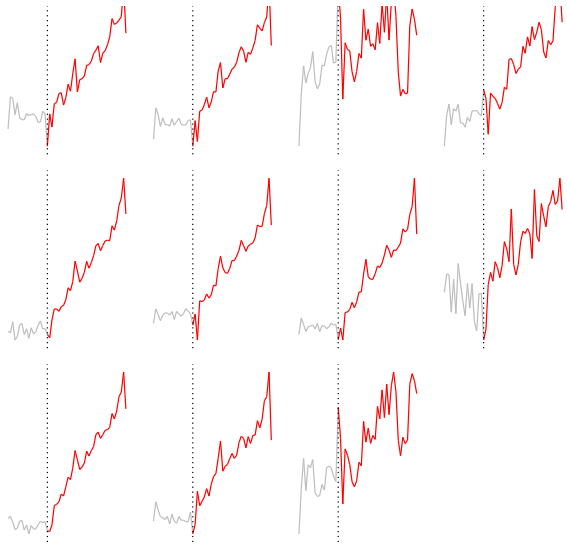

Figure 3. Eleven variables displaying an increasing trend after Tropical Cyclone Donna, which is represented by the dotted line.

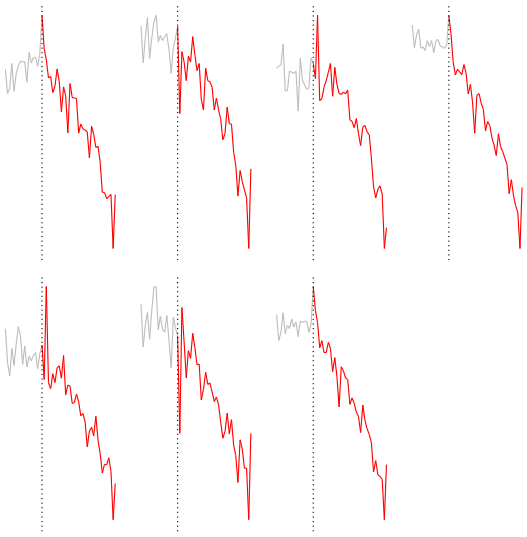

Figure 4. Seven variables displaying a decreasing trend after Tropical Cyclone Donna, which is represented by the dotted line.

Table 6. List of bandicoot variables with increasing trend

Variables with increasing trends after cyclone Donna	Definition
entropy_of_contacts__allweek__allday__call__mean	The entropy of the user's contacts on call.
interactions_per_contact__allweek__allday__call__mean__mean	The number of calls a user had with each of its contacts mean
interactions_per_contact__allweek__allday__call__std__mean	The number of calls a user had with each of its contacts SD of mean
number_of_contacts__allweek__allday__call__mean	The number of contacts the user called with.
number_of_interaction_in__allweek__allday__call__mean	The number of incoming calls.
number_of_interaction_out__allweek__allday__call__mean	The number of outgoing calls.
number_of_interaction_out__allweek__allday__text__mean	The number of outgoing text
number_of_interactions__allweek__allday__call__mean	The number of calls.
number_of_interactions__allweek__allday__text__mean	The number of text.
reporting__number_of_records	The number of records
reporting_has_call	The record contain calls

Table 7. List of bandicoot variables with decreasing trend

Variables with decreasing trends after cyclone Donna	Definition
balance_of_contacts__allweek__allday__call__mean__mean	The balance of calls per contact mean
balance_of_contacts__allweek__allday__call__std__mean	The balance of calls per contact SD of mean
interevent_time__allweek__allday__call__mean__mean	The interevent time between two calls of the user mean
interevent_time__allweek__allday__call__std__mean	The interevent time between two calls of the user SD of mean
percent_initiated_interactions__allweek__allday__call__mean	The percentage of calls initiated by the user.
percent_pareto_durations__allweek__allday__call__mean	The percentage of user's contacts that account for 80% of its total time spent on the phone.
percent_pareto_interactions__allweek__allday__call__mean	The percentage of user's contacts that account for 80% of its calls.

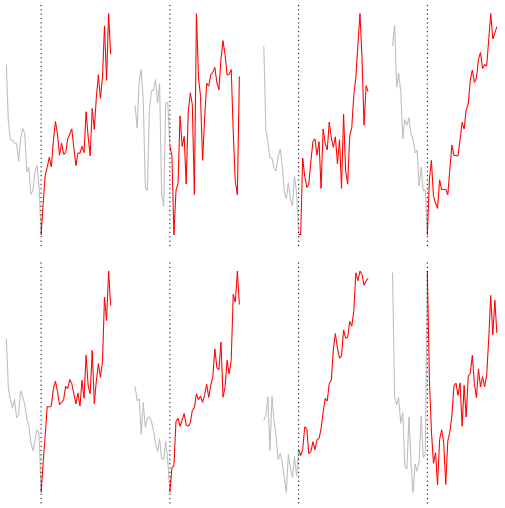

Figure 5. Eight variables displaying a V-shaped pattern, linked to Tropical Cyclone Donna, which is represented by the dotted line.

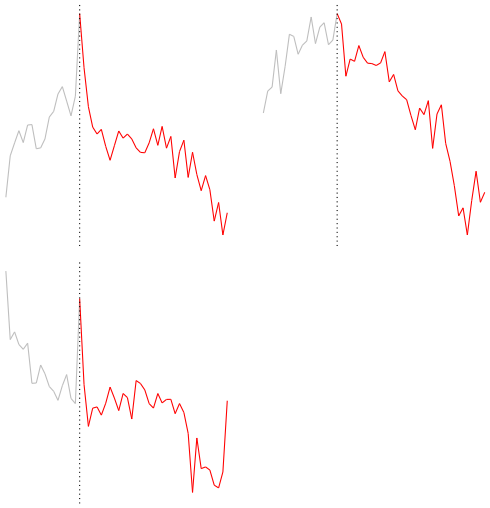

Figure 6. Three variables displaying other patterns including an inverted V-shape pattern, linked to Tropical Cyclone Donna, which is represented by the dotted line.

Table 8. List of bandicoot variables with V-shape trend

Variables with V shape trends after cyclone Donna	Definition
balance_of_contacts__allweek__allday__text__mean__mean	The balance of text per contact mean
balance_of_contacts__allweek__allday__text__std__mean	The balance of text per contact SD of mean
call_duration__allweek__allday__call__std__mean	Duration of call SD of mean
interactions_per_contact__allweek__allday__text__std__mean	The number of interactions a user had with each of its contacts.
interevent_time__allweek__allday__text__mean__mean	The interevent time between two text of the user.
number_of_interaction_in__allweek__allday__text__mean	The of number of text received.
percent_nocturnal__allweek__allday__call__mean	The of percentage of calls the user had at night.
percent_nocturnal__allweek__allday__text__mean	The average percentage of texts the user sent at night.

downward pattern that sit under three of the indicator categories: regularity (call inter-event time, and call inter-event variability), active behaviors (percent of calls initiated) and diversity (balance of call contacts, balance of call contacts variability[4], call percent pareto and total interactions percent pareto), some of which complement the insights from variables displaying an increasing trend.

For example, decreasing inter-event time is a natural consequence of a higher number of interactions. Additionally, the decreasing trend for balance of call contacts, percent initiated call interactions, percent pareto call duration and percent pareto call interaction, which exhibit opposite trends to other indicators in their categories, is a product of the scale free nature of the network. The absence of the indicator on call duration post-disaster among the indicators showing a declining pattern does not support the finding of Moumni et al. (2013). Finally, call balance of contacts and call inter-event time of show decreasing variability over time; this evidence adds more confidence to their central tendency post-disaster.

The V-shaped pattern (Figure 5, Table 8) represents a downward trend in the variable of interest prior to the tropical cyclone, that switches to an upward trend thereafter. In other words, this trend performs a sharp quadratic shape with a local minimum. We find this pattern for four metric categories: diversity (balance of contacts of text and balance of contacts of text variability), regularity (call duration and text interactions per contact variabilities, text inter-event time), basic phone use (total number of text) and active users behaviors (percent nocturnal of call and text).

[4] Balance of contatcs represents the fraction of outgoing interactions out of the total interactions (Almatouq et al., 2016)

Unlike the previous trends that are relatively constant pre-disaster, features with a V-shaped pattern already display a declining trend before Tropical Cyclone Donna. Text indicators for balance of contact, inter-event time, number of interactions and percent nocturnal decreased pre-disaster and increased post-disaster. In general, this evidence suggests that a disaster such as a tropical cyclone plays a role in returning texting behavior back into the mainstream of mobile communication. This is a new insight that is not revealed in previous studies. From the charts in Figure 5, most portray a clear V-shape, but the chart in the bottom right corner, representing the percent nocturnal of texts, actually displays a W-shaped pattern, which merits further investigation. The percent nocturnal for calls delivers another new insight that a disaster like a tropical cyclone could contribute to a shift towards evening phone calls.

The V-shaped pattern of the variability indicators (standard deviation) suggests that the dispersion of data points for the linked indicators shrank to the center around the time of the tropical cyclone, then the dispersion returned to normal levels following the recovery process. Indicator variabilities are usually not a major focus because they are nuance parameters; however, knowing that some features have non-constant variance is sometimes useful when implementing model adjustment.

We observe two final patterns: inverted V-shape and inverted decreasing (decreasing pre-disaster then constant post-disaster) displayed in Figure 6 and Table 9. We find that entropy of text contact (diversity category) and percent initiated call and text (active users behaviors category) rise pre-disaster, peaking around the time of Tropical Cyclone Donna and then decline post-disaster.

Inverted decreasing is found for the indicator on the percentage of interactions while at home (active users behaviors category, Figure 6, bottom left corner). The sustained nature of this trend may be due to infrastructure damage and the need for repairs to personal property as a result of the tropical cyclone, keeping users at home, as well as other social factors. If so, this could be an important variable to investigate and track following a natural disaster, as a measure of recovery time. Ground truth insights such as the location of damaged antennas are required to validate this intuition.

The overall findings suggest that given a natural hazard, call related metrics are more likely to produce either a longer term quadratic pattern or find a new equilibrium different to pre-disaster levels, as suggested by the increasing patterns. Meanwhile, text related metrics tend to show a short term quadratic behavior with more features following V-shaped and inverted V-shaped patterns. In our study, those patterns are not precisely correlated with the tropical cyclone; however, text behaviors might be useful for monitoring short term vulnerability, and further research on this observation is merited.

Meanwhile, resilience is both demonstrated and developed by "bouncing forward" (Manyena et al., 2011; Houston et al., 2015) as a positive consequence of successful adaptation to shocks and hardship. Through this lens, increasing patterns defined in this study are promising as the proxy indicators of resilience. We find two longer term possibilities, either the indicator returns to pre-event levels or it finds a new equilibrium at a different level. The time it takes to return to previous levels or to stabilise at the new normal is likely a good measure of resilience, but further contextual research is required on which patterns indicate higher resilience. We do not find strong evidence that predefined categories of indicators exclusively fall into a certain pattern. Another approach such as cluster analysis or principal component analysis might be an alternative to group the indicators into specific patterns in a more compact fashion.

Recent literature recognizes that communication is one of the elements of adaptive capacity (Norris et al., 2008; Pfefferbaum et al, 2015; Houston et al. 2015; Houston, 2018). Borrowing these framework, we argue that our findings on various patterns of human behaviors via mobile network data indicates a promising research agenda on further exploring mobile communications as proxy indicators for vulnerability, adaptive capacity and community resilience.

Changes in the Human Movement Network

By comparing the aggregate distance travelled by active mobile network users within each province for the ten weeks preceding the week of the early alert for Tropical Cyclone Donna with Monday 8th May (the day on which Cyclone Donna intensified to category five, which is displayed as a red diamond in Figure 7), it is clear that the impact on the human movement network is sizeable for the provinces near the eye of the tropical cyclone, as articulated by the aggregate distance travelled being well outside the range during 'normal' times.

Table 9. List of bandicoot variables with other trends

Variables with other shapes/trends after cyclone Donna	Definition
entropy_of_contacts__allweek__allday__text__mean (inverted V shape)	The entropy of the user's contacts on text.
percent_initiated_conversations__allweek__allday__callandtext__mean (inverted V shape)	The percentage of conversations (calls and text) that have been initiated by the user.
percent_at_home__allweek__allday__mean (constant after decreasing)	The percentage of interactions the user had while he was at home

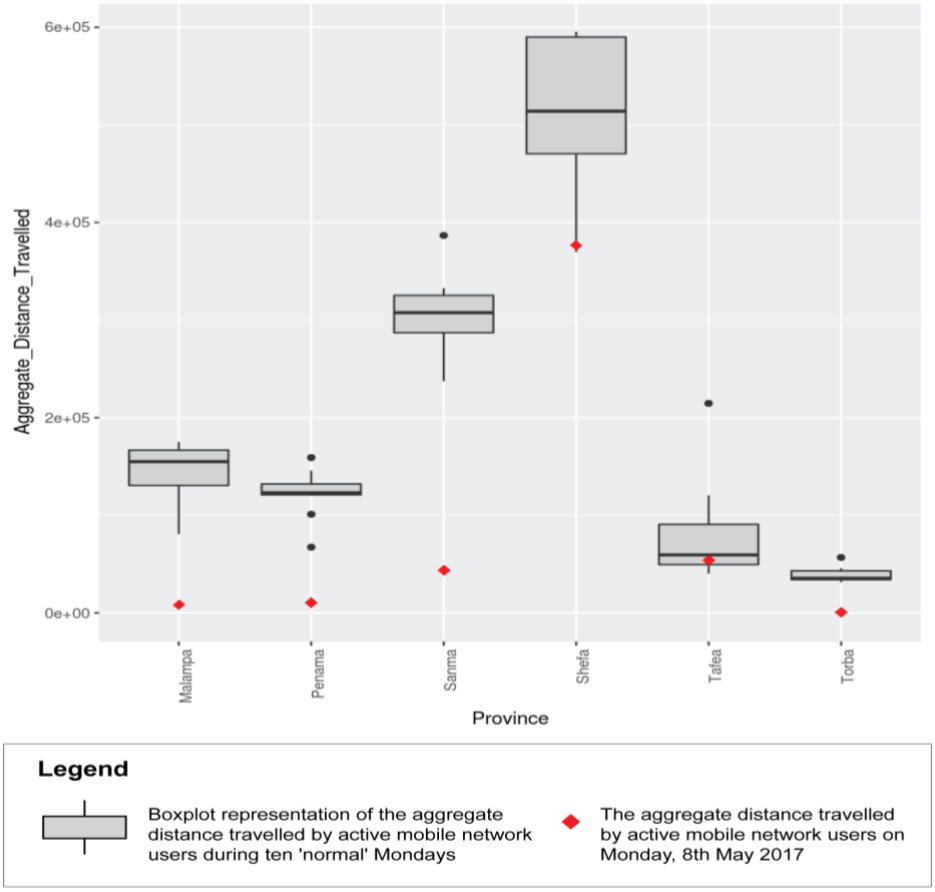

Figure 7. Human movements by province: aggregate distance travelled

The provinces of Torba, Sanma, Penama and Malampa all display diminished aggregate human movements on 8th May, well outside of the normal range captured by the boxplots in Figure 7. This finding is consistent with the trajectory and impact of the tropical cyclone described in the situation reports from the National Disaster Management Office of the Government of the Republic of Vanuatu (2017) and the UN Office for the Coordination of Humanitarian Affairs (2017). After crossing above Torba province in the north of the archipelago, the tropical cyclone headed south, along with the west coast of Vanuatu, hugging the western edge of the provinces of Sanma and Malampa.

The human movement network anomalies, generated for each day during the three weeks from 1st to 21st May 2017, add to our understanding of human movements before, during and after Tropical Cyclone Donna. Figure 8 shows these anomalies from four days of interest projected onto a map of Vanuatu: negative anomalies in human movements or an anomalous decrease in human movements are displayed in red, and positive anomalies in human

movements or an anomalous increase in human movements are displayed in blue, with the width of the line signifying the size of the anomaly.

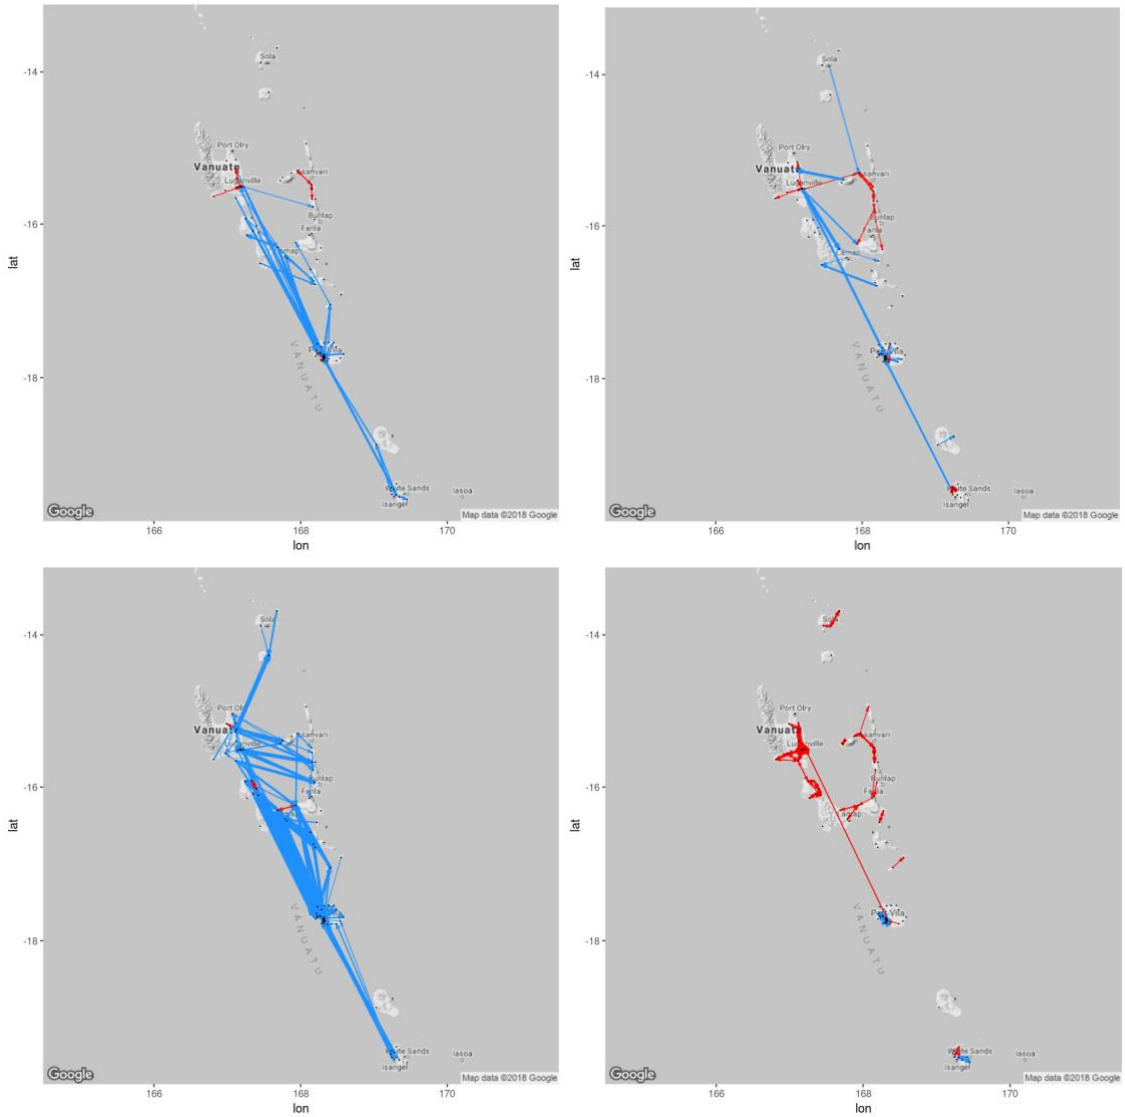

Figure 8. Human movement network anomalies pre-, during and post-Tropical Cyclone Donna (red = negative anomaly in human movements or an anomalous decrease, blue = positive anomaly in human movements or an anomalous increase; clockwise from the top left, 1st, 3rd, 8th and 12th May).

An early alert for Tropical Cyclone Donna was issued by the Fiji Meteorological Service on 3rd May 2017 (Vanuatu Red Cross Society, 2017); however, based on the human movement network anomalies, 1st May witness significant positive anomalous movements *into* Port Vila, the capital, and 2nd May witnessed significant positive anomalous movements *out of* Port Vila. These movements could represent people migrating to safer locations to sit out the storm, or returning from business trips early to protect loved ones and assets. Either way, it seems that some members of the local population were already acting in anticipation of the tropical cyclone.

From the day of the early alert on 3rd May until 7th May, we see broadly an increase in negative human movement network anomalies *within* the islands of the northern provinces and an increase in positive human movement network anomalies *between* the islands of the northern provinces, as well as predominantly positive human movement network anomalies in the southern provinces of Shefa and Tafea. Of note, on 5th May, the day on which Digicel sent text blast to all users warning of Tropical Cyclone Donna (Food Security Cluster, 2017), we see a step increase in negative human movement network anomalies within the islands of the northern provinces, and on 7th May we witness a surge in positive human movement network anomalies away from the Island of Ambae in Penama province. This suggests that the mobile data is capturing two behaviors: reduced movement

due to the cyclone, and evacuation. The increase in within island human movements in the southern provinces could be explained by the increase in population on these islands caused by evacuations from the northern provinces, or due to improved sampling caused by increased mobile network usage linked to the natural hazard.

As can be seen from the bottom-right image in Figure 8, the human movement network anomalies on Tropical Cyclone Donna's most intense day, 8th May 2017, on which it was classified as a category five tropical cyclone, are uniformly negative for the northern provinces, and predominantly positive for the southern provinces. As with the preceding days, the increase in within island human movements in Port Vila could be explained by the increase in population on this island caused by evacuations from the northern provinces, or by increased activity on the mobile network improving the detection of human movements on the island.

On 9th May, human movement network anomalies *within* the islands of the northern provinces remain negative; however, we also see the return of positive human movement network anomalies *between* the islands. This trend of positive human movement network anomalies between the islands increases on 10th May, with diminished within island negative human movement network anomalies. The trend of positive human movement network anomalies between islands continues until 21st May and possibly beyond, with a climax on 12th May, as highlighted by the bottom left image in Figure 9. The within island negative human movement network anomalies reverse to positive by 11th May but return to negative on 18th May until the end of the study period on 21st May, this trend is especially clear in Sanma province. With the increase in positive human movement network anomalies between the islands, especially between Port Vila and the northern provinces, we may be detecting both the return of evacuees and the beginning of the response effort. Regarding the within island behaviour, especially in Sanma province, we may be witnessing an initial boost to human movement due to evacuation or return post-tropical cyclone, followed by negative human movement as reconstruction efforts begin and damaged infrastructure suppresses all non-essential movement.

As highlighted above, it is also possible that some of the fluctuations in positive human movement network anomalies pre- and post-cyclone are a result of the improvement in sampling caused by greater use of the mobile network at that time. It is clear from the section on aggregate behavioural changes, above, in particular the increasing trend in the indicators under the *basic phone use* category, for example the indicator on the total number of interactions, that the network is experiencing higher usage connected to the tropical cyclone. For negative human movement network anomalies this is unlikely to be the case, as if the above observation is true, they appear in spite of the additional sampling and can therefore be analysed with more confidence. As highlighted in the section on data processing, due to the data scarcity relative to GPS-based trajectory data, active users shape the signal more than less active users, resulting in coverage bias, thus we make no attempt to generalise the findings to the entire population of Vanuatu. In addition, the patterns of human movements intra- and inter-island make the case study specific to an archipelagic context. We would expect to find different human movement trends and structure to the human movement network on a larger island or in a continental country.

Nonetheless, in an archipelagic context, the ability to detect persistent negative human movement network anomalies can be of use to humanitarians for identifying areas struggling to recover from natural disasters and for the targeting of assistance on this basis. The frequency and granularity of the data set, in particular, offers a step change in the speed of feedback on the efficacy of humanitarian assistance, which could enable more efficient resource allocation. This potential invites further exploration of insights from mobile network data in an operational context.

CONCLUSION AND FURTHER RESEARCH

Due to its detail and tractability, mobile network data holds the potential to inform humanitarian operations, especially in periods of high uncertainty in the hours, days and sometimes weeks following a natural disaster. The observed coverage errors and biases in the data set can be addressed with calibration methods by reference to the census, but these often require either good quality subscriber identity module (SIM) registration data, or a tele-survey of a random sample of the network subscriber base. Thus for the foreseeable future, mobile network data insights can complement traditional data collection methods common in the humanitarian sector. The research findings described above focus on general sense-making and anomaly detection with the mobile network data, functions for which full representativeness is desired but not required, and so offers value to humanitarian operations in archipelagic contexts.

Our identification of aggregate patterns indicates short term and medium term behavior changes after Tropical Cyclone Donna. We identify four different classes of patterns in the bandicoot variables related to behavior changes, which include increasing, decreasing, V-shaped, and other patterns. Patterns generated from text activities, although not exclusively, tend to revert to the pre-event levels. Patterns produced by call activities are more intriguing, since the indicators displaying increasing patterns show a potential longer term convergence that exceeds our study period. There are two potential future states, either a long term bouncing back to pre-disaster levels or a new equilibrium. Both cases are interesting because they offer potential as a measure of community resilience, both in terms of the return to stable states and the time it takes to achieve stability, as well as to inform the targeting of resources by governments and humanitarian agencies.

We also find interesting behaviors by processing the trajectories of anonymous mobile network users, creating insights on aggregate human movements. Findings of note include the nature of inter- and intra-island human movements, both before and after Tropical Cyclone Donna. These movements by a cohort of the local population at different stages during the crisis were hypothesized to represent people migrating to safer locations to sit out the storm, returning from business trips early to protect family members and assets, the return of evacuees and the beginning of humanitarian assistance and the reconstruction effort. Exactly where and when these activities contribute to the observed human movement network anomalies requires greater contextual knowledge and further research. It should be highlighted that the insights cannot be applied to the general population due to the absence of universal coverage of the mobile network and hence the possible presence of coverage bias. For example, due to the cost of using mobile network services, it is likely that the dataset is more representative of wealthier socioeconomic cohorts than the population at large. As highlighted above, this issue could be addressed by surveying a random sample of mobile network users and then calibrating the insights from the research by reference to the census.

In terms of further research on the general behavioral patterns based on the bandicoot variables, it would be interesting to compare behaviour changes connected with different natural hazards: for example, do differences exist between sudden onset hazards like earthquakes and relatively slower onset hazards like cyclones. The existing body of research suggests that this may be the case. The second area of further research could analyze regional level patterns, in particular comparing more and less severely impacted areas. This research could investigate the presence of causal links between the tropical cyclone and longer-term changes in behavior. A more rigorous conclusion would be expected if there are meaningful trend differences between Torba province, which was closest to the eye of the tropical cyclone, and other regions well beyond the reach of the storm, although the near-closed system status of an archipelagic country would complicate such an analysis. Since Tropical Cyclone Donna happened at an unusual time, it would also be interesting to compare the results with findings from other tropical cyclones that occurred during what is traditionally the cyclone season.

Regarding human movements, it would be interesting to examine population and mobile network user distribution, and tower-level activity to understand the positive human movement network anomalies in the southern provinces throughout the study period. Further research in this specific area should also include the use of a centroid-based human movement matrix gridded at a certain resolution or administrative level, as the tower-level human movement matrix used in this research may not capture human movement patterns as optimally. More sophisticated anomaly detection methods would be beneficial, as well as awareness of the possibility that tower or grids pairs which experience negligible flows during normal times produce anomalies based on only a small increase in the actual human movements between the two locations. In addition, it would be interesting to examine mathematically the correlation between the trajectory of the cyclone and decreased active human movements, as well as correlating aggregate mobile network activity volume with cyclone landfall. Exploring any differences in behavior between littoral and in-land communities could hold potential. It would also be interesting to conduct a network analysis of aggregated call and text activity to understand how the cyclone impacted behavior at this level, as well as investigate whether anomalies in airtime credit purchases in advance of the cyclone predict exposure to previous tropical cyclones or other natural hazards.

ABSTRACT

The cognitive demands and skills required of a fire engine company when assessing the scene of an incident and the systems they use to manage this information are a matter of life or death. We conducted a case study with an entire fire battalion in Florida (35 firefighters at varying levels of command) to assess their routine technology needs. Using a cognitive work analysis approach, we found that the firefighters in our study relied on mission critical systems that often failed, as well as disparate secondary systems that lacked integration. Capability gaps and inaccessible data also increased the likelihood of errors, creating frustration in the systems that both helped and hindered these firefighters in their daily job tasks. We describe what firefighters need from technology in its present state and we outline usability issues for technology designers and practitioners to leverage in the design of future systems.

Keywords

Fire service, case study, sociotechnical analysis, work analysis, information systems

INTRODUCTION

Every 23 seconds, a fire is reported in the United States (Haynes & Stein, 2017). From the time of the call, fire response teams must be on the move within 80 seconds for a fire call and 60 seconds for a medical emergency. This fast-paced response requires careful planning and coordination involving input from multiple sources, information from multiple devices, and communication from multiple people. With such a tight timeline for response, firefighters must be prepared to arrive on scene and successfully complete their mission, sometimes without accurate information or adequate time for pre-planning.

Despite a common need for accurate and real-time information, the fire service is very diverse in how it obtains, manages, and handles data due to variations in response areas and budgeting (Haynes & Stein, 2017). Consequently, firefighters may not have access to state-of-the-art equipment or facilities. For example, 15% of stations in the region we evaluated were over 40 years old according to the most recent National Fire Protection Association survey (NFPA, 2011). Additionally, aging equipment is also a concern. Recently, two firefighters in Massachusetts faced potentially fatal conditions after their radios failed to convey the "mayday" signals, indicating they needed aid in escaping the burning building (Firefighter Nation, 2017). These near-miss accidents require careful consideration of the system in which firefighters must operate, but more importantly warrant a closer look at the systems firefighters depend upon for conveying and obtaining information. Ideally aging equipment and outdated facilities would receive more attention, but the diversity in fire service conditions warrants a closer look to understand the holistic needs of each region and district.

Towards this end, our work focuses on better understanding the needs of 35 firefighters across the command structure from probational (newly trained) firefighters to fire chiefs with over 30 years of experience.

We conducted a case study in which the first author accompanied fire engine companies for an entire day to better understand the sociotechnical context surrounding the fire service. In this paper, we define *sociotechnical* as the interaction between the firefighters, the environment, and the systems/technology they use to operate in those environments. Our research was guided by the following questions:

- How does the sociotechnical system as a whole influence the behavior of the firefighters in our sample?
- More specifically, what are the main tools used by fire engine companies and rescue teams? Do these tools differ across ranks?
- How do these tools and technologies impact job tasks, job functions, and organizational values?

To better design technology to meet the needs of the fire service, we evaluated the broader sociotechnical system across all ranks of the fire service. To do this, we met with firefighters in six different stations (an entire battalion). We also interviewed three emergency operations center personnel responsible for sending information to first responders county wide, spanning over 40 fire stations. Drawing from the Cognitive Work Analysis framework as the theoretical a foundation for our research, we uncovered that the technology and systems used in our sample did not match the needs of the fire service (Vincente, 1999). Our key contributions include:

- An assessment of current systems and technology utilized by a fire battalion that services a large, metropolitan area in the Southeastern United States
- Translation of findings from cognitive systems methods into information that illustrates a richer understanding of the *sociotechnical environment* that firefighters work in
- Identification of areas where further investigation is required to create an effective system that can support firefighters across the command structure

RELATED WORK

Designing technology for emergency management and crisis response poses challenges due to the diverse number of stakeholders involved (Gomez & Turoff, 2007; Moynihan, 2009; Palen, 2007). The field of crisis informatics emerged from a need to better understand the perspectives of these stakeholders in a variety of disaster scenarios and emergencies by leveraging a multidisciplinary approach. Thus, this field has studied the implications of information dissemination across a variety of categories such as collaboration, community response, and information generation (Palen et al., 2007; Shklovski, 2008).

Efforts to better support first responders and emergency management personnel have largely developed from information sciences and decision-support tools. Research in this area has focused on ways to optimize tools and implement new systems at all phases along the system lifecycle. For example, previous work has focused on eliciting information requirements of first responders using a variety of approaches from sociology, grounded theory, and team performance research (Denef et al., 2009; Jul, 2007; Li et al., 2014; Prasanna et al., 2009; Toups & Kerne, 2007). The development of communication tools and systems has also been one of the defining research thrusts in this area (Dawkins et al., 2018; Groner et al., 2012; Jiang et al., 2004). Within the last year, research has assessed the attitudes of German fire departments on the acceptance of newly emerging technologies (Weidinger et al., 2018).

Due to the parallels between military operations and fireground command decision-making, the fireground was chosen as a domain to explore some of the most influential theories and models for decision-making in critical situations (Klein et al., 1989). More recent work in human factors has demonstrated the utility of focusing specifically on the fireground commander to better understand the barriers that impede successful mission management and ways to mitigate these through best practices (Gasaway, 2009). Similarly, work in HCI has focused on designing configurable systems that support the information requirements of four firefighter roles (Prasanna et al., 2013).

This paper directly addresses the role of technology for fire response in the United States. While we recognize that conducting a work domain analysis for firefighting is not novel, we provide a novel approach to the interpretation and presentation of key issues relevant to fire engine companies. We expand upon previous work

that identified some of the problems that incident commanders face by addressing the team across all ranks and updating it to be current with the advancement of technology (Dawkins et al., 2018; Jiang et al., 2004; Kapalo et al., 2018). The goal of our paper is to provide a *critical and current evaluation of the sociotechnical needs within current fire teams in the United States*.

We seek to summarize some of the important feedback to better inform the design of future technologies and to draw attention to the needs of firefighters, in our sample, who depend upon these systems in life or death situations.

METHOD

Participant Profiles

The participant sample consisted of n = 35 (32 male, 3 female) firefighters and n = 3 (3 male) emergency management personnel; n = 38 total. The fire service, while grounded in a para-military structure, has local and regional variations across the United States. All participants in this study are career firefighters and personnel. Although volunteer firefighting is prevalent in other parts of the United States, volunteer firefighting is uncommon in this particular area and state, since it is well populated. Participant quotes are denoted with their rank. Due to the possibility of potentially compromising participant anonymity, the term "chief" denotes any of the chief ranks such as battalion, district, assistant, or division. See Table 1 for an overview of ranks in the fire service.

Table 1. Firefighter ranks across the command structure

Rank	Role
Probational Firefighter	Newly Trained
Firefighter	Fire Suppression
Engineer	Driver/Operator of Equipment
Lieutenant	Crew Supervisor
Captain	Direct Operations
Battalion/District Chief	Highest Ranking Officer On-Duty
Assistant Chief	Operations
Division/Fire Chief	Operations/Administration

In this study, an engine company is composed of at least one firefighter, one lieutenant, and one engineer that all ride in the engine cab. The rescue team drives an ambulance separately and is generally composed of an emergency medical technician (EMT) and a paramedic. In this case, the firefighters all at least met basic EMT requirements, since it is common for firefighters to fill different roles depending upon their shift and response area needs.

Recruitment and Data Collection

The study occurred in two phases. Participants for the first portion of the study were recruited via email after Institutional Review Board approval was obtained. In the first phase of the study, the first author conducted focus groups with three Emergency Management Personnel and a group of five fire chiefs at the county Emergency Operations Center (EOC). This aligns with the recommended practice of conducting theoretical sampling in grounded theory-based research (Strauss & Corbin, 1994).

Following these two sessions, approval for a ride-along was granted to the first author through the fire rescue headquarters administration. The first author accompanied a battalion chief for five hours and a captain for five hours. Throughout this 10-hour ride-along, both the chief and captain were required to make stops at six different fire stations. The first author conducted eight additional ad-hoc focus groups throughout the duration of the study by obtaining verbal face-to-face consent from the firefighters at each fire station. The groups were formed based upon staff availability and interest. The first focus group was transcribed from an audio recording. Subsequent focus groups were not audio recorded due to the nature of incident response. All medical calls are subject to Health Insurance Portability and Accountability Act (HIPPA) regulations and patient privacy protections. Therefore, the first author took field notes for the remaining groups (2-10).

Table 2. Summary of data collection groups with participant counts and roles included

Study Number	Data Source	Participant Count	Group Constellation
1	Focus Group	3	Emergency Management Personnel
2	Focus Group	5	Assistant and Fire Chiefs
	RIDE ALONG (Conducted ad-hoc at fire stations & incident scenes)		
3	Interview/Observation	1	Battalion Chief
4	Interview/Observation	1	Captain
5	Focus Group/Observation	5	Fire Engine Company 1
6	Focus Group/Observation	4	Fire Engine Company 2
7	Focus Group/Observation	4	Fire Engine Company 3
8	Focus Group/Observation	6	Fire Engine Company 4
9	Focus Group/Observation	5	Fire Engine Company 5
10	Focus Group/Observation	4	Fire Engine Company 6

Data collection was informed by a cognitive work analysis approach (Rasmussen et al, 1990; Vincente, 1999). Cognitive work analysis developed from a need to understand the work of actors, the information behaviors surrounding the work, the environment in which work is performed, and the reasons behind the work performed (Fidel & Pjtersen, 2004). Our work employed this framework to guide the direction and scope of the studies conducted and the interactions with participants. A sampling of some of the questions asked during participant interactions mapped to major work analysis dimensions are captured in Table 3 below. Please note this is not an exhaustive list and meant to demonstrate how data was collected beyond observations on scene.

Data Analysis Approach

The first author coded all of the interview data. This coding process was completed by uploading all of the transcripts into MAXQDA 12. Two senior researchers reviewed samples of this coding to ensure agreement. The data was coded in three iterations, using the sociotechnical themes (people, technology, incidents) as an initial framework since these reflect the main tenants of the fire service work domain (Fidel & Pejtersen, 2004; Ramussen et al., 1990). These themes were chosen since they captured the broader dimensions of the cognitive work analysis framework: *environmental, organizational, social, activity, and individual*. However, because these dimensions are interdependent, the organizational, social, and individual dimensions were consolidated into a single code, categorized more broadly as *people*, since firefighting requires an understanding of how the command structure drives the social and organizational aspects of fire departments (Monynihan, 2009). As necessary, the interviewer performed sweeps to ask clarifying questions in order to capture information about a particular concept or term. Further sub-codes were added to better understand the three broad themes, leveraging the grounded theory approach (Goggins et al., 2013; Strauss & Corbin, 1994). Finally, a third coding iteration was used to check for accuracy and to ensure statements were categorized meaningfully and completely.

RESULTS

The structure of this section aligns with the themes emergent from our data and categorizes some of the end-user feedback we received to better understand the routine needs of firefighters in our sample. We first grouped these dimensions across three broad categories that comprise the sociotechnical environment of the fire department: people, incidents and technology. The revised coding structure, based upon the three code iterations, is captured in Table 4 below.

Table 4. Coding Structure

Sociotechnical Dimension	Sub-codes
People (Actors)	• Rank and expertise • Values • Expectations • Resource allocation
Incidents (Environment and Organizational)	• Operational constraints • Job tasks and activities • Responsibilities
Technology (Activities and Objects)	• Attitudes • Usability Concerns • Coping strategies • Constraints and failures

Table 3. Samples of Questions Scaffolding Data Collection Sessions

Framework Dimension	Sample Question(s)[1]
Analysis of User Characteristics	1. What information do you need to perform your job well? Can you provide me with some specific examples? Are you responsible for sending information to another teammate? a. What is their role? b. What kind of information is necessary for you to provide to them? 2. What kind of tools/equipment are available to you and which tools do you primarily rely upon? a. What information do these tools provide? If they do not provide information, what are their main purposes or functions? b. Are these tools located in the station, on the vehicle, where are they? c. How frequently do you use this set of tools during the day? Are there some that are rarely used?
Activity Analysis	3. From the time dispatch alerts you to the time you arrive on scene, walk me through an example call. What do you do first, and what information do you need to proceed and get to the scene? (may be real-life or a simulated training scenario) a. What are your goals in these scenarios and how do you plan your response? b. What do you prioritize first? ("size up") c. How do you know what to prioritize first? d. At a given moment, how many displays/devices are you obtaining information from? e. Can you explain to me in a few steps what that sequence of information gathering is like? Which device/interface do you look at first? f. Who are your teammates, and do they provide you with information? What does that sequence of information look like?
Organizational Analysis	4. Does your role change as situations change or do you generally perform certain tasks? Could you elaborate on this, if possible? Is it situation dependent or is it determined before your shift who will fill which role?
Work Domain Analysis	5. What are some actions that are taken to make sure a size-up is done correctly? Are you monitoring yourself or does leadership play a role in this? Who is in charge of making sure the team and plan adapt if the scenario changes? 6. In addition to your on-call responsibilities, what are some examples of other tasks you may be responsible for on-shift? (Administrative, maintenance, etc.)

[1] **Please note this is not an exhaustive list of all questions posed due to space constraints. Please contact the authors for the complete list of questions.**

People

Because our approach is grounded in understanding the dimensions of expertise and the self-organizing social structure driven by incident command, we sought to understand the unique roles across the fire engine company (LaPorte, 1996). We contend that within the company, there are prototypical roles each team member must fill, creating an opportunity to better understand the profile, values, and expectations of these team members. For example, the chief conceptualizes the engine company and arriving units as a sports team, with the incident commander acting as a coach. This organization structure provides further insight on how responsibilities are distributed and shared. It also provides context surrounding values and expectations more broadly:

> *"The IC [incident commander] is like a football coach who is calling the plays, absorbing the whole scene, delivering out the task in a priority fashion, their information is more global: where are all my units, what are the changing conditions, what are the needs that I have to address, what are the resources I have, and how do I get the resources I need?"- Chief*

Rank and Expertise

The above statement provides some insight into the challenges the incident commander faces regarding the amount of information they are required to process. In contrast, the crew on the engine has different priorities. They were likened to athletes carrying out plays, and take more of an offensive approach:

> *"I care about what is in front of me, what is overhead, what is in the room, I'm listening to what's around me."- Firefighter*

Despite these conceptualizations, there are some nuances in understanding the rank (social) structure on the fireground. One chief succinctly explained that there are multiple types of supervisors on the fireground to ensure that incidents move swiftly and quickly, but that those roles require different things from technology and tools. He stated:

> *"There are two types of supervisors in incident command: The first is somebody who is commanding a crew and navigating in the truck with them, a lieutenant. The second is somebody [like a battalion chief or captain] who generally is alone and arrives as an individual unit. So, they are navigating, orienting, and planning by themselves."-Chief*

Thus, the role of the battalion chief can be potentially more demanding due to the added requirements of navigating to an incident scene alone, while operating the vehicle, listening to the radio, and monitoring the MDC for changes in incoming information. They may also be required to access documents such as pre-incident plans. This details a richer understanding beyond that of the "prototypical" user in the sense that chiefs and company officers have different priorities than the engine crew when responding on scene. When considering the technical system and incident scene, it is clear that officers have different information needs.

Job Expectations and Resource Allocation

Expectations are emphasized as important, each member has a role to fill and as the incident progresses, it may become necessary for others to join the team. As a consequence, *flexibility and accountability* were two concepts that were consistently referenced in participant responses.

> *"The expectation for the IC [incident commander] is that he/she prioritizes accountability. They need to know where everyone is and what they are doing at the scene from start to finish." –Chief*

In addition to accountability, team members also explained how they coordinate tasks, sometimes with an implicit level of *trust*. For example, one engineer explained how he makes decisions regarding the appropriate amount of water flow. He recognized that this sort of behavior bounds the system, but not explicitly. Instead, he uses his judgement and understanding of his teammate's job tasks to fulfill the requirements of getting the water on the fire in a timely manner.

> *"There's an understanding there. I know that if I put out the maximum pressure required on the line [hose] it's going to knock the guy at the end of the line around and that would piss him off and slow us down. So, I use my judgment, it's not always by the book."- Engineer*

These values of *accountability and flexibility* were prevalent across all interviews but were typically emphasized at the higher levels of command, where the ranks become more supervisory and thus, more critical in terms of ensuring the team's safety.

Incidents

Generally, an "incident" is defined as an instance of a particular activity in which observations can be made and there are directly measurable consequences based upon the actions taken (Flanagan, 1954). In the fire service domain, an incident is any sort of call in which emergency medicine or fire suppression activities are involved. Although incidents vary in nature, in this paper we consider all incidents to be emergencies requiring a time constrained response that involved *protocols and action* among individuals belonging to the engine company. According to our sociotechnical approach, the incident represents the operational environment in which people are present and technical systems are utilized.

From our study observations and interactions with participants, we noted that the most prevalent themes surrounding incident response involved being *adaptable* to rapidly changing scenarios and the ability to think forward and plan ahead, regardless of role or incident. All firefighters had to be prepared to encounter situations that are time-sensitive and require methodical preparation. Across all of the themes in the incident category all participants emphasized the ability to adapt to the incident as one of the main values in this fire department.

Operational Constraints

Participants made frequent references to "playbooks," "thinking ahead," and time constraints. This theme of adaptability stems from a need to embrace the dynamic details of the situation in order to successfully complete the mission.

> *"There's not just one playbook, once one plan is null, we move to a back-up plan, and then we have another back-up plan if that one fails."-Lieutenant*

> *"I'm always thinking half an hour ahead."-Chief*

> *"As an incident commander I am already thinking about where the hydrants are, where to stage, how much room we need to leave, whether we have a decent water supply, where the trucks are going to go, all of this decision-making has to happen quickly."-Captain*

An emergency management center employee captured this requirement well in the following statement:

> *"Essentially there are three levels of response—task, tactical, and strategic. Our responders are filling different roles during the course of an incident; however, these levels determine the scope and perspective of each role." -Emergency Manager*

Despite this need for quick decisions, our study revealed that the systems firefighters rely upon do not necessarily meet their needs, and in some cases can constrain incident response. We describe this idea in more detail below.

Specific Job Tasks, Activities, and Constraints

Incident response is dictated by decision-making of commanders as well as team coordination, but it is also dependent upon other factors outside the control of the firefighters. For example, a demanding and challenging situation arises when a water supply is not readily available. The tanker shuttle is a strategy and protocol implemented when water sources are scarce or not accessible. In one instance, a recently developed community in the area did not contain enough fire hydrants to supply the hoses for a house fire. For this reason, a tanker shuttle is established to provide support for the water supply. However, the logistics of this protocol can be daunting. There is often not enough water on one tanker truck, so portable tanks and a system for replenishing this water needs to be established. Typically, one captain or senior officer is in charge of managing this process while the other serves as incident commander of the entire scene.

> *"One major concern with recently developed communities is the lack of fire hydrants. They are typically expensive, and some developers complete the bare minimum for coding and zoning. As a consequence, the logistics of putting out a routine house fire may be compromised by lack of water and you have to move to plan B." –Engineer*

Technology and Equipment

To support incident response, firefighters need information about the emergency at hand. Firefighters rely on technical systems to understand and react to the dynamic nature of incidents. Often this information is incomplete and lacks detail. Therefore, technology can convey what little information is known.

The Mobile Data Computer (MDC) represents a central component in the system as it facilitates the two-way exchange of information between the Computer Aided Dispatch (CAD) system, the system that transmits emergency information from dispatch, and the firefighters on duty (see Figure 1 and Table 5). While the MDC is equipped with navigational capabilities, these capabilities are augmented by separate devices, such as a Garmin (GPS). Because of this central role, we elaborate on this device further to explain its implications in later sections of this paper. The MDC represents the hub for information in which firefighters of all ranks access incident data, create reports, and log information. Despite its theoretical utility, in practice it is often the source of frustration and error due to connectivity issues, usability problems, and general lack of functionality. These themes were introduced by participants in the quotes below:

You have 45 seconds to understand information from several disparate systems, you are flipping screens, switching back and forth from the mapping screen and the incident screen..."-Lieutenant

"The MDC printout has more information than someone can read in 30 seconds..."-Firefighter

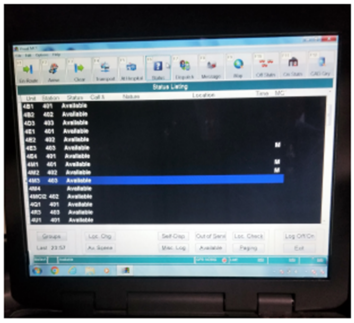

Figure 1. Example of a Mobile Data Computer (MDC) or Mobile Data Terminal (MDT) used by fire engine companies.

In addition to the MDC, firefighters rely upon several different technologies in their routine job tasks. Some of these technologies are listed in the table below. Please note that due to local variations, some technologies such as automated dispatch systems and tablets may exist in other departments. Additionally, there is other equipment stored on the fire engine that may be considered a major tool or technology (e.g. hydraulic tools). However, the goal of this table is to summarize the core technologies routinely used by engine companies.

Table 5. Summary of Core Technologies Used by Firefighters Daily

Device	Usage/Purpose	Users
Mobile Data Computer (MDC)	Information, Logs, Reports	All
Global Positioning System (GPS)	Navigation	All
Paper Map book	Navigation	All
Radio	Communication	All (In-Vehicle)
Camera	Crew Surveillance/Monitoring	All (In-Vehicle)
Mobile Phone	Communication	Officers
Portable Radio	Communication	All
Thermal Imaging Camera (TIC)	Mission Tasks	Lieutenant/Team
Self-Contained Breathing Apparatus (SCBA/" Air Pack")	Mission Tasks/Protective gear	Mission Team
SCBA Tracker	Mission Tasks/Monitoring	Incident Commander

Attitudes Toward Technology

Contrary to the need for flexibility that we noted from both the dynamic nature of incident response and the changes in staffing that may occur, we noticed that participants did not express that current technology reflected these values. Instead, much of the participant frustration stemmed from the inability to use technology that was flexible and mobile to fit with the dynamics of incident response.

> *"Usually we are given a system and it's not perfect. We make the best of it. We have to use it even when it slows us down."-Firefighter*

Some participants felt that these technologies were not appropriately tailored for their job tasks as exemplified below:

> *"Much of the technology we have was created for the S.O. [Sheriff's Office]. They just put a firetruck icon on it and hand it to us. There's not really much consideration about what we do."-Firefighter*

Generally, attitudes toward technology indicated ambiguity surrounding needs. On one hand, firefighters across all ranks expressed that technology was necessary to carry out their job tasks. However, some company officers indicated annoyance and irritation with new systems since they were often unreliable. Although there are electronic rosters, one chief felt that the traditional methods were more reliable since there was less of an opportunity for error:

> *"I prefer to stick with the things that work. My whiteboard with all the staffing details does not fail."-Chief*

Additionally, new technologies such as the automated dispatch system tended to fall short of expectations due to flaws with the system, causing negative perceptions of some of the newly integrated technologies.

> *"The automated voice that provides dispatch information is irritating at times. She often mispronounces things like the abbreviation for "drive" as "doctor." -Captain*

Usability Concerns: Data Inaccessibility and Capability Gaps

A majority of the devices the firefighters used in this sample were not entirely mobile or portable, see Table 5 above. The MDC is not actually completely mobile; it is typically mounted in the vehicle. Therefore, it presents issues with regard to functionality. For example, one Lieutenant commented:

> *"A command tab exists on the MDC for planning. But since the MDC is not portable, no one uses it. It would also require maintenance of another module." - Lieutenant*

A seemingly useful opportunity for planning or visualizing information is missed when a tool is not functional in the environment for which it will be used in. This command tab is not useful if the computer cannot be removed from the truck or if the MDC loses connectivity since new information cannot be added into the system.

Some of the participants on shift expressed that their needs were not currently met due to lack of features related to current technology. It was apparent that the radio was a source of frustration, but also a necessary form of communication. The lack of multiple input capabilities made it challenging since only one person at a time can "talk" on the radio. The quote below indicates that firefighters sometimes struggle with this bottleneck in communications.

> *"It's like talking through a straw [on the radio], one at a time, that makes it impossible."-Firefighter*

To illustrate another example, the officers on scene indicated a need for higher level information. Chiefs and captains expressed a desire for streamlined information that could be quickly visualized.

> *"Something that gives an overhead view would be important, but it does not exist. I can pull an overhead view on Google maps, but it's usually a picture from two years ago..."-Chief*

> *"Give me a report, I can send more stuff that way if it sounds like that is where the threat is, I need this kind of [summarized] information..."-Captain*

"It would be beneficial to have a quick picture and summary for size-up. If there was a way to summarize this information, more people would use it. It's also an issue of accessibility. I have to pull up a separate network just to access these plans. You don't have that kind of time to spend 15 minutes trying to get to a plan."-Captain

It was apparent from the field study observations that firefighting involves tasks that require heavy reliance on visual information. This includes line of sight information, as well as signaling and artifacts that manage the number of people on scene, air pack utilization, etc. Despite this, much of the technology used in firefighting does not present information in a way that easily consumed visually. For example, the MDC presents information in paragraph form and radio communications are exclusively auditory. Of the technologies that do present information visually, they are often cumbersome and difficult to use. Most notably, the MDC map only shows directions from a northward orientation. This means that when navigating, the firefighters must translate all the directions from north to get to the scene. This is a poor allocation of resources and visual attention because there is technology readily available to mitigate this capability gap. As one participant captured, there are too many interfaces for the incident commander to allocate attention to:

"You really need someone like a scribe or assistant to monitor the pack tracker (Self Contained Breathing Apparatus, SCBA) interface" –Engineer

Additionally, some participants identified capability gaps related to a lack of visual information. For example, dispatch can describe a picture of a motor vehicle accident scene taken through a red light camera to the incident commander over radio, but currently, in this department, there is no capability to send the picture to any arriving units or line officers directly.

"[For traffic accidents] Dispatch has control of the red-light cameras but they cannot send us the picture. So, they have to describe what they see. It would be nice if we could see the accident scene before we get there." –Chief

This also affected the ability for officers to plan strategies and prioritize tactics since information could not be easily accessed via the MDC interface.

System Failures and Coping Strategies

All (35) of the fire team participants reported at least one technology/device failure that is routine and occurs daily. Of these reports, the majority cited the MDC is as the piece of equipment most likely to fail. From observations, one call was missed by leadership due to lack of signal in the fire station. Additionally, the MDC experienced connectivity issues the entire shift. Judging by the more experienced leadership's reactions, it was completely normal for these failures to occur. Many firefighters expressed frustration with the failing tools and recently implemented technology. The more experienced leaders found methods of their own for coping with repeated issues.

"I have to keep a separate flash drive with information about local schools on them. Relying on technology that typically fails [the MDC] is not a good plan." -Chief

System failure emerged as one of the most frequent and rich codes in our analysis. Relying on errant technology creates a frustrating and stressful user experience. Using outdated technology or equipment that continuously fails does not support their mission and increases opportunities for error. We noticed this theme to be prevalent due to the disjointed systems that the entire fire battalion uses.

"When I can pull the information up, it is nice, but that is rare." -Chief

In addition to the implications for incident response (slower response times, less accurate coordination), these points of failure seemed to suggest that the firefighters in our sample believed their job functions came as an afterthought rather than a priority.

"For mass casualties/large scale incidents with 5 or more people wounded, it [the MDC] will usually provide you with a list of available hospitals. This feature [hospital suggestion] is sometimes down which complicates situations. Now I have to radio all the hospitals."-Chief

Several team members came to accept that sometimes failure was inevitable, and they needed to rely on other means for getting updated information, such as the radio.

"No way to know when system connectivity is lost because the MDC does not alert you."- Chief

This is also apparent when the radio and MDC provided conflicting information. For example, there was one instance during the observation shift in which the chief was canceled on the call. The MDC connectivity was lost, so the computer did not update this information. When you are operating a vehicle at sixty miles per hour and also listening to the radio and reading the MDC, this poses significant risks for not only the officer operating the vehicle, but also for the civilians on the road. Consequently, technology has the potential to compromise scene safety.

DISCUSSION

Emergent themes surrounding the lack of cohesion with the technical system provided support for the idea that both the *social* and *operational* environment place demands on the *technical systems*, which are not sufficient in their current state. We noted that the technical system comprised of disparate systems that evoked feelings irritation or annoyance, negatively impacting user perception. This theme was pervasive across all ranks, but more so at the higher-ranking end of the command structure. We interpret this as an artifact from expertise, since captains and chiefs typically have years of experience and have witnessed the changing dynamics of emergency management technology over a large period of time.

Based upon our findings, our contributions are two-fold. First, we contend that identification of existing problems can lead us to better understand the needs of firefighters *independent* of current systems, which is important for understanding how to create new technologies that support the work domain of firefighting. Second, we contend that a richer understanding of the sociotechnical structure surrounding the fire department's operations allows us to better address the *gaps and deficiencies* identified in this paper:

People (Individual & Social)

Upon analysis, our data is aligned with the idea that multiple users have different needs from the MDC. In its current state, the MDCs in this department were not sufficient for incident command and often frustrated the engine companies who were attempting to perform simple tasks such as navigation or pulling up planning information. The use of GIS-based systems has been suggested as a lower-cost solution for displaying information to crews and increasing interoperability (Abdalla et al., 2007). However, we recognize each department will have different needs.

Additionally, one of the major findings of this study indicated that back-up systems typically did not involve technology and were sometimes preferred over the use of current systems, depending upon user attitudes and values. One of the ways to mitigate negative attitudes toward these technologies is to consistently gather user input and provide ways to leverage existing, reliable, and lower-cost technologies that can be adapted for the fire service. For example, replacing MDCs with tablets, or augmenting MDCs with tablets, is an easier way to increase functionality. Small solutions such as implementing tablets or changing the mobility of the MDC could have a positive impact on user experience, enhancing productivity and safety. However, due to the complex nature of funding, such changes are not easily implemented. This is particularly true when a department is navigating several risks at once, they must choose between updating MDCs or purchasing a second set of turnout gear to reduce risk of carcinogen exposure. Additionally, environmental factors such as increasing resources, connectivity, and interoperability could increase trust in these technologies, thus aligning user values to match the system and reducing frustration or error. We elaborate on these points below.

Environmental

Incident response requires the ability to quickly adapt to changing conditions. Additionally, now more than ever before, firefighters are dealing with what are known as potentially violent situations (PVS). As a consequence, protocol now requires firefighters to wear protective gear on scene and stage where necessary. This fundamentally impacts operating procedures since scene safety must be conceptualized differently and prioritized in a way that has not been previously addressed. More importantly, the current technologies used by the fire engine companies created tension due to the conflicting information needs and the multiple functions the MDC must fill. Not only must it update with current information, but static information, such as planning or inspection data, also needs to be accessible on scene. Increasing connectivity and providing further resources such as unmanned aerial vehicles and other emerging technologies could enhance user experience and support firefighters operating in complex and dangerous situations. The use of dedicated broadband networks and

increased connectivity could facilitate more reliable technology. Finally, we elaborate on this at the organizational level as well, since firefighters are dealing with increasingly different and dynamic incidents.

Organizational & Activity

Although there have been strides made in understanding firefighter communication and coordination across the team, relatively few papers have exposed the research-practice gap that exists in a majority of the United States. That is, although we are designing and evaluating emerging technologies for use in the fire service, the majority of departments are severely understaffed with limited budgets. Although the necessary capabilities may exist, little work directly acknowledges the fact that most departments are not even operating with current technologies available.

For example, the department we evaluated consistently cited cost and budget as one of the limiting factors preventing the use of certain functions on the MDC and the use of upgraded technologies. Once a software product is purchased, much of the budget is spent on maintenance, rather than increased functionality. As a result, this department suffers from a lack of interoperability and is challenged with making the best of the resources available to them. In addition to technology, we also found that staffing/administration, time, response area type, and budget all play a role in the adoption and maintenance of technological systems. Perhaps one of the more interesting findings has to do with the way modern dispatch systems and technologies were developed from the needs of law enforcement (Brenner & Cadoff, 1985). This is still a current issue and these technologies are often later transitioned by manufacturers and implemented in fire departments without much consideration for fire-rescue teams who ultimately serve a different function than law enforcement. One common pattern that emerged in our research was the reiteration that fire response and law enforcement have two separate job functionalities. Despite this, there has been a movement to increase interoperability between law and fire in the form of rescue teams (Marino et al., 2015). As a consequence, these changes require reevaluation of current systems, to accommodate the changing interagency and multiagency response needs.

There are several limitations of this study that impact the generalizable content of our results. First, we did not survey multiple fire departments across the United States. While we recognize that this does not necessarily mean our work generalizes to all U.S. fire departments, we can say that our study supports prior work and seems to be aligned with most common practices in major fire departments (Dawkins et al., 2018; Jiang et al., 2004). Additionally, we were able to assess two different agencies within the same region, which enhanced the findings. However, it should be noted that in more rural parts of the country, volunteer firefighters are more prevalent. This poses safety and training challenges beyond the scope of this paper. Further research must be conducted to determine how the needs of volunteer fire departments can be addressed. We plan to leverage this data to inform the design process for both hardware and software prototypes in the next iteration of our study. By focusing on all ranks in the command structure, this work has directly pointed out where HCI practitioners, designers, and researchers can focus further investigations to enhance the user experience of firefighters across all ranks using the same systems.

CONCLUSION

In our study, we found that the technology firefighters depend upon is not reliable or configurable in its present state. The results of our work suggest that the dynamic and frequently changing operational environment needs to be reflected in the systems firefighters use to better support them in their day-to-day tasks. Furthermore, we noted the perceived needs of the firefighters across all ranks did not necessarily match the current systems they depend on. We contend that by using a cognitive systems driven approach that themes emergent from observations and qualitative data collection provide valuable insight. The goal of this work is to leverage this data set as a foundation for further research in building more resilient and adaptive systems for first responders.

ACKNOWLEDGMENTS

We would like to thank the anonymous firefighters and emergency managers who participated in this research. The authors would particularly like to thank Ari Schein, Billy Richardson, and Ken Henderson for their support. This paper is dedicated to the memory of Ron Plummer, John Perez, and Stephen "Shakey" Vanravenswaay. Any opinions in this paper are those of the participants and authors alone and do not represent the official views of the US government, any federal agency, or fire department.

ABSTRACT

Various sources report a low adoption of IT-based tools in emergency response, as well as a negative attitude of responders to such tools. The responders' needs, simply put, are not met by the IT-based tools offered to them. Observing this situation through a user-centered design lens, we note that such problems typically stem from insufficient or erroneous context analysis. The deficiencies become even more pronounced when considering that emergency response represents a complex, adaptive socio-technical system. We also note that the appropriate methodology for designing ER systems is rarely discussed in literature and in research papers. To fill that void, the present paper discusses a minimal set of techniques that, both in our experience and according to state of the art practice, can guide developers towards positively-accepted IT systems for emergency response.

Keywords

Acceptance of ICT, Methodology, User Centered Design, Complex Socio-technical Systems, Requirements Engineering, Emergency Response

PROBLEM STATEMENT AND INTENDED AUDIENCE

The allure of using IT in emergency response has long been recognized by both researchers and practitioners. (Turoff et al. 2004; Ganz et al. 2013; Adler et al. 2011; Elmasllari 2018a) propose complete frameworks for emergency-related IT systems, whereas (Elmasllari and Reiners 2017) report 111 articles on electronic triage alone. Paradoxically, even though both "supply" and "demand" for IT in emergency response are high, the actual adoption of IT-based tools is very low and the attitude of responders to them is negative (Paul et al. 2008; Orthner et al. 2005; Adler et al. 2012; Ammenwerth et al. 2006; Elmasllari and Reiners 2017). (Elmasllari 2018b) has identified 12 problematic areas at the root of this attitude, whereas (Schmitt et al. 2007; Wu 2009; Jennings et al. 2017) note several hindrances due to the technology itself. The increasing discrepancy between what is offered and what emergency responders need was also a pressing topic in the previous ISCRAM conference (Tapia 2018).

From a software engineering perspective, the current situation represents a discrepancy between what users need and what IT systems implement. This problem, stemming from missing or wrong requirements, is a classic in the IT industry (see figure 1). It arises from the use of inappropriate or insufficient methods to elicit and understand user needs in the first place. Already in 1993, (SW Thames 1993) identified the correct methodology as crucial for the success of emergency response systems. Five of the six acceptance dimensions and 8 of the 12 problem areas for acceptance of IT identified by (Elmasllari 2018b; Elmasllari and Reiners 2017) can be completely avoided by using the correct analysis and development methods.

Given the above, there is a clear need to educate system designers about good methods for eliciting user needs in emergency response. Such knowledge, however, is not freely published by commercial suppliers, who prefer to keep their methods secret, nor by academic researchers of ER systems, who include very little details about

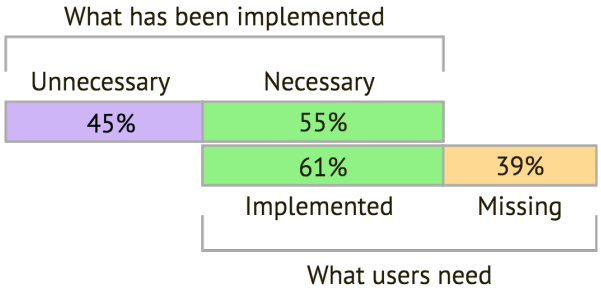

Figure 1. The mismatch between user needs and IT system implementation. Source: (The Standish Group 1995; Fowler 2002)

methodology in their papers – just enough to describe the study. To fill the void, the present paper is dedicated to educating system designers about good methodologies. We do not aim to produce a tutorial on the methods we list, but we do aim to discuss a minimal set of techniques that, both in our experience and according to state of the art practice, can guide designers and developers of ER systems towards positively-accepted products. We also provide recommended readings to further the proficiency in the details of each technique.

This paper is based on our decade-long, hands-on experience developing various complex socio-technical systems related to emergency response, security in large events, work in dangerous factory environments, sterilization of surgery tools, etc. The methods we propose were all successfully used in the research and development of 10 different IT-based systems in all areas of emergency response as part of the EU FP7 BRIDGE project. By the end of development all systems passed rigorous tests by real users in real conditions; at least four systems became commercially available, while the rest had reached TRL7/8.

FUNDAMENTAL CONSIDERATIONS ON EMERGENCY RESPONSE SYSTEMS

To better understand the problem, a short discussion on complex systems is necessary. (Simon 1962) defines "complex systems" as "made up of a large number of parts that interact in a non simple way", and where "system properties and behavior are hard to infer based on the properties of the parts". Complex *socio-technical* systems (CSTs) are complex systems where some of the components are humans or organisations, i.e. the social and technical aspects are equally important. Finally, complex *adaptive* systems are complex systems that adapt and organize themselves without being deliberately managed or controlled (Holland 1995).

Complex systems are not merely "big and complicated". They have particular characteristics and behaviors that make them very particular:

1. The properties and behavior of a complex system are hard to infer, even when the properties and behavior of each part or component are well-known (Simon 1962).
2. Complex systems cannot be studied or designed using a reductionist approach, such as decomposing the system top-down in parts and studying or designing each part separately.
3. The behavior of a complex system is nonlinear: tiny changes can lead to large differences in the outcome (Waldrop 1993).
4. CSTs have very tight coupling between people and technology, especially in regard to social, communication, and interaction aspects.
5. CSTs emerge over time and organize themselves without being under the full control of any singular entity (Holland 1995).
6. Complex adaptive systems are intrinsically resilient and will try to sustain their operation under all conditions (Hollnagel 2013).

When considering the emergency response effort as a complete "system of response", it can be shown that ER is a complex socio-technical system with a very strong adaptive element (Elmasllari 2018a). The traditional software engineering approach – split the problem top-down into parts, solve the parts, then combine the solutions – clashes directly against point 2 above. As a result, traditionally-developed solutions either do not match users' needs and

get rejected, or they exhibit unexpected and emergent behaviour, undermining both the capability of the engineer to understand the system and the trust of the users on the system.

Characteristic 6 above, resiliency, implies that complex adaptive systems will protect themselves by resisting *external* efforts to change the system. This means that efforts to *impose* a new tool or technology in ER will be met with resistance and rejection. The best illustration of this is the failed introduction of the dispatch tool for the London Ambulance Service, which was sabotaged by users (SW Thames 1993; Shapiro 2005). The implication is that successful, well-accepted IT tools for ER must arise from within the ER system, i.e. must be developed by the responders themselves.

One objection to our view of emergency response as a single system is that, in practice, commercial suppliers focus only on aspects of ER, such as "logistics management", "communications", etc. This objection misses the point. It does not matter that the supplier addresses only a tiny part of the response. What matters is the view from the responders' side. The responders' context is the *complete* response, which is a complex system. To gain trust and acceptance, any IT solution deployed in this context has to take the complexity characteristics into account.

A second objection is that "there is a difference between a methodology to develop one specific functionality (e.g. detect a crisis location from tweets) and a methodology to develop a tool for use in emergency response". Strictly speaking this is true, but as soon as the specific functionality is used in a complex context, the argument reduces to the previous objection and is similarly rejected.

The correct way to design IT systems for emergency response was outlined already by (SW Thames 1993; Shapiro 2005), who recommended that, when designing emergency systems in the future:

- The emergency response context and users need to be studied very carefully.
- Emergency professionals' trust in the system needs to be earned, otherwise they will distrust and sabotage systems imposed on them.
- Emergency-related IT systems must be designed with constant and wide participation from the users.

Seeing that acceptance of IT in emergency response has changed little in the last 25 years, the aim of this paper is to extend those recommendations and show concrete methods how to study the ER context, how to involve users, and how to design systems that easily gain the responders' trust for successful adoption in the ER practice.

HIGH-LEVEL APPROACHES AND PARADIGMS

Only two commonly-used development paradigms match the recommendations from (SW Thames 1993). We present these paradigms shortly below; an in-depth view is provided by (Norman and Draper 1986; Ritter et al. 2014; Ehn 2008; Shapiro 2005).

User Centered Design

User Centered Design (UCD) is a design and development paradigm that puts the end-user at the center of the "design universe" (Norman and Draper 1986; Norman 1988). The UCD paradigm first analyses the context: capabilities, characteristics, and goals of the user, as well as the environment within which the system is to work (see Figure 2). This analysis is then expressed as requirements and further, in step 3, is implemented in a prototype to be tested with actual users in real conditions. The test insights are used in a new iteration, deepening the understanding of the context, clarifying the requirements, and making better prototypes until all user needs and expectations are fulfilled and the system can be successfully used in the intended environment.

UCD does not draw a distinction between the technological part and the social part of the system, but considers both of them holistically (Ritter et al. 2014). With UCD, the development effort cannot stray too far from users' needs; the resulting systems tend to match the users' workflow, capabilities, and needs extremely well. These qualities make UCD appropriate for the complex, critical, and change-sensitive systems related to emergency response.

UCD also has some drawbacks, but these can be easily avoided by Participatory Design (details in the next section):

- UCD was meant for human-machine interaction, but the dominant interaction today is human-human, mediated by machines.
- When the user is at the "center of the design universe", she is unaware of how the system itself interacts with the world (Slavin 2016).
- Users do not live isolated from other technology, nor do they keep a coherent set of beliefs and preferences (Visciola 2003). A pure-UCD development can waste time catching-up with shifting preferences.

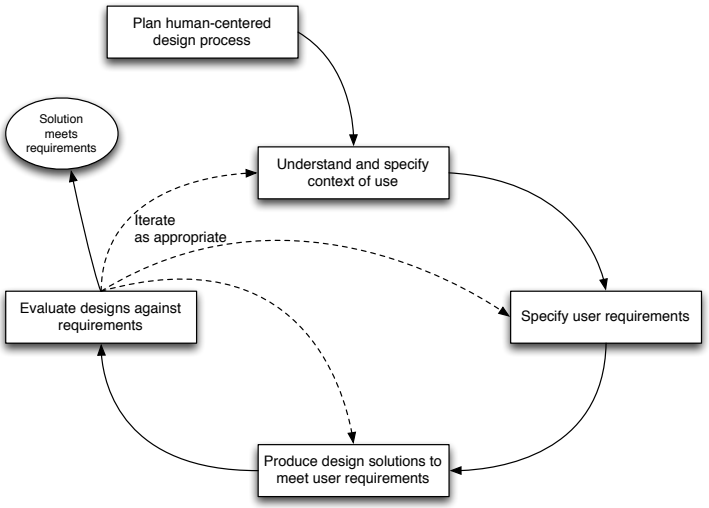

Figure 2. The ISO 9241-210 human-centered design process. Source: ISO9241.

Participatory Design

Participatory design (PD) keeps UCD as its foundation, but postulates that, because the system affects how users work, users themselves should take part in designing that system, i.e. responders must be part of the design team.

PD is ideally suited to emergency response. The responders' mistrust against IT can be entirely overcome by letting them shape the new tools. This way, the resulting product is "designed by them" as opposed to "forced upon them". The responders who participate in the design effort also become the initial, most vocal supporters of the new product. Such "social proof" leads to much higher acceptance rates than mandatory usage (Venkatesh and Davis 2000).

METHODS FOR DESIGN AND DEVELOPMENT

The following methods, grouped below by the step of UCD in which they are used, have been the most effective, in our experience, for the design and development of complex systems in emergency response. For deeper insights and details on the methods, readers are suggested to consult (Hollnagel 2013; Rasmussen et al. 1994; Endsley 2011).

Methods for analysing the context of use

Methods for context analysis can be broadly organized into two categories: analytic methods, whose basis is the analysis of formal documents and other available data, and ethnographic methods, whose basis is inquiry by interacting with users and their environment. Analytic methods are good at finding out the "formal" context, or how things should be done "by the book", but are blind to the informal "bending of the rules" by practitioners in the real world. Ethnographic methods are good at finding out how things are really done on the ground (i.e. informally), but they are blind to those requirements and processes that practitioners neglect or circumvent. Analytic and ethnographic methods must always be used together, because only so can all user needs and requirements towards a tool or system be identified[1]. Details on the best ways to combine the proposed methods under a tight budget can be found in (Elmasllari 2018a).

Analytic methods

Document analysis focuses on *written* documents and rules, for example laws, standards, process descriptions, codes of conduct, etc. These are necessary for understanding what would be a legally acceptable solution. **Literature research**, instead, learns from existing research and production efforts, i.e. from the experience, insights, and mistakes of others. Both methods should be used together in order to identify "spaces of opportunity" – areas where new approaches can be tried without conflicting with existing rules.

[1] Not all needs are equally easy to identify. Explicit needs, such as "The stretcher must be 2m long" are easily recalled and expressed by users when you ask them. Observable needs are not expressed in words, but they are obvious to an observer, e.g. "The stretcher must have a handle". The so-called tacit and latent needs are the most difficult to identify: users either cannot express them in words, or they are not even aware of having such a need.

Ethnographic methods

It is only thanks to informal, gray-area behavior, that organizations – especially emergency response organisations – can function. Understanding this behavior is crucial and can be facilitated by the ethnographic methods below.

The study of **incident reports** and **ER case evaluations** straddles the border between analytic and ethnographic methods. It is obviously similar to document analysis, but due to the detailed nature of incident inquiries and case evaluations, a good amount of ethnographic information is included. As a system designer, these reports do a great job of teaching you about past failures and events, but include little detail about behaviors that have not (yet) caused an incident or are not (yet) seen as problematic. Additionally, these reports can never transmit the visceral feeling and first-hand experience of the context, which is extremely helpful for complex system designers. This feeling and experience must be acquired through one or more of the methods below.

Observation methods (Participant and Non-participant Observation) are based on observing users as they go about their work. Behavior and movement patterns, tools, and interactions among users are noticed and documented. A **non-participant observer** tries to not influence the users' actions in any way. In **participant observation**, the observer takes part in the process as a guest and can ask questions, can experience the same physical and emotional environment, can listen to the communications more closely, and can achieve a holistic understanding of the users and their context. Participant observation is good for finding out latent and tacit needs, whereas non-participant observation uncovers the observable needs. In our experience, participant observation is best when the time for research is short and there are not many opportunities to observe responders from afar. In addition, participant observation helps with creating a rapport with the responders.

Observation-based methods have two drawbacks: i) the observer's own background and emotions may influence how he/she *interprets* the observed events and ii) the results may be tightly related to the individual responder, i.e., they may be non-generalizable.

Interviews span the complete spectrum from informal and spontaneous, to formal, with a list of questions known in advance to the subject. Two techniques, semi-structured interviews and contextual inquiries, have proven to be especially useful for understanding the context of emergency response.

Semi-structured interviews are built around a list of questions drafted before the interview, based on document research, prior knowledge of the context, or standardized question sets, e.g., (DAkkS 2010). The order of the questions is not important; they are just a checklist of what not to forget to ask.

The **contextual inquiry** method is a variation of an interview that is appropriate for tacit needs, i.e., needs that cannot be verbalized. The responder is interviewed in his or her work environment, while working. The researcher or designer becomes thus an "apprentice", asking questions and learning how to do the work. The needs and behaviors that responders take for granted because of their experience, become obvious and explicit to the researcher who is struggling to learn. As a beneficial side effect, contextual inquiries help establish trust and rapport with responders, because they feel more at ease "teaching an apprentice" than being interviewed.

Interview-based methods require a skilled interviewer (Hamill 2016). Even so, interview write-ups should always be validated with the responders, so that they can correct misunderstandings. To maximize the amount of useful data, interview subjects should be carefully chosen to have as diverse fields of expertise as possible, but they should also span all levels of experience. It is counterproductive to interview, e.g. only very experienced responders, because then the needs of younger or less experienced ones would be ignored.

Affinity diagramming, sometimes known as **card sorting**, is a method in which keywords that come up during discussions, interviews, observations, and other activities are first written on post-it notes, then grouped on a whiteboard according to similarity and other relatedness criteria (see figure 3). This helps identify topics of particular importance. We have had very good results organizing affinity diagramming "workshops", where we invite several emergency responders *from various backgrounds* and let *them* group the post-its. Because of the participants' different backgrounds and viewpoints, the sorting and grouping stimulates discussions about how the topics influence their work and how they really relate to each other. This provided us with much more domain detail than we could have inferred by interviews and observations alone.

Participatory Design methods for analysing the context of use

The methods presented below *require* the participation of responders in the design and development team and help elicit expertise and ideas from the responders themselves. For further approaches, see also (Klann 2007).

A **focus group** is a discussion with a small group of participants, which centers ("focuses") on certain topics and questions of interest to the designer or developer. Focus groups have an inherent advantage over interviews, because

Figure 3. An affinity diagramming session (left) and resulting topic relations (right).

they highlight important points better. When doing an interview, the researcher may not recognize some points as important, but those same points will be obvious in a focus group: they will stimulate lively discussion, related thoughts, and experience exchanges among the participants.

Our experience using the focus group technique with emergency responders showed that it is best to a) invite responders from different backgrounds and response entities, but b) at the same level of experience and c) at the same level of "power" or hierarchy within the respective organisations. Point a, having experts from different backgrounds, ensures that the discussed topics will be new or unfamiliar to some of the participants. The needs that are tacit or latent for the "experts" of one field will be explicit – hence verbalizable – for participants from the other fields. Points b and c, having the "same power level" and "same experience level", are necessary so that participants can discuss as equals and are not shy to express their thoughts in front of higher-status peers.

Just like interviews, focus groups require a skilled moderator. The knowledge achieved from focus groups should be verified by testing a prototype or by administering questionnaires to a larger group of users. Academic literature points out that people in focus groups tend to give "socially desirable" answers and skirt around controversial topics, but we have found emergency responders to be immune to this problem. It is, after all, part of their job to take the right action, even when it is not socially desirable or comfortable.

Sandbox sessions are discussions where participants use play figures and toys to explain their part, role, or view of a complex activity (see figure 4). This method provides a way to access users' knowledge independently of verbal or memory skills, which other methods require. Sandbox sessions are particularly useful with emergency responders, because the latter are familiar with using play figures to plan exercises.

Figure 4. Toys and play figures used in a sandbox session.

Requirements specification

While we have successfully used both "The Working Model for Usability Engineering" (ProContext Consulting GmbH 2003) and "The Volere template" (Robertson and Robertson 2018) to distill requirements from the context

analysis, we find that the exact process of extracting requirements is not as important as doing the context analysis correctly in the first place. Furthermore, our experience with different development teams has shown that each team has its own, often deeply ingrained and formalized methods for requirements engineering. As long as those methods are correct, we see little advantage in switching to another method; the cost and delays from the changeover often offset the benefits.

That said, user requirements in UCD subtly differ from traditional, system-centered requirements. UCD user requirements do not describe how the system will be implemented (e.g. "The system must have a textbox for the username"), but what the user must be able to do at the system when it is implemented (e.g. "At the system the user must be able to input his identity"). The distinction is powerful: whereas system-centered requirements define one single solution (the textbox), user-centered requirements define the outcome but allow for multiple solution possibilities (textbox, voice, fingerprint, etc.). We have found that the "Working Model" from (ProContext Consulting GmbH 2003), despite a steeper learning curve at the beginning, does a better job of forcing the designer to think in user-requirement terms and to see things from the user's point of view. The model, therefore, makes visible many more design opportunities that would otherwise be missed.

Methods for prototyping

Prototyping is required by the UCD process, and is, in our view, indispensable when designing tools for emergency response.

Scenarios are the simplest prototypes: a high-level, textual description of how a proposed tool can be used to fulfill a certain task. **Storyboards** do the same job as scenarios, but are presented as a drawn comic strip. They encourage visual thinking and can present spatial and physical-size relationships much better, e.g. the size or handling of the tool or system. Both methods invite critique and feedback from users and help understand domain requirements better. We have successfully used both scenarios and storyboards in our work with emergency responders, but we found these techniques to be most useful in the first iterations of the process, for presenting initial ideas. For later iterations we found that observation, focus groups, and contextual inquiry worked much better.

Interface sketches, **wireframes**, and **physical prototypes** make ideas concrete and graspable, both physically and figuratively speaking. They set a baseline for discussion between users and developers, they help train users, and, when created via participatory design, they make users accept and advertise the system to their peers instead of opposing it. Prototypes can (and should) be created at various levels of fidelity, from simple sketches on paper, to mock-ups of interfaces and devices with simple materials, to partially-implemented IT systems. The level of fidelity depends on the phase of development (earlier = lower fidelity) and on the questions for which developers need answers (rough estimates = lower fidelity; detailed questions and interactions = higher fidelity).

It is crucial to see the prototype as a throw-away item; the only features implemented in the prototype should be the ones necessary for getting an answer to specific questions about the domain and user needs. The prototype should look unfinished, cheap, temporary, and open to criticism; if it "looks finished" or "looks too good", users will withhold negative feedback in order to "be nice to the designer".

Methods for evaluation

The **Scenario Walkthrough** method is the cheapest, easiest method to evaluate the design of a tool or system. It consists in having one or two domain experts enact a typical task with the tool and noting difficulties or inconsistencies. The evaluation is usually done in a lab or office, not necessarily in the real environment where the system will be used. It is crucial that the experts have extensive and practical knowledge of the emergency response domain, because nobody else can put themselves in the responders' shoes.

Prototype workstations are stands in a simulated "fair", where all the developed prototypes are shown and "pitched" to small, multidisciplinary groups of domain experts and users (see figure 5). The experts give feedback and critique the proposed system, pointing out both positive features to be kept and problems to be solved. The "prototype workstations" method is more intensive than simple scenario walkthroughs, but it delivers much more feedback and can point out many more problems, thanks to its multidisciplinary approach.

As reported in (ISO9241) and (Simon 1962), the complex behavior and problems of a system do not stem from any single part in isolation, but from the interplay between the parts: users, tools, tasks, and the environment. By the above reasoning, to properly test a new tool or IT system for emergency response, the *actual users* must *use* the tool in the *actual context* to do their *actual job*. This is called **user testing under realistic conditions** and is the single most important of all evaluation methods used when designing for emergency response. Unlike business systems, which can be tested in a lab, testing emergency response tools in a lab is worthless. The pain, suffering, destruction,

Figure 5. A "Prototype workstations" session.

and chaos that one typically finds in a crisis area create heightened levels of stress that alter the responder's behavior or his/her mental ability, so that test results gathered in the lab are not transferrable to the actual incident field.

As a staple method of usability research, **user testing with thinking aloud** is distinguished by having users verbalize their thoughts *while* working with the tool or system. This allows the researcher to notice discrepancies between the user's mental model (i.e. the user's expectations) and the actual implementation. The method is not appropriate in task-loaded environments, or when the user is hurrying, because the user's behavior, speed, and actions are influenced or slowed down by having to think aloud. Such environments, which include the front lines of emergency response, benefit most from **silent, non-participatory observation**, combined with a **retrospective review**. The latter is just an interview: After having observed the responder work with the new tool or IT system, the researcher asks questions to clarify what was going on at certain notable points during the observation, esp. if the user seemed to have problems with the tool.

As a final note on evaluation, it is tempting to test prototypes only with the responders that are part of the design team (assuming participatory design). This kind of testing is indeed cheaper, but is guaranteed to give wrong results, because those responders know the prototype too well. For this reason, testing is always done with responders from outside the development team.

CONCLUSION

While there is no doubt that IT can revolutionize emergency response, practitioners have made it clear that IT tools and systems being offered to emergency responders are not satisfactory and helpful enough to be widely accepted. Existing research, too, has confirmed that the causes of rejection lie with the IT systems themselves (Paul et al. 2008; Orthner et al. 2005; Adler et al. 2012; Ammenwerth et al. 2006; Elmasllari and Reiners 2017; Elmasllari 2018b). The present paper posits that the root of the problem lies in the wrong or insufficient context and requirements analysis. This, in turn, stems from using development methodologies that are not suitable for the emergency response domain.

As a special characteristic of emergency response, we argued that the response effort is a complex, adaptive, socio-technical system. A reductionist, top-down mindset and system architecture, as is typical from common IT engineering, is counterproductive for this domain. A holistic approach which takes both social and technical parts of the system into account was argued to be necessary.

This paper presented two such holistic approaches, which we have successfully used in designing for emergency response and other complex systems. A variety of concrete methods and techniques were also presented together with their drawbacks, our critique on them, and our experience on when and how they could be best used. Far from being a detailed tutorial on any particular technique, this paper positions itself as a high-level analysis of the how, when, why, and what approaches and methods to use when designing IT systems for emergency response.

ACKNOWLEDGEMENTS

Structured crisis training with mixed-reality simulations

ABSTRACT

We argue that current technology for crisis training does not explicitly cater well enough for managing training objectives and skill building metrics throughout the lifespan of training. We suggest how successful crisis training may be enabled by interoperating next-generation exercise management tools with mixed-reality simulations. We propose an architecture consisting of (1) a front-end in which training objectives, essential skills, corresponding events and metrics can be declared, (2) a back-end consisting of simulations that implement the events and metrics and (3) a middleware which transfers information between the front-end and back-end to enable semi-automatic composition of the simulations and performance analysis. The purpose of this architecture is to facilitate learning through the principles of deliberate practice. We indicate where emerging technologies are necessary to achieve this.

Keywords

Exercise management, Mixed reality, Simulation, Deliberate practice, ADL, MSaaS, C2Sim, ExConSim, ExManSim

INTRODUCTION

Civilian and military crisis management organizations regularly conduct training and large-scale exercises. For example, over 50,000 participants, 250 aircraft and 65 vessels from more than 30 nations recently partook in NATO's Trident Juncture 18 exercise. More than 300,000 soldiers, 36,000 military vehicles, 1000 aircraft, helicopters and drones, and 80 warships from three nations joined the Vostok-2018 in Eastern Siberia. On the civilian side, most large cities regularly conduct city- or region-wide exercises that involve fire, law enforcement and healthcare organizations over the course of several days.

Although often deemed highly successful, such exercises are also extremely costly and often infringe on society in unacceptable ways. Moreover, although there is a lack of systematic observations as to the effects of exercises, discussions with subject matter experts, trainers and observers suggest clearly that exercises often do not have clear and structured training objectives, that lessons identified are recorded in an *ad hoc* manner, and that lessons identified are often not transformed into lessons learned. These are unfortunate shortcomings to the demands that heightened levels of readiness pose in today's global situation.

The use of simulations for training and exercises has been investigated over several decades by industry, academia and practitioners. Indeed, simulations are an integral part of many training and exercise regimes in both the civilian and military domains. Well-known examples are flight simulators and various vehicle and equipment simulators for safe operator training. Moreover, planning, coordination, collaboration and decision-making protocols are trained using various computer-aided simulations. This happens in dedicated training events, but is also done in conjunction with large-scale exercises such as those mentioned above. Trainers use exercise control (ExCon) systems to administer events and injects in a timely manner. Simulations are perceived to save time, cost and increase quality for training and enable training not possible otherwise (NATO Modelling and Simulation Group 2012; NATO Research and Technology Organization 2010; Hannay, Brathen, et al. 2015).

In all this extensive exercise and training activity, there is an explicit tool focus on *what* should happen in exercise and training scenarios. The explicit mention of *why* is not prevalent; that is, the skills underlying task performance – the actual target of training – are not addressed to the same extent in exercise management tools.

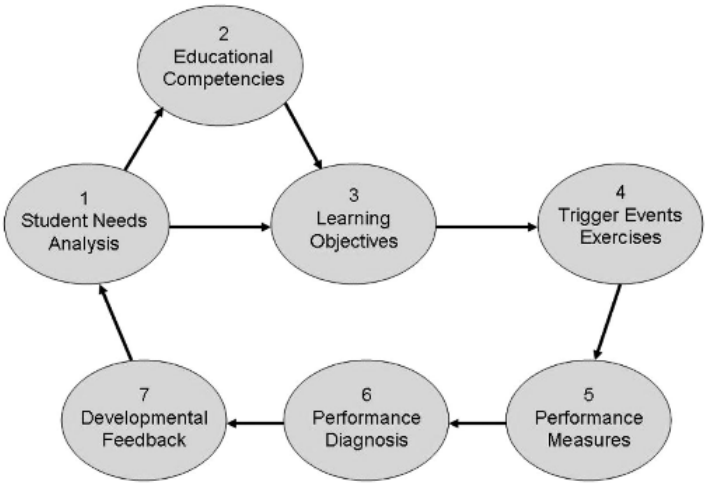

Figure 1. Simulation-based training loop (Salas et al. 2009)

THE INTENT IN SIMULATION-BASED TRAINING

The, by now, hackneyed simulation-based training loop diagram due to (Salas et al. 2009) proposes how simulation-based training should be an incremental and reflective process, rooted on learning objectives.

Anecdotal evidence suggests that this loop in many cases is broken. A governmental Emergency Planning College recently summarized participants' perceptions of exercises (which are so-called *Live* simulations) as follows; see also (Pollestad and Steinnes 2012):

- Exercises have little effect
  - Continuity:
    - Exercises are conducted in isolation and without any connection to earlier exercises
    - Experiences from one person or group are not used by others
    - Lessons identified are not processed further to lessons learned
  - Objectives
    - Exercise objectives are not formulated clearly
    - Objectives are not differentiated on roles
- Exercises are scary
  - Exercises are given as tests or "exams", rather than as a means for improving performance
  - Challenges are given that participants do not have the means to master
- Exercises are time-consuming and demand excessive resources
  - Exercises are something one does not really have time, nor resources, to conduct
  - The benefit of conducting an exercise does not justify the cost.
- Exercises are difficult
  - Exercises are difficult to plan and organize
  - Exercise objectives, events and scenarios are difficult to define
  - Exercise results are hard to grasp

These anti-patterns for learning in large exercises are also found in day-to-day training. Most simulators and simulations are capable of recording a lot of relevant data. We are aware of a number of instances where such data are not used at all; seemingly because there are neither routines for collecting data, nor tools at hand to analyse data. Also, clear learning objectives are a prerequisite to determine what data to collect. Further, the notion of continuity with the possibility to compare training results over time is often not rooted in the organization. Lessons are identified, but there are insufficient mechanisms for transforming those into lessons learned and integrating them into the daily work (Skarpaas and Kristiansen 2010).

In the following, we argue by design that current technology in use does not give enough support for keeping the simulation-based training loop alive.

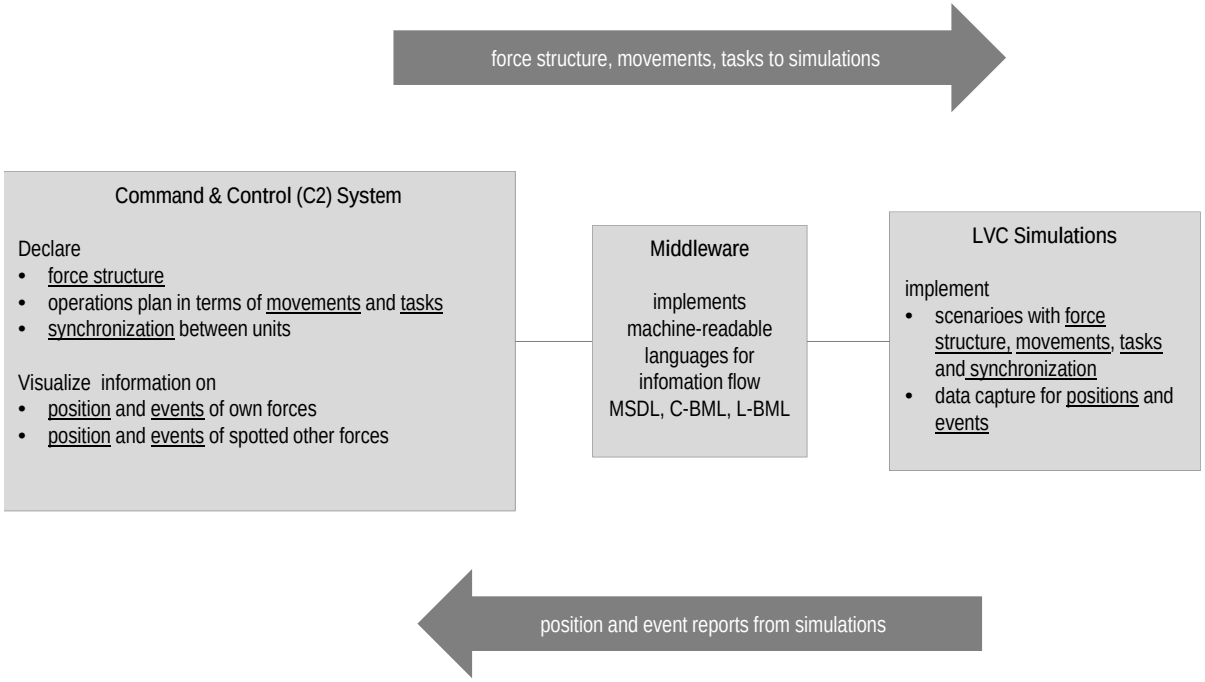

Figure 2. C2Sim configuration

COMMAND & CONTROL WITH SIMULATIONS

Command and control (C2) information systems (C2IS) are used for planning, commanding and monitoring military operations, usually in a geographical map-based user interface. There are similar systems for the civilian sector. In the defence domain, substantial effort is being laid down to enable C2IS to interoperate with simulations (Simulation Interoperability Standards Organization 2014b; Tolk 2012a; Tolk 2012b). The purpose of this is that personnel can use their normal working tools when participating in simulation-based training. Thus, machine-readable languages have been developed, so that force structures, unit movements and task that are specified in the C2IS can be automatically sent via these languages to a simulation, where the planned operation can be simulated. C2IS also receive position and event updates from the simulation, and can render these to users on the C2IS map; see Figure 2. In particular, the Military Scenario Definition Language (MSDL) (Simulation Interoperability Standards Organization 2008) is a standard for describing force structures and their initial positions, the Coalition Battle Management Language (C-BML) (Simulation Interoperability Standards Organization 2014a) is a formalized language for expressing a commander's plans, orders and reports across C2IS, simulation systems and autonomous systems, and Low-level BML (L-BML) (Alstad and Mevassvik 2013) is a language to specify more detailed movements and tasks to simulation entities from a break-down of C-BML orders (Løvlid et al. 2018). A number of system demonstrators have been developed to explore the concept; e.g., (Pullen et al. 2012; Allen and Schroeder 2011; Coolahan and Allen 2011; Bruvoll et al. 2015).

Efforts toward further interoperability between C2IS and simulation systems are consolidated in a C2Sim initiative (Simulation Interoperability Standards Organization 2014b; Heffner et al. 2014), now also involving ontologies for enhanced conceptual expressiveness at the machine level (Singapogu et al. 2016). These efforts build on earlier work based on large data models such as the Joint Consultation, Command and Control Information Exchange Data Model (JC3IEDM) (NATO standard STANAG 5525) and its successor, the Multilateral Interoperability Program Information Model (MIM) (Gerz and Bau 2016) that specify the minimum set of data that needs to be exchanged in coalition or multinational operations.

All this makes it possible to achieve interoperability between C2IS and simulation systems. As is evident from the above, there is a substantial focus on being able to represent entities and tasks accurately in the military domains. However, even though the initial motivation for all this was training, there is no explicit mention of training objectives, what skills to be trained or skill performance metrics. Indeed, besides interoperability between C2IS and simulations, C2Sim languages are now also designed for connecting C2IS themselves and for controlling and monitoring unmanned vehicles from C2IS.

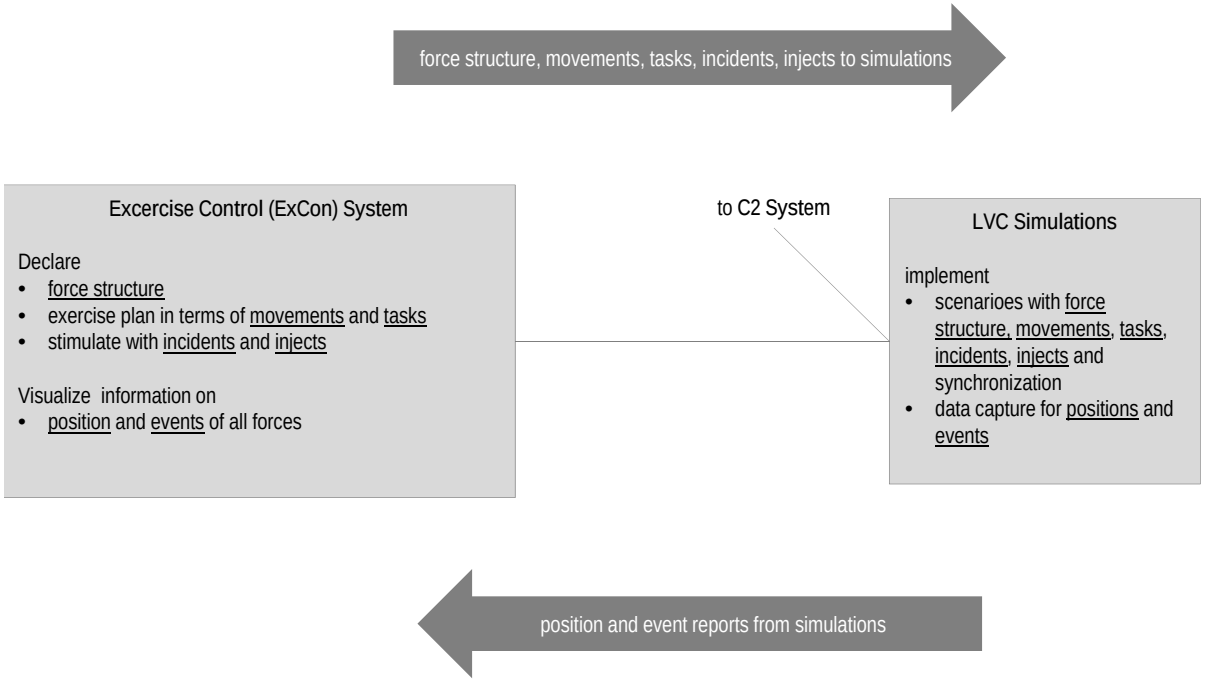

Figure 3. ExConSim configuration

EXERCISE CONTROL WITH SIMULATIONS

Of course, the C2Sim initiatives above are extremely important. Simulations have to be sufficiently detailed and accurate to be of any value to training. Usually, trainer staff have their own consoles in which they control and monitor exercises and training using an exercise control (ExCon) system integrated with simulations (ExConSim); see Figure 3. These are often direct front-ends to simulations, but can also be third-party products designed to administrate training simulations. Thus, while trainees in the C2Sim configuration above participate in a simulation via their C2IS, trainers monitor and control the simulation via the ExCon system.Trainers can stimulate training with incidents and injects, but ExCon systems usually do not have functionality to define training objectives or any higher-level functionality to support, say, learning principles. They usually have functionality to record entity positions and events and can thus present reviews based on this data.

EXERCISE MANAGEMENT WITH SIMULATIONS

Beyond C2Sim and ExConSim, there is a need for a more explicit approach to support the simulation-based training loop and to alleviate the problems that seem to be integral to crisis training. We now outline an architecture which, by design, addresses the shortcomings in the preceding architectures. Figure 4 presents this architecture; where an exercise management tool interoperates with mixed-reality simulations. The architecture consists of three main components: A front-end, a back-end and a middleware component.

Front-end

The front-end consists of a user-facing system (a web application for easy access on portable devices) that allows exercise management staff

- to declare training objectives,
- to select which essential skills to be trained to reach those objectives,
- to select events to stimulate development of those essential skills,
- to select corresponding metrics for measuring essential skill performance in the events and
- to compose vignettes and scenarios from the selected events.

This design promotes the idea of composing exercise and training scenarios and vignettes (sub-scenarios) from a selection of predefined events that are designed to stimulate given essential skills. The events have associated skill metrics. Scenario composition can range from manual (Simulation Interoperability Standards Organization 2018) through semi-automatic to automatic; e.g., (Martin et al. 2009) or (Zook et al. 2012) who describe a method for

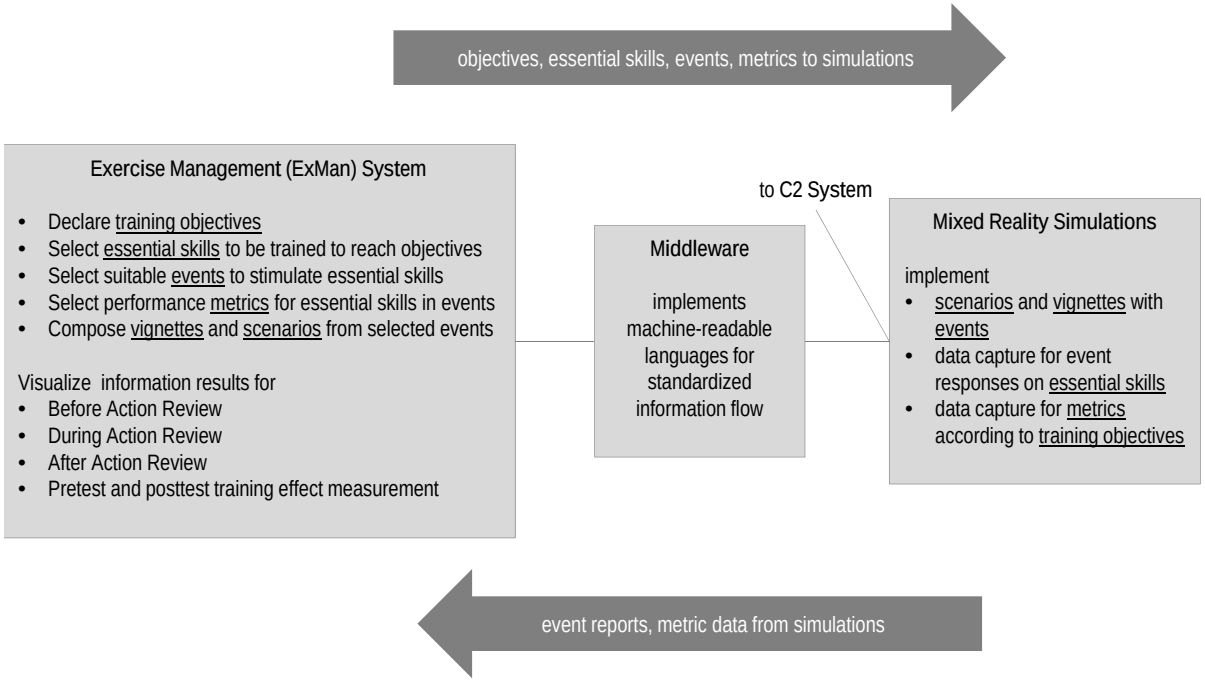

Figure 4. ExManSim configuration

generating scenarios using combinatorial optimization: An algorithm constructs a scenario by choosing events and determines the appropriateness of the scenario using a fit function over training objectives. Events may be designated as *mandatory* or *preferred*, giving degrees of variety in the generated scenarios.

When events and their associated skill metrics are combined, a new combined event and combined metric is generated. Also a skill may have varying metrics according to roles and combination of roles. How this should be done in the face of combinatorial explosion and validity is a topic currently under investigation. Another topic under investigation is how an essential skill as a generic construct; e.g., acquiring shared situation awareness, should be instantiated in a range of domain-specific events, with some sort of reuse of the concept and associated metrics in the various domains.

The front-end also allows exercise management to visualize information for use in

- Before-action review (BAR); in which a training session or an exercise can be pre-run in a simulation for validation of the consistency and coherency between objectives, skills, events and metrics.
- During-action review (DAR); in which identified learning and performance issues can be addressed immediately during training and exercise in simulations, thereby giving trainees direct feedback.
- After-action review (AAR); in which learning and performance issues can be analyzed and addressed in after action simulations; thereby turning identified lessons identified into lessons learned immediately after training or an exercise.
- Pretest and posttest effect measurement; in which essential skill performance can be measured in controlled simulations before and after training and exercises for measuring the effect of training and exercise.

The purpose of these functions is to support *deliberate practice* (Ericsson 2006); a framework that addresses the short-comings of "learning on the job", by a strong focus on difficult aspects, immediate and tailored feedback (by a coach or computer-adaptive system), followed by tailored re-trials integrated into the larger sequence of tasks.

Further, it is common to emphasise the importance of training on realistic tasks in a realistic environment. However, research has shown that training that simply reflects actual circumstances is not sufficient (Shadrick and Lussier 2009). Using artificial, rather than realistic, elements in training is common in other domains. For example, an athlete will not spend all her training time practising the exact sequence of actions she will perform during competition, but will spend considerable time on specific training of muscle groups, on mental preparation, and even on other sport disciplines. A musician will repeatedly focus on difficult passages, thus engaging in artificial behaviour compared to an actual performance, while still using his actual instrument.

For tactical decision making, normal realistic training is, in general, insufficient, because it does not target the development of decision-making skills (Shadrick and Lussier 2009). Judgement and decision tasks are often

so-called inconsistent (different people develop differing successful strategies) (Campbell et al. 1993; Campbell 1990) or ill-defined (hard even to define successful strategies) (Johnson 1988; Simon 1973; Reitman 1965; Voss and Post 1988). Research shows that practitioners on inconsistent and ill-defined tasks may spend half their careers apparently *not* learning and *not* improving performance beyond, perhaps, a very narrow subset of (consistent) tasks. Instead, the idea is to train adaptability; i.e., how to adapt to unknown and surprising situations. In line with this, the notion of *adaptive thinking* has been adopted in the defence domain for tactical decision making (Shadrick, Lussier, and Hinkle 2005; Shadrick and Lussier 2009) based on a concept of adaptive job performance (Pulakos et al. 2000).

Thus, it may be necessary to engage in artificially enhanced tasks to heighten performance. Such tasks are the result of *task analyses* and depend on the actual task at hand. Particularly relevant for judgement and decision-making tasks, *cognitive task analysis* uncovers a range of unconscious processes as well as how decision-makers of varying degrees of proficiency think (Mussweiler 2003; Gigerenzer and Todd 1999; Klein 1997; Kahneman and Frederick 2004). The ExManSim architecture has a focus on events targeted at essential skills, and the idea is that training and exercises can be explicitly planned with events containing such artificially enhanced tasks when appropriate.

Back-end

The back-end consists of mixed-reality simulations. Simulations are often divided into *Live*, *Virtual* and *Constructive*. *Live* simulation has live personnel using real equipment, but where, e.g., live ammunition is replaced by laser pulses and detectors; all networked to combine event and positional data for a comprehensive digitized view of events. *Virtual* simulation has live personnel in a virtual environment (e.g., flight simulators and vehicle manoeuvre in gaming), and *Constructive* simulation has totally computer-simulated entities. Combining the three modes in so-called LVC simulation in a distributed system is assumed to increase training capabilities and training effect. Using appropriate standards such as the High Level Architecture (HLA) (IEEE Standards Association 2010) or the Distributed Interactive Simulation (DIS) standard (IEEE Standards Association 2015), all entities and movements in the combined simulation can be seen in the various *Virtual* and *Constructive* simulations (Hannay, Mevassvik, et al. 2014). *Live* players can see simulated entities in their C2IS (using C2Sim) (Hannay, Mevassvik, et al. 2014), and when equipped with augmented reality technology, may also see and interact with simulated entities in their field of view. This combination of LVC simulation modes with player interaction in all three modes constitutes *mixed reality* simulation.

In addition to the the general benefit/cost arguments in favour of simulation-based training, simulation is essential for conducting artificial tasks and deliberate practice regimes. Moreover, mixed reality simulations are necessary when crisis response personnel need to train in simulations with their regular working equipment. Personnel training for road tunnel fires would not enter a burning tunnel in real life but would train in a virtual simulation. Virtual reality headsets may be used for better immersion, but to enable trainees to use their normal equipment such as radios, firefighting equipment, first aid equipment, etc., they would rather use augmented reality headsets, so that they can see and interact with their real surroundings and tools and interact with the virtual simulation at the same time.

Once a scenario has been composed in the front-end, the simulations for running the scenario must be composed quickly and accurately. Today, it typically takes months or even years to develop simulations; see e.g., (Edgren 2012). This is a serious disabler for generating simulations that match differing training objectives and skills to be stimulated though appropriate events in a flexible manner. Initiatives on *Modelling and Simulation as a Service* (MSaaS) work toward setting up simulations for operations and training readily and rapidly (Hannay and van den Berg 2017; van den Berg et al. 2017; Asprusten and Hannay 2018) from simulation services. The *service* concept embodies reusability by standardization of common functionality, and composability through loose coupling and standardized service descriptions. Thus, events can be reflected by simulation services at the back-end. Then, composing events to vignettes and scenarios on the operational level in the front-end map to composing simulation services to composed simulations at the back-end.

Metrics selected in the front-end must also be implemented as data collectors and/or measurements in simulations. For example, (Cornell et al. 2007) describe an automated process for measuring human performance. A performance measurement pipeline is developed to assess human performance in virtual training, so that raw simulation output data is transformed to give meaningful event assessments. Using this, C2Sim data, say, may be transformed to event metric information in the ExManSim setup.

Middleware

The middleware component handles information flow between the exercise management system (front-end) and the simulations (back-end). As for the C2Sim configuration, machine readable languages must handle this.

ExManSim requires a language that can express not only what to do, as MSDL and C-BML do, but also for what objectives and for what training effect one is doing those things. This requires additional language structures. An immediate thought is to combine C-BML with Experience API (xAPI); a language from the Advanced Distributed Learning (ADL) initiative (Fletcher et al. 2007) that is used to collect experiences online and offline in a structured and standardized way. This combination might be used to track a trainee's learning when using a simulation system to reach certain training objectives, since xAPI has structures to store information and results about an activity. This means one can define criteria on when performance in an event is considered successful, and one can define more advanced scoring algorithms based on that. For further pointers, see (Durlach 2018).

Example

To illustrate how the ExManSim architecture is intended to function, consider the domain of *fire crisis management*. Recent fire incidents in road tunnels give rise to a training objective "Improve communication and collaboration between first responders at the scene of road tunnel fires". One essential skill (among several others) in crisis management is *acquiring shared situation awareness* (SSA), which is the overlap in situation awareness (SA) between members of a team (Nofi 2000).

Situational awareness is defined in (Endsley 2000) as "...the perception of the elements in the environment within a volume of time and space, the comprehension of their meaning, and the projection of their status in the near future." Hence, this definition can be split out in three levels (Valaker et al. 2018):

1. the position of all entities in an area of interest, regardless of their identity
2. in addition to the above, the relationships between the entities
3. in addition to the above, the possible future configurations of the entities and relationships

To stimulate the development of this essential skill in this particular domain, one conceivable event would be a collision in a road tunnel and subsequent fire with human casualties. This event requires personnel in different roles collaborating to respond to the event: Firefighters must extinguish the fire, health personnel must treat the injured and police must secure the scene. SA, and especially SSA, is crucial to execute the required tasks successfully and to create a safe working environment for all personnel. To acquire SSA, the trainees must first be aware of the relevant entities and their relevant relationships (car fire close to flammable tunnel lining) and what resources can be drawn from the other roles (SA Levels 1 and 2). Then, the trainees must understand how the situation might evolve; for example, if there is a danger of a second fire and if further civilians may become at risk (SA Level 3).

For this example, an exercise manager would use the front-end to select the domain of "fire crisis management" and declare the objective "improve communication and collaboration between first responders at the scene of road tunnel fires". The front-end then allows the exercise manager to select "acquire SSA" (and other skills that the ExManSim system supports) from a list of essential skills to be trained in that domain. For each selected essential skill, the front-end then presents a list of events (for example the "car collision event") supported by the ExManSim system. Each event has associated metrics for measuring skill performance. For "acquiring SSA", appropriate metrics would be sorted under the three categories above. To make an evolving scenario, subsequent events may be selected as well; e.g., "secondary fire in flammable material on tunnel wall".

Acquiring SSA involves several roles acting on the same events. For an impression of some of the complexity in composing metrics when combining roles even in a single event, consider again SSA: To acquire SSA, the team members must share and enquire each others individual situation awareness (ISA).

Figure 5 shows this schematically, suggesting that there are different SSA configurations depending on the number of personnel and roles involved. For example, *X123* in this example consists of the information that is available to

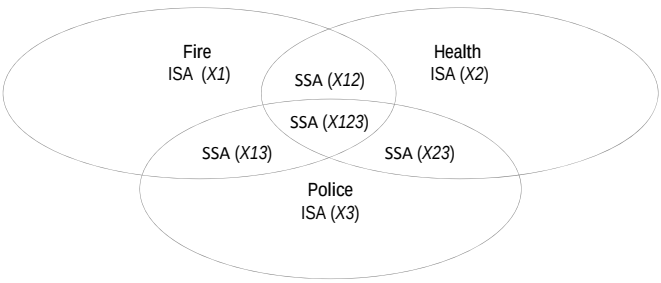

Figure 5. Schematic visualization of individual situation awareness (ISA) and shared situation awareness (SSA)

all personnel. One might think that the more information that is shared, the better. However, interviews with subject matter experts suggests otherwise: It is often the case that personnel receive too much information, resulting in lower performance. Hence, trainees should train to achieve *effective* SSA; that is, the amount and type of SSA that results in higher task performance.

Effective SSA depends on the role of a person. A task force leader may need a more extensive SSA than personnel with a more individual role. When composing SA-dedicated events into vignettes and scenarios in the front-end, effective SSA must be expressed in the combined skill metrics that result when composing those events.

At the back-end, a virtual simulation might be composed by a simulation service implementing the car collision event and a simulation service implementing the tunnel wall fire. Separate metrics services composed to measure effective SSA for each intended trainee role may be composed into the simulation. Trainees may use virtual or augmented reality equipment, or other media, depending on the need to interact with real equipment.

For information flow between the exercise management tool and the simulation, the scenario composed of the events and metrics would be transmitted in a machine-readable language to the back-end, where a simulation composer may semi-automatically compose the simulation from simulation services and metrics services. SSA skill metric information would flow back to the front-end for presentation in the various action reviews.

CONCLUSION

There is a strong focus on accurate representation of entities and events, and a paradoxical lack of focus on structures and standards that explicitly address training and learning, in architectures for simulation-based training. We propose the need for an architecture for exercise management and simulations (ExManSim). This architecture is designed to take on the challenges faced in simulation-supported exercises and training, so that the intents of simulation-based training may be realized. The architecture relies on emerging technologies within machine-readable semantic representations of events at the model level, and associated simulation services at the implementation level.

The architecture is proposed based on arguments of design. Current research is refining this architecture in collaboration with stakeholders from a range of crisis management organizations and industry. A working prototype for some of the functionality in the architecture is planned to be released in increments in the near future.

ABSTRACT

For successful firefighting, information is key. In this work, a general overview of the current challenges and trends of data management for firefighting in Germany and the Netherlands are examined. This was accomplished by conducting a literature review to find out the current state-of-the-art in research. The results of the literature review are then compared with expert sentiments and gaps between research and practice are revealed. Through the review, six challenge categories are identified: cartographic data harmonization, IS standardization, information gathering from unstructured data, canonical bodies of knowledge, and data-driven firefighting support. The challenges and trends are discussed in the context of Germany and the Netherlands and significant differences are presented. Lastly, the gaps between research and practice are thoroughly analyzed and potentials for future work revealed.

Keywords

Data management, challenges, trends, firefighting

INTRODUCTION

To understand how data management can facilitate successful work practices in the domain of firefighting we must look beyond the for-profit context (Walton et al. 2016 p. 85). The National Institute of Standards and Technology (NIST) released a research roadmap in 2015 which also addresses data management during an emergency event (Grant et al. 2015). In the roadmap, it is concluded that "[t]here are several factors which affect the ability of individual jurisdictions to address the delivery of actionable data to first responders during an event" (Siebert and Venkatasubramanian 2015 p. 139). Additionally, periodicals and research have mainly focused on very specific problems and "literature is significantly limited" (Siebert and Venkatasubramanian 2015 p. 140). Considering these aspects, there is a lack of general overview on how data is managed during a firefighting operation and on what trends and challenges emerged in the past years. It is also unclear, how different jurisdictions adapt to data management innovations. Two countries that adapt very differently to advances in the firefighting sector are Germany and the Netherlands. Germany has problems with adapting innovation (Weidinger et al. 2018 p. 688), especially in rural areas (Müller 2009 p. 81), while the Netherlands have many factors that stimulate high innovation (Nijenhuis and Borninkhof 2015 p. 23). In this article, the current challenges and trends of data management for firefighting in Germany and the Netherlands should be examined (research objective).

To accomplish this overall research objective, the following three sub-objectives have been achieved:

(1) A database and keyword literature search were conducted to identify current pivotal challenges and trends in firefighting which can differ from those that are occurring in practice.
(2) To see how these trends and challenges are adopted in the Netherlands and Germany or whether there are even new trends and challenges in practice, two additional interviews were held with firefighting experts from Germany and the Netherlands.
(3) The literature research was then subjected to a "reality check". The results of the expert interviews

(i.e. the local challenges and trends) were contrasted with the general results from the literature search. Through that, it should be made apparent what trends are popular in the literature but have not made the transition to practice yet and what challenges are currently the focus in each country respectively.

METHODOLOGY

Methodologically, this work is structured in two parts. To identify current trends and challenges, a systematic literature review was carried out. Then, the results of the literature review were juxtaposed with the situation in Germany and the Netherlands by means of expert interviews.

The literature research was based on the systematic literature review process of VOM BROCKE ET AL. (2009). First, a database search was carried out within the Scopus database. Scopus is the biggest database of peer-reviewed titles. To search for literature, the database was first queried with the keyword term *ALL (fire AND fighting AND (trend OR challenge) AND data AND management AND (germany OR netherlands))*. To be able to create an overview of modern challenges and trends, only sources which have been published from 2016 to 2018 were considered initially. The 270 resulting articles (initial hits) were checked for relevance by title evaluation and all but 34 articles were discarded, because they were deemed irrelevant (e.g. medicine, arts etc.). A subsequent abstract evaluation led to 13 relevant hits which were thoroughly analyzed by a full text review. Lastly, the literature research was supported by an internet search of relevant online sources. This was especially crucial for examining what the current state of these trends is, as they were often rapidly changing or were discontinued (e.g. Twitcident: http://www.wis.ewi.tudelft.nl/twitcident/).

The general trends and challenges which have been identified in the literature research were then compared to their local counterparts in Germany and the Netherlands. To do that, two 30- to 45-minute-long interviews were conducted with local experts from the respective country. The interviews were carried out in four steps (Flick 2002 p. 294f.): 1) The interviewer obtained general knowledge of the topic and phrased appropriate questions. 2) The interviewer contacted the appropriate interviewee with the topic. 3) The interview was conducted and recorded. 4) The interview recordings were analyzed, generalized and compared with the results from the literature.

The German expert is head of a department in a big federal firefighting institute and thus a specialist on German firefighting. The department is responsible for crisis management and research and the expert has deep research knowledge, as well as extensive field experience.

The Dutch expert is a firefighter and a CEO of an enterprise that offers data solutions for fire services. He also holds a guest research position at a university in the Netherlands with the research topics emergency response and knowledge management.

THEORETICAL BACKGROUND

To get an understanding on how firefighting works in general and how Germany and the Netherlands operate on a national and local level, some basic processes are introduced to the reader.

Firefighting and Data Management Need

To fight fires a firefighting operation is generally divided into four steps:

(1) Prevention

(2) Preparation

(3) Fire response management

(4) Recovery

This work focuses on the response phase of a firefighting operation (i.e. fire response management).

Due to the complex nature of firefighting, the operators must collect and manage a lot of data throughout these steps. These data can be structured in a lot of different formats (e.g. climate data, time series data, geographic data, textual data). Often the format is proprietary to its private or public organization (Zlatanova et al. 2010). This causes problems when data needs to be harmonized or shared across organizations.

Firefighting in Germany

Who is responsible for firefighting and emergency situations in Germany is organized very differently depending on the local jurisdiction. Responsibility for firefighting is delegated from the state to the cities and counties and thus firefighting institutions are independent from each other and very heterogeneous. Thus, small fires are fought by autonomous fire departments and fires who span multiple regions and cause a lot of damage are fought through a staff organization consisting of multiple local authorities. This tactical-operational staff organization is generally defined in the FwDV 100 ("Feuerwehr-Dienstvorschrift 100") which has been established in Germany in 1999 (Lamers 2016 p. 84). It is important to note that this regulation is not legally binding on a national scale and it is up to the federal states to adapt it in their laws. The defined management staff organization comprises a leader who supervises the staff that is divided into six different areas and additional external consultants (Figure 1). The areas are human resources (S1), location (S2), mission (S3), supply (S4), public relations (S5) and information and communication (S6) (Lamers 2016 p. 85f.).

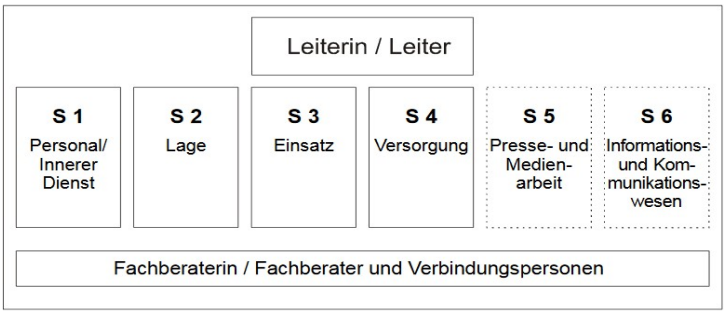

Figure 1. Management staff defined by FwDV 100

Between these specialist areas exists a need for the exchange of information and data, so that they can work together as effective and efficient as possible. LAMERS (2016 p. 88) identified four edges between the different areas, where a close collaboration - and thus a heavy data exchange - is necessary:

(1) S3 and S2 for mission judgment.
(2) S1 and S3 for the reorder of human resources.
(3) S1 and S3 for the management of emergency staging areas.
(4) S4 and S1 for the resupply mission.

Firefighting in the Netherlands

Firefighting in the Netherlands is organized completely different to Germany. The Dutch fire service is a centralized syndicate of all fire brigades of the nation. The brigades are all subordinate to a board of fire chiefs ("Raad van Brandweercommandanten"). In total, the board comprises 25 fire chiefs, one for each safety region ("Veiligheidsregio's") of the Netherlands (Boersma et al. 2012 p. 13). The board has an executive committee, one chairman and six program heads. The program heads are responsible for the following six areas of the national fire service program ("Landelijk Programma Brandweerzorg"):

(1) Risk control and fire-safe living.
(2) Incident control.
(3) Skills and knowledge.
(4) Crisis management.
(5) Information management.
(6) People and business operations.

As many topics are important for each fire department (response times, wide-spread fires in nature or general business management), they are dealt with at a national level. Of course, regional differences are considered (Brandweer Nederland 2015). Work of the programs is carried out in networks and research groups consisting of firefighters under supervision of the central office of the Netherlands Fire Service. Due to this centralized government mode, all safety regions have adopted the so-called netcentric method when working together. This method enables standardized communication between the different partners (Instituut Fysieke Veiligheid 2018). It becomes obvious that the centralized Dutch organization of the fire service is in stark contrast with the federal, decentralized German fire service.

RESULTS

The majority of the results were not exclusive to Germany and the Netherlands. Because of that, the results of the literature are juxtaposed with the results of the expert interviews, which in turn are restrictively focused on the local situation.

Current Challenges

GRASSO ET AL. (2018 p. 625) name "trans-boundary cartographic data harmonization and management for environmental protection and common policies" as big challenges in firefighting operations. The lack of cartographic data is especially critical for widespread fires and access to geographic data is often only possible by accessing different interfaces and thus data of different formats. Because there are different cartographic platforms, so-called geographic information systems (GIS), they are often hard to access in a standardized way, due to their different meta data. Also, integrated into an emergency response system, they often tend to focus only on specific and few parts of the firefighting operation steps, such as command and control (response) or simulation (preparedness).

In city scale scenarios, fires more often occur at places that are more populated (Song et al. 2017 p. 834). Experts are lacking a tool to accurately predict fires, because the explanatory variables that facilitate fires (such as average ground temperature, humidity, etc.) are not collected. This is due to three challenges: 1) the explanatory variables are not recorded in a system, 2) the systems are proprietary, and the data are not stored in an open format and 3) it is unknown how to use these big data to predict fires.

Also, there exist data which are commonly and openly available, but whose potential has yet to be discovered and used. In crisis situations, social media can be a resource of unexplored capabilities. People share their evacuation plans (Chaniotakis et al. 2017) or share information about damages and casualties. This could be used to improve evacuation efforts or to assess incidents by damage, casualties or risk. Again, practitioners are unsure on how to cope with the huge amount of data that is generated by social media sites. Twitter users, for instance, produce over 500 million tweets in a single day and these tweets are polluted with spam, typos and slang (Weiler et al. 2017 p. 329), thus making it hard to extract useful structured data that can be connected to a fire emergency.

Data generation is not a problem anymore as most people carry around GPS ready devices who can put out a lot of geographical information on the go and geographic information technology is more sophisticated than ever. However, consolidating this information into a central knowledge base is still a challenge. GRANELL AND OSTERMANN (2016 p. 231f.) examined volunteered geographic information and geo-social media and concluded that the building of canonical bodies of knowledge has not happened yet, as most studies focus on the challenges and potential of data handling. This stage comprises steps such as merging of data sources, cleaning, annotating, filling missing values and filtering which must be done before an actual analysis of the data at hand can be carried out. Another necessity of canonical bodies is the usage of a shared terminology. For instance, if a dispatch center registers a medium-sized fire it must be known by each participating fire department, what resources to allocate to a fire and therefore it must be known what medium exactly means. An integrated data management for firefighting situations that includes heterogeneous knowledge bases is therefore still out of reach in research, as well as practice.

All challenges are grouped by some general categories and presented in Table 1.

Table 1. Results of the literature review: Challenges

Challenges
Cartographic data harmonization (Grasso et al. 2018)
IS standardization (Granell and Ostermann 2016; Steinhäusler, Friedrich Hällström et al. 2018; Steinhäusler et al. 2018)
Information from unstructured data (Chaniotakis et al. 2017; Weiler et al. 2017)
Creation of canonical bodies of knowledge (Granell and Ostermann 2016)
Creating data-driven firefighting support (Song et al. 2017)

Current Trends

There are some trends that directly tackle previously mentioned challenges. For instance, to harmonize data and establish common policies, a European directive, called information for spatial information in Europe (INSPIRE: https://inspire.ec.europa.eu/), has been setup (Grasso et al. 2018 p. 625). INSPIRE is an initiative of the European parliament and aims at establishing a central GIS. It forces all European countries to 1) standardize their data and

create conform meta data and 2) publish their spatial information over network services. It is in place since 2007 and should be fully implemented in 2021, thus making it at a big current trend in data management for firefighting. GRASSO ET AL. additionally propose a method to design and implement a GIS that fulfills the standards of INSPIRE. The proposed GIS comprises the three major object categories command, land and event which are represented in an INSPIRE-compliant UML model (Grasso et al. 2018 p. 629). For the implementation open source software is used, because it facilitates interoperability through open formats.

Another EU-wide initiative is SAYSO. SAYSO has been initiated in mid of 2017 and should be completed in 2019. It stands for standardization of situational awareness systems to strengthen operations in civil protection and strives to accomplish two deliverables which are relevant to data management. The first deliverable is the specification of open data format standards for crisis management organizations and includes digital map formats, geospatial data, meteorological data, media streaming and many more (Steinhäusler, Friedrich Hällström et al. 2018). The second deliverable is a specification of a multi-stakeholder standardized situational awareness system which is based on requirements of crisis managers, international surveys and several expert meetings (Steinhäusler et al. 2018). When adopted in the future, SAYSO will be a big milestone towards data management standardization in firefighting.

Another trend in the times of big data is the data-driven prediction of fires. Today, researchers have tools of the domain of artificial intelligence at hand which could help to improve prediction. It was mentioned earlier that often data are not recorded sufficiently. Especially data on fire occurrence at the city scale are scarce and site-specific. To tackle this problem, SONG ET AL. (2017) present an econometric model and a random decision forest algorithm which use several variables to predict fires on the scale of Hefei City, a city located in China with a population of almost eight million. The methods work on a reduced set of variables such as elevation, slope and average temperatures. While this study delivered promising results, the research was only done in a case study and its main limitation is that better predictions still rely on an integrated information system (IS) that can deliver a multitude of explanatory variables in real-time (Song et al. 2017 p. 836).

In contrast to data which are not accessible, there is also a lot of data which are available, but whose potential has not been recognized. Through social media, the decision process of people in evacuation situations can be analyzed and used to improve in such conditions. CHANIOTAKIS ET AL. (2017) examined Twitter data from an evacuation in Oroville, USA and created a model that uses historical data to predict the behavior of evacuated people. Twitcident is another online data mining tool that allows to filter tweets related to incidents. The tweets can be filtered by region or topic and can be used to assess damage, casualties and many more. WEILER ET AL. (Weiler et al. 2017 p. 836) proposed an experimental analysis on event detection techniques. Event detection techniques try to extract events (i.e. real-world occurrences that take place in a geographical location over a certain period) out of unstructured data. The analysis should give researchers and practitioners the possibility to choose the best algorithm to extract event data based on their preferred properties such as precision, recall, memory usage or run-time performance.

Another trend tries to answer the challenge of insufficient canonical bodies of consolidated knowledge laid out by GRANELL AND OSTERMANN (Granell and Ostermann 2016 p. 231f.). One example are different definitions of the same term between two different organizations, e.g. our medium-sized fire example from the previous section. To solve this issue, Firebrary (http://www.firebrary.com/) was developed to provide a data dictionary for common terms for the Dutch services. Firebrary uses the SKOS-XL standard to provide open access to people and software (Spaling et al. 2018 p. 122).

Again, all trends are grouped by some general categories and summarized in Table 2.

Table 2. Results of the literature review: Trends

Trends
INSPIRE (Grasso et al. 2018), Digital plan (Weidinger et al. 2018), OpenFireMap, Fireboard
SAYSO (Steinhäusler, Friedrich Hällström et al. 2018; Steinhäusler et al. 2018), Firebrary (Spaling et al. 2018), on-site IS (Weidinger et al. 2018)
Twitter model (Chaniotakis et al. 2017), twitcident, event detection (Weiler et al. 2017)
Firebrary (Spaling et al. 2018)
Econometric model (Song et al. 2017)

Expert Interview: The Situation in Germany

The expert interview with the German expert yielded the following results. If not indicated differently, the source of information is the expert interview.

The recording of the first response in an emergency in Germany is sophisticated. A caller is referred to a control center in which an employee poses structured questions. The answer is put into an IS and subordinate questions are posed until the dispatcher can conclude a so-called alarm key word, a single word that describes type and magnitude of the fire. If agreed, the caller can be located over the mobile network. The gathered information is forwarded to the responsible fire department and resources are allocated depending on the alarm key word (this is defined in the "Alarm- und Ausrückeordnung"). While data of the call is stored in a control center system, the smaller fire departments often have a non-compatible IT infrastructure and thus, the information is printed on an "Alarmdepesche". The "Alarmdepesche" contains information about the route to the operation site, water supply and the caller. For special sites, construction blue prints and maps are stored in paper format at the local fire department. It is rare that a fire department has fully digitized this process, but this is likely to change in the future. A first example is the FIRE application of the department in Berlin where the "Alarmdepesche" is fully substituted by an IS on a tablet (Bäker 2018 p. 479f.). Additionally, the FIRE App is equipped with a hazardous substance database, rescue data sheets and a fire wiki (Bäker 2018 p. 482f.). A similar system has been deployed in Saxony (FwA - "Feuerwehrapp"). The app comprises four modules: a map module with hydrants and water sources, rescue data sheets, a hazardous material information module and a respiratory protection module (Heyne 2018 p. 492f.). More prominent than a digitized "Alarmdepesche" is the automatic transmission of the route into the navigation systems of the fire trucks which is implemented almost everywhere. However, during the actual firefighting almost no IT is used (an exception is the respiratory protection module of the Saxon "Feuerwehrapp"). Afterwards, the operation is documented in an IS.

As identified in the general challenges and trends, GIS are very topical. Due to the independently acting federal states and local fire departments, there are multiple geodatabases. For instance: There exists an ALKIS geo database for Lower Saxony which can be integrated easily with generic interfaces (Dunkel 2018 p. 134), but this is a solution on federal state scale. DUNKEL suggests that all future applications should be encoded in the DIN 14095 standard to increase interoperability on a nation-wide level (Dunkel 2018 p. 140). BERNSDORF identifies four challenges of the usage of geo information for firefighting in Germany: internet connectivity, data actuality, training of executives and operability of these complex systems (Bernsdorf 2018 p. 155f.).

The biggest challenge in the process is the standardization between the local institutions. Due to the independent and autonomous nature of the fire departments, there is a big heterogeneity in IS. HEYNE sees the usage of proprietary systems as the biggest inhibitor of a dissemination of successful software (2018 p. 499). Unfortunately, there is no binding regulation on systems standardization in Germany and a new regulation is costly for the administration of the federal state, due to the "Konnexitätsprinzip", i.e. the state must carry the costs for tasks which it imposes. Control centers of different jurisdictions use proprietary systems. North Rhine-Westphalia alone consists of 52 autonomous control centers. Some federal states have already consolidated their control centers (e.g. Hesse and Bavaria). Additionally, the alarm key words are only standardized within a county. A country-wide glossary or general semantics do not exist. This is especially critical for fires which span multiple regions.

For such fires, a crisis staff must be established and here, the problem of standardization is even more critical. The go-to data management device is still e-mail and telephone communication, as no integrated software solution is implemented. There are some efforts to offer central data management tools. North Rhine-Westphalia has a database where resources such as water reserves are stored ("Informationssystem Gefahrenabwehr NRW"). There is also an EU wide project for the standardization of situational awareness tools (project SAYSO, mentioned earlier). Still, crisis management is relying on traditional methods for communication which partially exists since multiple decades (e.g. paper message and radio). Rarely, more advanced technologies such as fax or scans are used. The whole procedure is slow and full of misunderstandings.

All in all, politics, federalism and the decentralization of responsibilities to the local authorities are the main reasons for the non-standardization of data management for firefighting in Germany and this is one of the biggest challenges.

Expert Interview: The Situation in the Netherlands

Because of their safety-regional structure, the Netherlands are not as federal as Germany and thus systems standardization is much less of a problem. The safety regions are not centrally governed; their geographical borders are defined by law, but their mode of operation is autonomous. Still, there is a nationally standardized radio communication system and a central national dispatch system, which are standardized even across the autonomous safety regions. Only some systems, such as human resource management systems, are procured locally.

The expert sees the biggest challenge in data management in the qualification of the fire fighters. When fire fighters are employed, they are tested on practical skills, rarely are they tested on IT competence or trained while on the job. Of course, this stems from firefighting requiring a whole different set of base qualifications.

Another challenge is the inertia of the fire service as a governmental institution. For the innovation of legacy information or data management technologies within the institutions, a complex procurement process needs to be initiated because investments are often very big. Due to the complexity of the procurement that is often subsidized with only small budgets, innovation is very tedious.

It is notable that while IS standardization is a smaller issue than in Germany, the creation of a canonical body of knowledge and shared semantics is very important in the Netherlands. To allow effective communication between different firefighting departments, there must be a taxonomy of firefighting terminology and information architecture of the IT systems must be improved. A notable endeavor to do this is Firebrary, a data dictionary for common terms for the Dutch service which was introduced earlier.

Also, the expert mentions that "the road to AI leads through IA [information architecture]". This means that first, the data in the systems must be harmonized, before it can be used for artificial intelligence, due to its data-driven nature. The Netherlands also employed first trials with artificial intelligence. While artificial intelligence is not used for predicting fires, it showed very promising results when fighting a fire and looking for similar environments or buildings to gather helpful information. Another data-driven firefighting support tool is RESC Info Insight that allows to combine forensic research data, internal statistical data and publicly available data to gain additional insights (https://netage.nl/resc-info-insight/).

All in all, the Netherlands are also concerned with some more traditional challenges such as building of canonical bodies of knowledge, as well as more advanced technologies, such as data-driven firefighting support.

DISCUSSION

To get a concluding overview on which challenges were identified and which trends are answering these challenges, Table 3. **Challenges and trends of data management in firefighting**

Challenge	Trend
Literature Review / International	
Challenge	**Trend**
Literature Review / International	
Cartographic data harmonization (Grasso et al. 2018)	INSPIRE (Grasso et al. 2018), Digital plan (Weidinger et al. 2018), OpenFireMap, Fireboard
IS standardization (Granell and Ostermann 2016; Steinhäusler, Friedrich Hällström et al. 2018; Steinhäusler et al. 2018)	SAYSO (Steinhäusler, Friedrich Hällström et al. 2018; Steinhäusler et al. 2018), Firebrary (Spaling et al. 2018), on-site IS (Weidinger et al. 2018)
Information from unstructured data (Chaniotakis et al. 2017; Weiler et al. 2017)	Twitter model (Chaniotakis et al. 2017), twitcident, event detection (Weiler et al. 2017)
Creation of canonical bodies of knowledge (Granell and Ostermann 2016)	Firebrary (Spaling et al. 2018)
Creating data-driven firefighting support (Song et al. 2017)	Econometric model (Song et al. 2017)
Germany	
Cartographic data harmonization (Bernsdorf 2018)	Feuerwehrapp (Heyne 2018), ALKIS (Dunkel 2018)

Table 3 is presented. The table visualizes the results of the previous sections. To do that in a simple manner, categories of challenges were formed and one or multiple challenges were grouped by these categories.

The results from the literature review (international) were diverse and range from more traditional challenges,

Table 3. Challenges and trends of data management in firefighting

such as geo-data and IS harmonization and standardization to more innovative trends. When looking at the more innovative trends such as information gathering from twitter data or econometric fire prediction, it becomes apparent that these were not implemented through persisting and sustainable solutions, but through pioneering case study research. This is a small hint that these trends might not have made the transition to practice yet. On the plus side, there is no international category of challenges which is not addressed by at least one trend.

On the German side, challenges and trends look completely different. Information gathering from unstructured data and data-driven firefighting support are not addressed at all. The more traditional topics such as cartographic data and IS standardization are currently under heavy implementation. Because these topics take a lot of effort and are often a prerequisite for more advanced technology, current practice in Germany will probably take some time to fully adopt them. Due to Germany's federal nature, it will take some more years, before the more pioneering technologies will be integrated.

In the Netherlands, cartographic data and IS standardization are not a current challenge, because the Netherlands employ an integrated IT infrastructure within their safety regions. Canonical bodies of knowledge and a taxonomy are very important and already tackled by some approaches. The Netherlands additionally touched some areas which are currently unreachable for Germany. These comprise data-driven approaches. The Netherlands have also some more advanced challenges, that have not been answered, such as lack of qualifications and governmental innovation inertia. These two categories were not even recognized by the literature review. This may potentially be, because the used key words were focused on information systems research, while the two problems should be viewed through the lens of organization science.

CONCLUSION

Some unique revelations could be made through the combination of a literature review and interviews with local firefighting experts.

All in all, one can say that most of the current challenges are answered by at least one trend. Still, the situation of Germany and the Netherlands could not look more different, which is an interesting finding as both countries are alike in many other areas. While the former is determined by its federal political system, it cannot yet adopt newer technologies, because the basis of IS standardization is missing. It will take some more years (or even decades) for Germany to adopt newer trends and even then, the solutions will be pushed by single local fire departments instead of being established on a national scale. These phenomena are almost non-existent in the Netherlands, due to their centrally regimented safety regions, and more progressive trends emerged in the last couple of years. It is notable that challenges of the Netherlands are not only limited to the domain of information systems, but also organization science, and thus an interdisciplinary approach, that cannot be achieved by technological advances alone, is required to solve them.

For further research, some improvements can be made. The keywords could be extended to conduct an exhaustive literature review in future work. The authors also suggest, that the scope of the literature review should be extended to include literature from organization science which was not possible with the used key words. Additionally, it must be questioned whether a structured literature is the right means to identify (local) trends and challenges. Because much information is intangible and not accessible in research databases, more experts must be interviewed to get a more comprehensive and objective overview. This also increase the objectivity of the expert judgements. Additionally, the work is very descriptive, a structured comparison of countries could lead to learnings one country could gain from another country, thus making the research more prescriptive.

These limitations therefore address some gaps that must be bridged. For future research the authors recommend following research agenda which is concluded from the results and limitations:

(1) Standardized IT infrastructure in Germany.

(2) Lack of qualifications in the Netherlands.

(3) Governmental innovation inertia in the Netherlands.

(4) Practical applicability of information retrieval from unstructured data.

(5) Prescriptive analysis of practices to facilitate the adaption to challenges and adoption to trends.

To determine what happens with data management in the near future is dependent on how technology advances further and even more dependent on how the political systems in Germany and the Netherlands will facilitate innovation in the area of firefighting. One thing is sure, for the coming decades it will be a topic of high interest and constant change.

ABSTRACT

Virtual teams are an important form of collaboration, especially in the context of transboundary crises. Achieving team effectiveness through good sensemaking is key to virtual teams' success in responding to crisis. However, there is still a lack of understanding about the relationship of this sensemaking in a virtual team during crisis to the virtual team's development of swift trust. Adapting from a model of sensemaking, in this paper, we propose a research model to describe the relationships among swift trust, sensemaking and virtual team performance in the context of virtual teams during crisis.

Keywords

Virtual teams, crisis, sensemaking theory, swift trust, team performance.

INTRODUCTION

Organizations are constantly adapting to contextual changes (Albu & Wehmeier, 2014). One such "change" happens when organizations face crises. Organizational crisis are events that represent the most extreme and severe situations and are characterized in terms of their high risk, low probability, high uncertainty, and time pressure (Weick, 1988). Ineffective responses to a crisis can threaten organizational identity and potentially damage the reputation of the organization (Harden & Fulop, 2015). For example, Equifax a consumer credit reporting agency, faced a major cybersecurity crises in 2017, when it discovered and reported that over 143 million U.S. customers' personally identifiable information (PII) was breached (Agnes, 2017). Agnes (2017) summarized the response to this crisis by Equifax as follows: "While their messaging was weak coming out, their strategy of communication dissemination has since been quite strong." She adds "They (Equifax) will inevitably be defined by this incident, whether they like it or not. And yes, they will also be defined by the way they choose to respond."

Crisis research, in particular, organizational crisis research has burgeoned over the past decade (Jong, Dückers, & Velden, 2016; Paraskevas, 2006; Sauer, Felsing, Franke, & Rüttinger, 2007; Stachowski, Kaplan, & Waller, 2009). In particular, **sensemaking**, a process oriented construct, has been used as an effective theoretical lens for capturing the underlying path to successful crisis management. However, most studies in this line of research either focus on identifying the constituting elements of sensemaking (e.g. Hamm et al., 2015) or treat sensemaking as an endogenous factor to organizational or teams' performance in crisis (e.g. Higgins & Freedman, 2013).

Therefore, in this paper we attempt to fill the aforementioned theoretical gap by identifying "swift trust" as an important exogenous antecedent of sensemaking. We conceptually begin the exploration of the following research questions: How does swift trust influence sensemaking and its components? Can sensemaking in turn influence virtual team performance? We propose a research model for studying how sensemaking and swift trust influence virtual team performance during organizational crisis. Virtual teams generally have diverse

members with different skills and status. Prior research has found that under such a circumstance, virtual team members develop a priori "swift trust" (Meyerson, Weick, & Kramer, 1996). Swift trust is a key condition of virtual team members' sharing of information that is essential to virtual teams' sensemaking. Swift trust is an indicator of team capability and plays a key role in facilitating sensemaking (Waller, Lei, & Pratten, 2014).

CONCEPTUAL FOUNDATIONS

Sensemaking theory

Sensemaking *is the process through which individuals and groups attempt to explain novel, unexpected, or confusing events* (Weick, Sutcliffe, & Obstfeld, 2005). Sensemaking usually occurs at the early stages of a crisis (Boin et al., 2014). Key activities associated with sensemaking include information gathering, information dissemination, information sharing, and interactions among members (Thomas, Clark, & Gioia, 1993). Weick suggested three categories of sensemaking tasks: perceptions, interpretations, and actions. Sensemaking is one essential behavioral indicator of teams that begin actively engaging in cognizing, understanding, interpreting, and sharing among team members (Sackman, 1991; Weick, 1988). During sensemaking, individuals may develop different interpretations of the situation (Maitlis, 2005; Reissner, 2011; Weick & Roberts, 1993) .

Research that discussed sensemaking during organizational crisis has primarily focused on the topics of leader communication strategy (Boin & Renaud, 2013; Dixon, Weeks, Boland, & Perelli, 2017; Salicru, 2017), organizational transparency (Albu et al., 2014), individual's sensemaking of risk (Wall, 2014), inter-organizational cooperation styles (Boin et al., 2014), and reducing ambiguity in organizations (Burke et al., 2006). Generally, researchers agree that during crisis, organizations have to balance between the effort of collecting a complete and accurate information set and the choice of comprehending the gathered information in a timely manner.

A concept that is important for understanding the notion of sensemaking is *ambiguity*. Ambiguity is a distinct characteristic of all crises. A critical task for people involved in sensemaking during crisis is to reduce such ambiguity by better comprehending the crisis (Stieglitz, Mirbabaie, & Milde, 2018). Caroll (2015) proposes three categories of ambiguity during crisis: fundamental ambiguity, causal ambiguity, and role ambiguity. Fundamental ambiguity refers to the situation when no one is capable of putting a label or category on the crisis. Subjects experience causal ambiguity when they know what is going on but struggling to determine the causal attribution of the crisis. Role ambiguity describes the individuals who are accountable for specific tasks during the crisis. The outcome of sensemaking should be a shared and accurate understanding of ambiguity across these categories during a crisis.

Another important concept for sensemaking is "relationship." During crisis, organizational leaders have to manage both the internal relationships within organizations and the external relationships with stakeholders and the public. Crises can lead to a high degree of uncertainty and anxiety. Negative feelings and emotions, such as fear and anger, can cause irrational decisions with unintended consequences (Elfenbein, 2007). Environmental changes can also lead to cognitive disorders, confusion, anxiety and nervousness (Mckinley & Scherer, 2000). The distrust of organizational leaders' competence can also affect an individual's understanding of crises (Yin & Jing, 2014). In addition to the internal relationship, external relationships with the public and stakeholders are also very important. Research has shown that following a crisis, a transparent communication strategy can enhance the credibility and trustworthiness of a company in crisis (Albu et al., 2014).

Swift trust

Compared to co-located teams or traditional face-to-face teams, ICT enabled virtual teams experience more challenging issues when working together. In particular, building trust among members is one of the most significant challenges for virtual teams. For geographic, temporal, and physically dispersed teams, trust is essential for team members to work together toward their goals (Jarvenpaa, Knoll, & Leidner, 1998). Due to the loss of body language and non-verbal cues, virtual teams' trust development is difficult when most of the collaboration and coordination rely on ICT.

Prior studies have found that effective virtual teams formed "swift trust" when teams are temporal and were working a time-constraint (Meyerson et al., 1996). Swift trust was found to be a special kind of trust unique to virtual teams when members with little to no co-working experience worked together temporally (Meyerson et al., 1996; Suzanne & Weisband, 1997). Distinct from social-interaction based trust, swift trust is not cognitive or affective and occurs in the early stage of team formation (Suzanne et al., 1997).

Swift trust is especially useful for understanding effective team operations during crisis (Curnin, Owen, Paton,

Trist, & Parsons, 2015). Prior studies have revealed that the establishment of swift trust in virtual teams cannot only affect how teams communicate and interact with each other, but also can affect how well the team accomplishes its goals (Henttonen & Blomqvist, 2005; Kanawattanachai & Yoo, 2002). In addition, swift trust is important for virtual team members to engage in sustainable cooperation under ambiguous situations (Hyllengren, Larsson, Fors, Sjöberg, Eid, & Olsen, 2011; White, Plotnick, Addams-Moring, Turoff, & Hiltz, 2008). Researchers have found that teams in crisis are more inclined to establish swift trust that accelerates the team process and task accomplishments.

RESEARCH MODEL

In the context of the use of virtual teams during crisis, Figure 1 presents our research model depicting the hypothesized relationships among individual's swift trust, sensemaking and team performance. In particularly, we adopted three sub-dimensions of sensemaking proposed by Basu and Palazzo (Basu & Palazzo, 2008), i.e. cognitive development, linguistic development, and conative development.

With regard to operationalization of sensemaking, the study conducted by Basu and Palazzo (Basu et al., 2008) offers a viable approach. Basu and Palazzo propose three dimensions of sensemaking, i.e. *cognitive*, *linguistic* and *conative* (Basu et al., 2008). According to them, *cognitive* refers to thinking about the organization's relationships with its stakeholders and possible impact on key relationships; *linguistic* involves justifying, communicating and sharing the rationale of particular crisis response actions; and *conative* involves the actual behavioral posture the organization adopts and the commitment and consistency it shows with the activities conducted. Contrary to other studies of crises that predominantly focus on the role of the external environment in an institutions' reaction to crisis, Basu and Palazzo assert that attention to the institutions' internal cognitive and linguistic processes is also important. They argue that these are key processes and can affect how institutions view their relationships with stakeholders during crisis and how the institutions may engage during crisis response. Adapting Basu and Palazzo's (Basu et al., 2008) model to the team level, we propose studying virtual teams' reaction during crisis by going beyond a content analysis driven-approach. Thus, based on prior understanding of sensemaking, we assert that a particular **cognitive process (i.e., the team's interpersonal process), two linguistic processes (i.e. team knowledge sharing, team mutual awareness), and two conative processes (i.e. process conflict, shared temporal cognition)** mediate the relationship between swift trust development and virtual team performance (refer Figure 1).

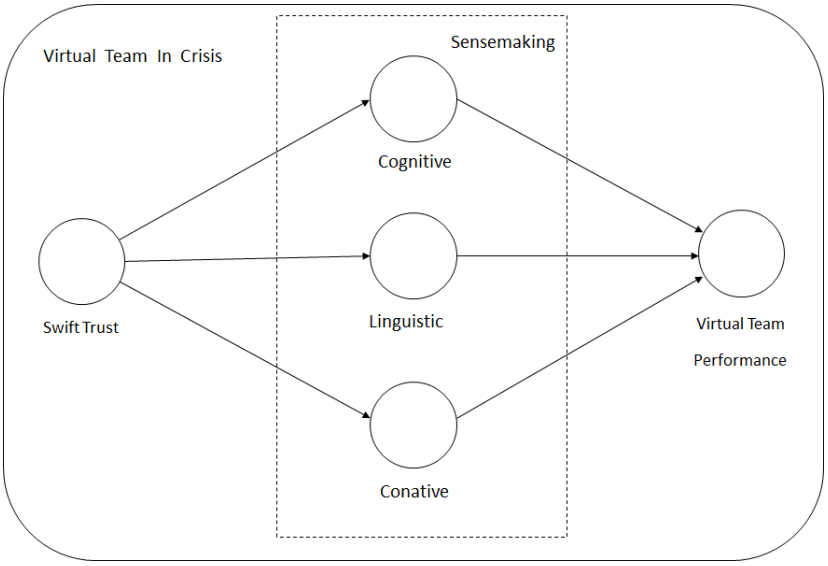

Figure 1. Influence of Swift Trust on Virtual Team Performance through Sensemaking

DISCUSSION AND IMPLICATIONS

Crisis can lead to severe breakdowns of organizational norms that result in ambiguity and negative feelings among stakeholders, public, as well as internal employees (King, 2002). One challenge of virtual teams in crisis is to develop shared understanding, i.e. cognitive development, of the consequences of crisis on organization's internal and external relationships (Basu et al., 2008). Establishing swift trust enhances knowledge sharing and increases

frequency of interactions, which lead to greater level of cognitive development in virtual teams. In addition, in the virtual team context where effective leadership can be significantly different from collocated teams, swift trust contributes to cognitive sharing among team members (Al-Ani, Horspool, & Bligh, 2011). Therefore, as illustrated in Figure 1, **swift trust promotes the formation of cognitive structure**, which allows work in virtual teams to be coordinated and synchronized (Curnin et al., 2015).

Swift trust is critical for promoting free information flow and knowledge exchange in virtual teams. Prior research has shown that in virtual teams' context, members are more likely to build situational attributions against perceived negative behaviors of other members than collocated teams (Cramton, Orvis, & Wilson, 2007). One study found that during crisis, virtual teams' communication frequency dropped significantly resulting from the seriousness of the threat and time urgency (Kamphuis, Gaillard, & Vogelaar, 2011). Though during crisis, virtual teams may reduce level of social interaction and learning about one another's preferences and behaviors, swift trust promotes free interaction among team members in a short period of time (Radcliffe & Schniederjans, 2003). Further, based on free conversation, our research model incorporates the notion that **trust makes the team members more willing to interact and communicate both formally and informally** (Fischbacher et al., 2014).

Swift trust ensures commitment and consistency as virtual teams conduct activities in crisis, i.e. conative, dimension of sensemaking (Basu et al., 2008). Virtual team enter the conative stage when they start action following decision-making (Hazel & Kang, 2018). Researchers have shown a positive correlation between organization strategy consistency and organization performance (e.g., Bourgeois, 1980). Swift trust plays an important role by speeding up the decision-making process, eliminating obstacles in the process of knowledge sharing, promoting a win-win cooperation within the team, enhancing communication and cooperation among team members, and achieving consistency in problem solving strategies (Higgins et al., 2013).

Sense making can help resolve ambiguity, **facilitate information sharing and mitigate negative feelings such as stress and fear during crisis.** We expect that this generalized relationship will also hold true in the virtual team context. In complex situations, such as crises, teams cannot rely on intuitive decisions, which can be very risky without review and evaluation (Higgins et al., 2013). A good cognitive development of the crisis can enhance virtual teams' understanding of the full complexity of the crisis, forming a more thorough and correct picture (Waller et al., 2014).

Communication and transparency are two most discussed topics in crisis management. To achieve a better performance, effective and timely communication is critical (Cheng & Macaulay, 2014). With linguistic development, i.e. clear communication and appropriate information disclosure, virtual-teams are able to promote shared understanding the crisis and the rationale for the team's actions during crisis. Such shared understanding helps enhance team effectiveness and adaptability in crisis (Nemiro, Beyerlein, Bradley, & Beyerlein, 2008). Communication is also critical to distributed-team success in that the condition through which divergent members' skills and knowledge, and cognitive style can be integrated and leveraged to achieve synergies (Kroenke, 2011). Through efficient communication, virtual team members are able to build strong ties which was suggest to influence members' comfortableness of working together (Benetytė & Jatuliavičienė, 2014). Effective communication can facilitate the development of a conversational space where all perspectives are heard and discussed, all possibilities are explored (Benetytė et al., 2014; Harden et al., 2015; Harush, Glikson, Nouri, & Shokef, 2013).

CONCLUSION

The main objective of this paper is to propose a research model based on prior literature that allows us to examine the relationships between virtual team swift trust, sensemaking, and team performance in the context of organizational crisis. Specifically, we assert that the establishment of swift trust has a positive influence on the three sub-dimensions of sensemaking - cognitive, linguistic, and conative. Overall, our research contributes to both crisis and IS literature by offering a research model depicting the relationships among swift trust, sensemaking, and team performance. We are currently in the process of empirically testing the proposed research model.

Dark Web, Black Markets: Crisis as Opportunity

Kathleen Moore
School of Integrated Sciences
James Madison University
Moore8ka@jmu.edu

ABSTRACT

Black markets that develop after disaster events have potential to disrupt recovery efforts, and the Dark Web is the perfect facilitator of these markets. Lack of knowledge about the Dark Web: how to access it, how to safely, efficiently navigate the space, and prevailing myths about its dangers likely lead to this deficiency of research. To date, this area is a critically unexplored area of the Internet in the crisis research literature. This work examines this area of the Internet for utility and insight relevant to crisis managers. A pilot study on Puerto Rico in the months following Hurricane Maria reveals possible indicators of the development of black markets for prescription drugs, food, and water, which can impact long-term recovery and reconstruction efforts when these items are diverted from legal supply chains. As more people adopt this hidden part of the Internet, researchers and managers must do more to pay attention to activities that occur in this space.

Keywords

Deep Web, Dark Web, Surface Web, Black Markets, Crisis Response, Crisis Management

INTRODUCTION

Markets can suffer disruption and even failure during natural disasters or crisis events, which in turn can affect the recovery of an area (cite). Visible indicators of market disruption in the form of open-market price gouging are easily recognizable dealt with (Skarbek, 2008), however, invisible indicators in the form of supply chain diversions resulting in black markets are less recognizable. Supply diversions into black markets can impact the availability of goods, and with legal authorities often tasked with recovery activities during these chaotic times, illegal markets easily go undisturbed during these events (Dunlap et al, 2012). Illegal activities such as human trafficking is well-known to flourish immediately after crisis events (Stout, 2018), even paper currencies of countries in crisis are subject to this phenomenon (Flannery, 2018).

Since invention of digital (crypto) currencies in 2009, Dark Web illegal markets (DWIMs) have flourished, and to date, there are 54 active markets on the Tor Network. In theory, DWIMs are the perfect facilitator for black markets, however, have not been studied in the canon of crisis research. This is likely due to the complexity of the technology of the Dark Web, lack of understanding about this space, and the relative newness of its activities in the public consciousness, and also, until just recently, the capture of illegal market data was exceedingly difficult outside of government sponsored research national security agencies. However, prior to the emergence of DWIMs, goods were primarily sold in Dark Web forums and message boards, and in some cases, still are, thus allowing researchers an opportunity to examine this space for linkages and indicators of black-market activity.

After Hurricane Maria struck Puerto Rico in September 2017, and in the months following, certain activity in Dark Web forums suggest the development of a black market for supplies and prescription medicines that correspond with specific news announcements from the US Federal Emergency Management Agency (FEMA) in the year following. While this activity shows the potential for a black market, it may also signal the further need for a specific type of aid on the island. Lessons learned from this pilot study not only highlight the problems of studying this area of Internet, but also help establish guidelines for structuring future research in this space.

BACKGROUND

Black Markets and Disasters

Dark Web markets and forums are digital black markets, which are offline systems (markets) that operate outside the normal means of production and acquisition of goods and services (Folger, 2010). These markets often serve to subvert government control of prices and quantities or payments of taxes and have an impact on the forces of supply and demand of regular marketplaces (Michaely, 1954).

Black markets thrive best during and after crisis events when normal operations of a country are in disarray (Reynolds, 1998). Human Trafficking is an issue long known to increase during natural disasters when legal authorities are more engaged in rescue and relief efforts rather than dealing with crime (UNDOC, 2009). Drug related activity and diversion from normal supply chains have also long been an issue that thrives in this space and time (Forgione et al, 2001). More recently, countries whose currency falls in value during time of crisis experience the emergence of higher-value foreign paper currencies in black market (Flannery, 2018).

The Internet has long been a facilitator of black market activity where crime, fraud, and goods sold are facilitated by the coordinating benefits of the digital technology and the anonymity it used to offer (Baker 2002). As law enforcement became more apt at combatting certain types of cyber-crime, the need for increased anonymity and payments systems by criminals was satisfied by the Tor Network and new digital currencies that by-passed traditional banking systems and digital forensics (Gregg, 2012).

DARK WEB AND THE ONION ROUTER NETWORK

The Internet is a vast ecosystem with definable areas of content, and terminology not readily understood by many. The Internet itself is merely communications infrastructure consisting of hardware and software that allows enabled devices to connect. The World Wide Web (WWW) is an overlay or an application of the Internet that serves as an information space for resources and online documents that are searchable through Uniform Resource Locators (URLs) and are connected via hyperlinks. This structure makes the WWW highly interconnected, and thus, information discovery relatively simple. The Internet and WWW occupy the space referred to as Clear Net and Surface Web respectively.

There is also an "underbelly" to the system which includes areas of storage and hidden services, namely Deep and Dark Web. Deep Web is where Surface Web stores information not indexed by common web search engines such as Google, Explorer, or Safari. Content may include large databases, paid content, dashboards of websites or social media services, web mail, banking, etc. WWW users access this information daily and is a common online activity. Businesses, organizations, and government entities may employ the use of "Dark Sites" which are identical or "mirror" versions of their web sites that offer continuity of operations should their website go offline due to an emergency such as a technical problem or an emergency/crisis event. The sites are also known as hot and cold sites, where a hot site maintained by a company, in parallel to their functioning website, whereas a cold site is a site with the basic infrastructure, not updated in parallel but after crisis has struck, and is often maintained by a third-party vendor (SearchCIO, 2019).

Dark Web refers to hidden services available on the Internet but only accessible via a technological overlay to the Internet called Dark Net. Dark Net requires a specific tool called The Onion Router (Tor) to connect. The concept was invented by the United States Naval Research Laboratory in the mid-1990s and the technology was refined by the Defense Advanced Research Project Agency. Its purpose is to protect and secure intelligence-based communications online. Tor was launched in 2002, is free and available to the public, and is now managed by The Tor Project, Inc., a nonprofit organization devoted to the management of the network, research, and education (Tor Project, 2019).

When Tor is engaged, a user is able to access a volunteer network of nodes where the user's identity and data requests are anonymized, encrypted, and routed through a series of different servers before reaching the user's requested destination site (Figure 1). Users may use the technology to access and browse Surface Web sites, but the technology also allows them to access *.onion* sites, or hidden services sites which are Dark Web locations not accessible otherwise. The masking of IP addresses means users of this network may go relatively undetected, though technology is ever fully secure. Without IP addresses, this also means that much of the content on this network lacks the ability to be geolocated.

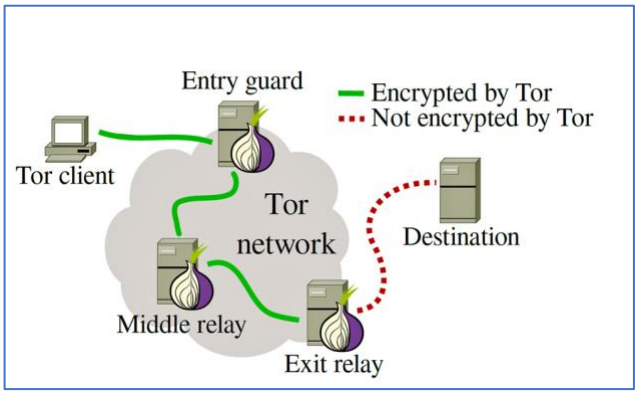

Figure 1: Tor relay network. Source: The Tor Project.

For nearly a decade, Tor not only secured intelligence communications, but was also utilized by activists, whistle blowers, and journalists around the globe in order to protect their identities online (Tor Project, 2019). This type of use continues alongside everyday citizens using the network who are concerned with protecting their data from overly intrusive collection practices by governments and corporations. Other Dark Web hidden areas exist such as i2P, Freenet, Gnu.Net, but due to lack of discernable activity, have been excluded from this study.

Dark Web's reputation took a turn in 2011 when Ross Ulbricht launched The Silk Road, an *.onion* site that allowed the anonymous purchase of illegal and prescription drugs, and other items using anonymous cryptocurrencies (Weiser, 2015). Tor also came to greater public attention when Edward Snowden, a former United States national security employee, exposed questionable, online, data collection practices by the US government. Since 2013, Dark Web has proliferated its number of drug markets, and other criminal services such as human trafficking, and child pornography (Power, 2014).

However, Dark Web is not the exclusive domain of illegal crime. Many myths and misconceptions abound concerning the use of Tor and Dark Web, and what type of content it contains. Many people believe that using Tor and/or visiting Dark Web sites constitutes illegal activity. In more repressive countries with strict laws on Internet use, this may be true, (Paul, 2015) but for most countries, this activity is legal provided the individual user does not engage in illegal activity in this space. While there is certainly disturbing information on Dark Web, many researchers speculate that much of it is benign (Winter, 2015) (Bartlett, 2015).

Dark Web also does not function like Surface Web. The Surface Web is highly interconnected and information easily discovered or suggested, whereas the shape of Dark Web is more clustered or siloed, with some sites existing as "islands" or "orphans" where one needs to know it exists and navigate directly to the site because it cannot be discovered by search engines (Hyperion Gray, 2018). Lastly, there is no "Google" for Dark Web. Instead, there is perhaps a dozen of privately maintained search engines that require manual updates of available *.onion* sites since they lack the ability of automated indexing due to the technology of the Dark Web. These engines have arying levels of indexing, so persons need to visit a variety of them and enter search terms in order to find information. Overall, this makes exploring the Dark Web cumbersome for most people.

Dark Web is also subject to fraud, malware, and hacking, similar to Surface Web, but the infrastructure of Dark Net poses unique concerns where users are encouraged to layer technology to protect their personal machines (Beltov, 2016). Everyday users may employ firewalls and virtual private networks, while researchers often add virtual machines and virtual operating systems so as not to be attacked or banned when scraping data from sites.

DWIMs are sites similar to Surface Web marketplace sites like Amazon or Alibaba except in that they facilitate the sale of illegal goods. Until very recently – the time of this paper's writing – capturing data from these illegal markets was prohibitive for technological reasons. While one can visibly see what is being sold on DWIMs, one cannot see if a sale is conducted and where items are shipped. As such, when analyzing this sale activity, it was easier for researchers to study sales through forums, a precursor to DWIM sites, to analyze phenomenon. Forums posts not only notify readers of an item for purchase, but often provide threads speaking to the trustworthiness of the seller and answering question such as payments accepted and shipping locations.

Between myths and misconceptions, the difficulty in exploring Dark Web, and potential issues in collecting data, alongside the more pressing concerns of understanding illegal markets and human abuse, it is not surprising that this space has not been more thoroughly researched in crisis management and response. However, with specific information targeting and software, there is evidence of the Dark Web being utilized following a disaster event. With this in mind, this research seeks to answer the following questions:

RQ1: Given Tor's reliance on anonymity and lack geolocated data, is there other observable data that may indicate development of black markets in a disaster ridden area?

RQ2: How should the data garnered through the study of Dark Web be regarded?

DATA COLLECTION AND METHODS

Data for this study was collected from publicly available sources. Metrics regarding the use of Tor in countries around the world are available via the Tor Project website. Since Tor is a necessary component for accessing these forums and markets, understanding its use before and after the hurricane was essential.

Four forums on Dark Web were randomly selected for analysis. Though drug markets are numerous, and the availability of prescription drugs are apparent, transactions occur privately thus researchers are not able to determine shipping locations (in this case, whether drugs of concern are shipped to Puerto Rico). Additionally, most drug markets have mirror sites, similar to legal businesses for continuity purposes. Mirrors are useful when the original site generates too much traffic for a single server to support, or in the environment of Dark Web, when a single site has been seized and closed by legal authorities, operations is able to continue on other versions of the site. Aside from being unable to determine shipping location, and since these web addresses shift constantly, they are effectively a moving target that are difficult to capture and were excluded from this research.

The focus of data collection then became forums. For the sake of this work, "forums" is used as an umbrella terms for forums, message boards, chans, and chat rooms. The forums chosen for analysis were *onionland, eightchan, hiddenanswers, and intelcutout*. The sites were chosen due to their wide popularity and the variety of topics discussed. There are no formal metrics available for sites on the Dark Web, thus forum choice was determined by recommendations from the Hidden Wiki, a site that provide semi-regular updated lists of available forums. The four forums chosen have long been associated with this site.

Search terms included: Puerto Rico, emergency supplies (which varied as a catch-all for food, water, tools, medicine, and other miscellaneous items), water, food, medicine, and commonly needed prescription medicines such as insulin and antibiotics. Antibiotics were searched for by both generic and brand name and chosen due to the long list of available drugs, and also due to reports of bacterial disease outbreaks following the hurricane. All search terms were employed in both English and Spanish (though Spanish terms yielded no results). Since a structured collection platform was used to analyze captured data, Boolean String searches were performed using all the search terms to capture posts meeting the search criteria. The terms for medicine were chosen based on their common association to black markets. The terms food, water, and emergency supplies were chosen based on news reports of common needs during the period of data collection which was after the impact of Hurricane Maria on 20 September 2017, through 31 August, 2018.

ANALYSIS

Prior to Hurricane Maria striking the island of Puerto Rico, Tor use on the island averaged a modest 1,000 users on a daily basis (Tor Project, 2019). The population of the island is an estimated 3.1 million (Census.gov, 2019), so while this amount of use appears low (.00032 percent), Tor use on the United States mainland is only marginally higher (.0018 percent) (Tor Project, 2019). Since the island's infrastructure experienced large-scale damage, above electrical and telecommunication lines were inoperable on most of the island months after the event (Nestel, 2018). Naturally, connecting to Tor was impossible for many and use dropped to nearly 100 daily users at the end of 2017 before rebounding in 2018 up to 750 daily users through either direct or connection or through a proxy server (Figure 1).

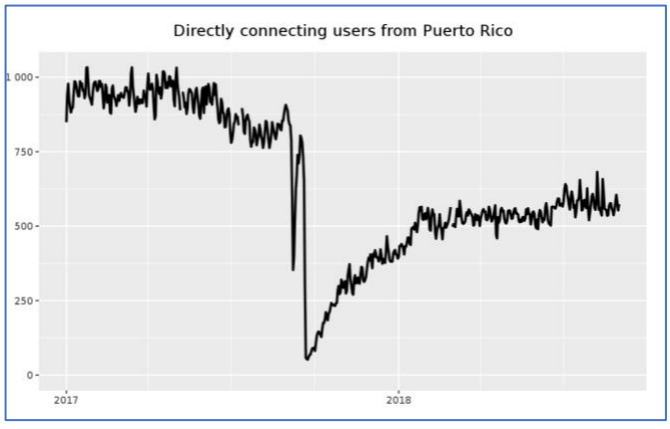

Figure 1: Direct Tor connection in Puerto Rico 2017 through August 2018.

Dark Web forums are not often explicit when it comes to understanding sale transactions. Participants in these forums can offer to sell, state an intention to buy, or pose a question about a particular good which is code that the post author intends to sell or buy then encouraging a backchannel communication. Of the four forums examined, the onionland forum yielded the largest number of search results in (Figure 2). For visualization purposes, the charts were condensed by moving average, meaning onionland yielded over 500 search results.

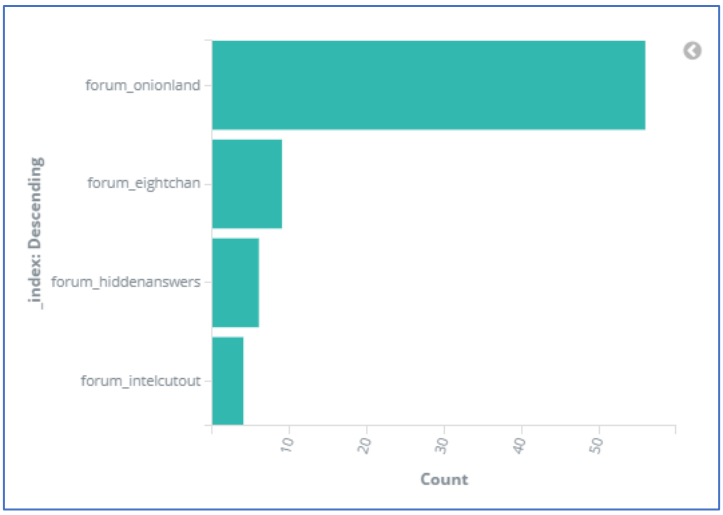

Figure 2: Search results by average of 10, by forum.

Comprehensively looking at all forums, and filtering for references specific to shipping to Puerto Rico, basic amenities such as food, water, and medicine were consistent throughout the period of analysis, but exhibited specific spikes in June 2018. Requests to buy food, water, medicine, and general supplies in bulk were the most requested at 500, 300, and 250 individual requests respectively during this time frame (Figure 3).

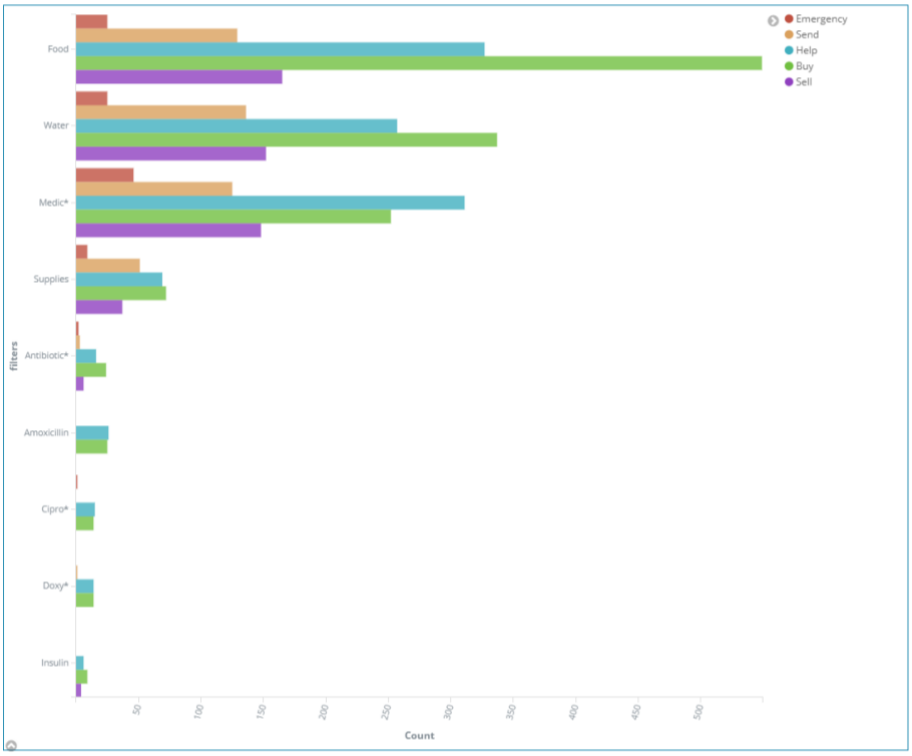

Figure 3: Items for sale or requested in Puerto Rico, June 2018.

When prescription drugs were analyzed across forums during the period of analysis, the occurrence counts shift from those looking to buy to those looking to sell. This phenomenon happens several times during the months following the hurricane but shifts to more posts explicitly offering to sell antibiotics during June 2018. An analysis of news events concerning Puerto Rico during this time reveal most of these spikes corresponding with news reports on 1 June concerning FEMA scaling back operations on the island, and reports on 29 and 30 June concerning citizens losing FEMA provided housing and stores of bottled water being stranded in airports (FEMA, 2018) (Figure 4). Charts were condensed by moving averages of 10, meaning the large spikes in June report nearly 300 requests.

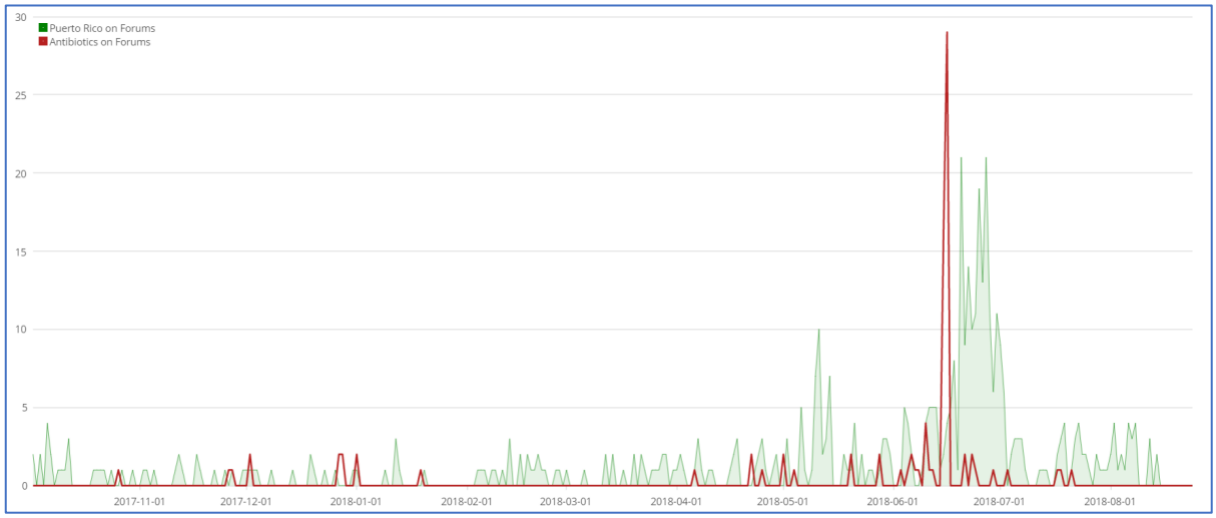

Figure 4: Antibiotic buy/sell spikes, by average of 10, on Dark Web forums in June 2018.

DISCUSSION

Because Dark Web does not possess multiple comprehensive search engines, and because items can be sold in a variety of places, compounded by the fact that drug market sites do not publicly discuss sales locations, it can be difficult to identify information in this environment that signifies a problem in long-term disaster recovery. To capture sales information, particularly geolocated data, different technology capture mechanisms must be employed when scraping drugs market sites. At the time of this writing, there were 59 recognizable drug markets either on or offline (Dark Web News, 2019). Since drug markets are effectively a moving target where their site addresses change as they add mirror sites to escape detection, unless using a specialized software to capture data, researchers must be diligent in discovering new *.onion* addresses where the market may also be operating. However, despite these difficulties the more resilient DWIMs offer technological security and take the burden of payment processing off the vendor, making them the obvious choice for those looking to sell goods in this space. It is likely that less experienced black marketeers may be going to forums due to ease of use.

Within forums, the dynamic is different. Posts stating offers to buy or sell that result in a potential sale also hold further communication in a backchannel, such as a direct messaging functions, and that information is also not available to data scrapers. The utility of analyzing forums lies in the fact that posts can become location specific. Sellers offer to ship to a location and buyers will ask if a product can be ship to a specified location. Public replies to either type of posts also help geolocate a potential sale. In this case, while there was consistent low-level activity of this nature in the time frame following the hurricane, there was an unusual and marked increase in June 2018. In examining both English and Spanish posts concerning these items and recovery efforts, and the specific timing of news versus spikes of activity, it is reasonable to assume that the FEMA news reports precipitated these increases. In the end, the question becomes: if this activity is present within forums, how much more activity can we assume is occurring in the DWIMs, which are now the preferred method for selling and buying. With the technology more recently available to researchers, analyzing DWIMs may now be an option.

In light of this, crisis managers must decide whether the mere presence of an offering or a request for an item, and in what discoverable numbers, may indicate a specific need in an area of recovery. Though the numbers reported in this research appear low, it is important to compare the number of requests to the number of online Tor users. In this case, there was an average of 700+ daily Tor users in Puerto Rico during the data capture period but nearly three-times the number of unique requests for emergency supplies and medicine in June alone. Proportionally,

this number is significant. And while these items may be used to fuel black markets, authorities should keep in mind that these types of markets also operate under general principals of supply and demand, meaning acquiring these items for re-sale is very likely reflective of demand on the ground (Nayeri and Lopez-Pardo, 2005). On an island like Puerto Rico which is governed by the Joes Act restricting who may deliver goods, any diversions from legal supply chains to black markets can have an immediate and noticeable effect.

What is most concerning in this analysis is not the sell/request for prescription drugs diverted from legal channels and funneled to black markets, but the higher number of requests for food and water. Federal authorities can more easily assist with drug diversion activities, but are less likely to help with food and water theft adding to already overwhelmed local police agencies. This information may indicate to crisis managers either an existing or an anticipated need.

How do managers effectively use this information highlights an issue of trust. How trust is extended when the environment is purposefully anonymized and is known to facilitate illegal activity is serious question. Accepting information in this area of the Internet may be akin to the problems social media faced in its early days. New technology and lack of its adoption often breeds mistrust (Tapia et al, 2011) (Tapia et al, 2013). Crisis managers may consider this type of information as ambient, meaning they could use this information contextually to supplement on-the-ground knowledge of existing conditions. Comparing Dark Web posts to Surface Web social media may help further illuminate whether there is true on the ground need or help legitimize data from Dark Web as many assumptions must be made about information derived in this environment.

Lastly, where Tor Network is available, novice black marketeers will not remain so permanently. As novice vendors become more comfortable with the technology and the environment, they are less likely to remain with forums and move to DWIMs over time, thus highlighting the need for more crisis research on the Dark Web.

CONCLUSION AND LIMITATIONS

Data for this pilot study was scraped from a small number of sources well after the occurrence of events, so there was no opportunity to re-target search terms or scrape additional sources. Data collection sites included only four forums. Given the number of available markets where location is difficult to ascertain, and the unknown number of forums, future researchers should monitor as many as they can identify. With high proportional results presented in this pilot study, expanding the number of collection sites will very likely yield significantly more evidence. Given the unknown size of the Dark Web and its lack of interconnectedness, it is difficult to know how many sites exist. Some numbers range from as little as 7 thousand to as high as 40 thousand *.onion* sites (Hyperion Gray, 2018). For context, the WWW, even with interconnectedness and robust search engines, is equally unknowable due to its size and estimated to have as many as 1.5 billion (Internet Live Stats, 2019).

Further, despite the posting of sale items or requests to buy with Puerto Rico as the proposed shipping location, any completed sales transaction would occur privately in backchannel communication areas, so whether the sale was completed is unknown. Also, it is not uncommon for markets and forums targeted by government agencies for illegal activities to frequently go offline due to seizure or from being blocked. These sites may reappear after a while on a different *.onion* site, or may be permanently closed, thus data capture is time sensitive in this environment. Since data capture of these markets is now available outside of government circles, examining both forums and illegal markets sites during future events may help determine size and scope of emerging black markets in a given area after a crisis.

As more people adopt anonymous web browsing and as illegal markets continue to flourish, and as researchers develop more tools to safely and efficiently navigate this environment, the Dark Web yields tremendous potential in crisis research in the context of information systems. Researchers with knowledge of this environment knowing where and how to target data, opens potential new research opportunities in areas of: GIS, Social Media, Logistics and Supply Chain Management, Privacy, Healthcare, and Community Engagement.

ACKNOWLEDGEMENT

Data for this research was derived using a platform provided by a US-based company who monitors Dark Web activity for commercial and government clients, as such, this company wishes to remain anonymous.

ABSTRACT

Although they can make a significant contribution to crisis response and management, citizens tend to be underestimated and under-integrated by official crisis responders. There is a necessity to take citizen contribution into crisis management tools, both for the information they can provide (*information-focused volunteers*) and the actions they can carry out (*action-focused volunteers*). Therefore, professionals need to be aware of the diverse ways citizens can help them to manage a critical situation: obviously by improving the situational awareness, but also by spontaneously performing tasks to meet specific needs on the ground.

After presenting the RIO-Suite software, a crisis management tool based on collaboration of stakeholders, this paper suggests ideas about how to make the most of action-focused volunteers to improve the orchestration of the crisis response. Given a volunteer action, four possible decision types are identified: Ignore, Stop, Consider and Support, and their consequences on 1) the crisis response and 2) the collaboration process are presented.

Keywords

Citizens, Volunteers, Integration, IT Solution

INTRODUCTION

Information and Communication Technologies (ICT) and social media drastically changed the way information is shared and structured in times of crisis (Alexander 2014). Thanks to these powerful tools that give them a voice, citizens are becoming more and more influent in crisis situations. Their participation is fostered, and the concept of volunteerism in crisis situations is broadened, to include emergent unaffiliated citizen initiatives (Stallings and Quarantelli 1985; Whittaker et al. 2015). More than simple information sources, they sometimes act directly on the ground, or use social media as their own crisis management tools (to organize the response, exchange information, communicate about their actions…). Sometimes formally organized as official helping groups, sometimes acting independently, spontaneously and with unpredictable skill levels, citizens play heterogeneous roles, and the volunteer behaviors are many and varied.

With such a diversity of new unconventional actors to take into account, some important challenges are rising up. Among them, the question about the collaboration between official crisis managers and citizens. Indeed, among the profusion of volunteer types in crisis situations, some emergent groups tend to be more difficult to understand and to manage than traditional crisis management stakeholders. Official crisis responders must be aware that unsolicited volunteers will always show up during crisis events (der Heide 2003). Thus, there is a definite need to

integrate social media data and volunteer initiatives in crisis management tools to improve the situational awareness and take more appropriate account of citizens' help (Vieweg et al. 2010; Yin et al. 2015).

Considering cooperation and communication of stakeholders as keys to crisis management efficiency, RIO-Suite is a suite of tools that aims to provide decision makers with a visual model of situation and a computable collaboration process model to orchestrate the crisis response. However, in its current stage of development, the only stakeholders taken into account by the software are official crisis responders. Thus, given the diversity of contributions that citizens can bring to the crisis response, the software development is now focused on broadening its scope to less formal stakeholders, aiming to be able to make the most of volunteer initiatives, and thus to support a collaborative answer to the crisis.

After studying the current status of citizens in crisis management, this paper will present the software RIO-Suite, which aims at integrating citizen initiatives into the situational awareness and the crisis response processes. Then, it will present the early stages of thinking regarding the integration of volunteer initiatives into the software. For the research presented in this paper, it is important to keep in mind that the goal is not to change the way citizens react to a crisis, but to help decision makers to understand volunteers' behavior on the ground, and be able to take decisions regarding how this behavior could improve the response.

LITERATURE REVIEW

Citizen consideration in crisis situations

About cooperation between professionals and citizens, Reuter et al.'s communication matrix for a social software infrastructure (2011) presents the current communication paths between official crisis response organizations and ordinary citizens (see Table 1). In some ways, professionals go no further than just picking information from social media (case (a)), and providing information or safety instructions to citizens (case (b)) through these tools.

Table 1. Reuter et al.'s (2011) communication matrix for a social software infrastructure

Sender \ Receiver	Organizations	Citizen
Organization	(d) Inter-organizational crisis management	(b) Citizen communication
Citizen	(a) Integration, aggregation and validation of citizen-generated content	(c) Self-help communities

As this matrix is focused on communication, it does not give a comprehensive point of view on the current cooperation considerations between professionals and citizens. In general, official crisis responders have preconceived ideas regarding citizen behavior. In a disaster, when by definition the resources and capacities of official crisis responders are insufficient to handle the needs, professionals tend to treat citizens as an unwanted nuisance (Glass 2001). They often establish a physical and psychological perimeter around the event, to keep the public out. This is what Glass (2001) calls the "yellow-tape" effect.

However, many research works regarding volunteers' role in times of crisis have shown that citizens can be much more than just senders and receivers of information (Glass 2001; Scanlon et al. 2014; Wenger et al. 1985). Although it is believed that the typical reaction of an ordinary citizen to a crisis situation is shock, panic, stress and disorganization, several social science studies have demonstrated that these responses do not represent the reaction of the majority of disaster victims (Perry and Lindell 2003). Several examples of crisis situations show how citizen groups can organize themselves in times of crisis, whether it is on the ground (Scanlon et al. 2014) or online (Eriksson and Olsson 2016). Thus, being aware of all these citizen initiatives to improve the situational awareness and the crisis response remains an important challenge that professionals have to cope with (Scanlon et al. 2014).

Citizen contribution in crisis response

The positive value of citizen organization and crowdsourcing

Several studies show how social media can be a powerful tool for communities to build disaster resilience (Dufty 2012; Rizza and Pereira 2014). Sometimes used as an alternative communication channel to improve the information responders have regarding the situation (Vieweg et al. 2014), sometimes used as a backchannel when

traditional communication channels are out of service (Sutton et al. 2008), sometimes used by citizens to provide psychological first aid, or foster solidarity and ethics of care (Rizza and Pereira 2014; Taylor et al. 2012)... Citizens appropriate social media in many ways to meet their needs. A variety of examples in the literature and related to several crisis contexts describe the many ways ICT in general have been used, and sometimes taken into account by professionals. To name a few, we can talk about the Facebook groups created and used by citizens to share and structure information regarding victims after the 2011 Genoa floods (Rizza and Pereira 2014), or the significant impact of crowdsourcing (Horita et al. 2013; Meier 2013) such as the 2.3 million people using the Tomnod[1] website to find the Malaysian Airlines flight MH370 (Fishwick 2014).

Even outside of social media, several examples show the organization that citizens can demonstrate on the ground, when they are faced to a crisis situation. Indeed, unlike what is shown in "disaster" movies, novels and press coverage, most citizens respond constructively and rationally to the crisis by addressing their needs with the most effective mobilization of the resources in their possession (Perry and Lindell 2003). Several examples of such behavior are given by Scanlon et al. (2014), highlighting how ordinary people can play a relevant and important role in disaster response.

Still some challenges to cope with

Although the contribution of citizens in crisis situations is convincing, challenges remain, particularly through the integration of social media into crisis management processes. According to extensive research on the subject, social media integration rises challenges both on technical and social aspects (Crawford and Finn 2015).

On the one hand, we can cite the data volume, quality, trust and format challenges, that need powerful algorithms to extract relevant data from a diversity of sources (Alexander 2014). To quote Goolsby (2009), one might say that finding useful information during a major event is "a little like panning for gold in a raging river".

On the other hand, beyond digital divide and access to information issues (Easton 2014), social media use to manage a crisis can lead to rumor propagation, panic or rise several ethical challenges, such as privacy or governance concerns (Rizza et al. 2014; Watson and Finn 2013).

Attempts to integrate citizens

From information gathering to crowd tasking: a variety of tools to benefit from citizen contribution

Several research projects have already taken the first steps towards the integration of citizens into the crisis response. Regarding social media data, a multitude of research projects are focused on gathering, filtering, analyzing, and interpreting data from social media to improve the situational awareness. Among them, we can present Aupetit and Imran's tool (2017) to help official crisis responders to monitor social media data and find critical information regarding the situation. Working closely with an American 9-1-1 call center, Grace et al. (2019) compare several social media data filtering methods to improve the situational awareness in local areas for emergency managers.

Outside of social media, several tools also tend to help crisis management organizations to get closer to the citizens and take advantage of their potential help. For example, the ISAR+ European research project[2] aims to make the most of ICT by developing a platform to empower citizens and Public Protection and Disaster Relief (PPDR) organizations in online and mobile communications (Flizikowski et al. 2014). For example, Auferbauer et al. (2015) present RE-ACTA, a tool under development which aims to selectively distribute tasks to a crowd of volunteers, resulting in a specified form of crowdsourcing: *crowd tasking*. However, although crowd tasking could be relevant for a certain type of volunteers wanting to play their part in the crisis management, some spontaneous unaffiliated forms of volunteerism will always remain independent, and for such types, attempts to command and control their tasks may be misguided and counterproductive (Whittaker et al. 2015).

Among the already deployed IT solutions to make the most of citizen contribution in times of crisis, several applications tend to register volunteers to be able to task them when needed. For example, *PulsePoint*[3] or *Staying Alive*[4] are two mobile applications aiming to alert the closest CPR-trained citizens and localize the closest Automated External Defibrillator (AED) in case of cardiac arrest emergencies. In a broader scope, the Facebook Safety Check aims to help people to declare themselves safe, provide local assistance or connect to providers in

[1] https://www.tomnod.com/
[2] https://www.zanasi-alessandro.eu/projects/isar/
[3] https://www.pulsepoint.org/
[4] https://www.stayingalive.org/

case of emergency or disaster. In a more indirect way, crowdsourcing-based tools such as Waze[5] can also help professionals to get information or modify the road traffic in a crisis situation, and thus benefit from the crowd contribution to improve the crowd geographic distribution.

The potential of Intermediary Organizations

Following the idea that collaboration from the officials' perspective is hampered by a lack of an intermediary person to create a link between emergent groups and public authorities (Stallings and Quarantelli 1985), Zettl et al. (2017) defend the need of *intermediary organizations* to bridge the coordination gap. After presenting a long list of research projects which aim to fill this gap, they present two tools to support this concept of intermediary organizations: City-share, a situated public display application, and Security Arena, an inter-organizational platform. The purpose of these two crowd-based tools is to foster collaborative resilience between professionals, organizations and emergent volunteers.

The objectives of such tools are in line with the current status of the Volontaires Internationaux en Soutien Opérationnel Virtuel (VISOV) association, the French-speaking equivalent of the Virtual Operational Support Teams (VOST). Indeed, the VISOV association has signed agreements with official crisis management institutions in France, and its volunteers act as an intermediary link between citizens sharing information through social media, and official crisis responders. When a crisis occurs, the VISOV are 'activated', and they use collaborative tools to filter and share useful social media information to professionals.

Moreover, even in less formal contexts, many crises have seen the emergence of organized groups of citizens who remain in place after the events, building organizational networks and strengthening community resilience. For example, we can think about the Facebook group "Angeli col fango sulle magliette" in Genoa (Rizza and Pereira 2014), or the networks *Second Planet* in Frankfurt and *Train of Hope* in Vienna (Zettl et al. 2017), all of them created to address specific needs during a crisis, and remaining several years after to keep sharing crisis-related information.

Professionals and citizens: a need to cooperate

Organizations in charge of emergency management need to realize that involving citizens does not interfere in their protocols by making them less efficient (Díaz et al. 2013). Actually, according to Benaben et al. (2016), collaboration and coordination of stakeholders are key requirements of crisis management. Thus, by improving their cooperation, professionals and citizens could both be aware of others' needs, and thus contribute together in a more effective way to (i) improve the situational awareness and (ii) organize the crisis response.

However, to date, there is a lack of frameworks to create a comprehensive and manageable process to ensure the most effective and safe response with the aid of spontaneous volunteers (Orloff 2011). Thus, more adaptive and inclusive models of emergency and disaster management must be developed to integrate these volunteers into the response and harness the capacities and resilience that exist within and across communities (der Heide 2003; Whittaker et al. 2015).

RIO-Suite, a suite of crisis management tools based on collaboration between stakeholders

To provide professionals with the best possible understanding of the situation all along the crisis response, and to orchestrate the tasks carried out by stakeholders in real time, researchers at IMT Mines Albi's Industrial Engineering Centre developed the RIO-Suite platform. This platform is based on a *metamodel* (i.e. a set of generic concepts and their relations) for knowledge management in crisis management, presented by Benaben et al. (2016). Thanks to a diversity of data sources, such as sensors, official crisis management procedures, or social media, the RIO-Suite software aims to *instantiate* (i.e. identify) concepts of the metamodel in the crisis situation. In other words, the goal for the software is to provide the most comprehensive digital representation of the situation on the ground, to then be able to deduce the most appropriate collaborative behavior schema and then orchestrate it as the crisis response.

[5] https://www.waze.com

This metamodel (see Figure 1) consists of a *Core* part, representing the concepts presents in any collaborative situation, and four packages that are an extension of the core concepts, dedicated to crisis management situations:

- **The Partners** (left part): these concepts represent the stakeholders, their capacities and their resources, that might be needed during the crisis response.
    - E.g.: A firefighter (*actor*) has the ability to extinguish a fire (*service*) with a fire hose (*resource*).
- **The Context** (top part): these concepts are all the stakes and contextual elements that can take part in the crisis situation.
    - E.g.: A museum (*good*), the visitors inside it (*people*) or a regional nature reserve (*natural site*) might be affected (damaged or injured) by an intrinsic risk of flooding (*risk*) if they are present in an area liable to flooding (*danger*).
- **The Objectives** (right part): Whereas given a geographical area we might be able to know the *Partners* and *Context* concepts, the *Objectives* are concepts given by the crisis itself. These concepts represent all the elements that define the crisis and can have an effect on the events.
    - E.g.: A starting fire (*fact*) and a fragilized building (*emerging risk*) must be considered as objectives (*mission*). Besides, the wind or the rain will change the seriousness of the fire (*gravity factor*) while a bad social climate may change the nature of the crisis (*complexity factor*).
- **The Behavior** (bottom part): This package is slightly different from the three previous ones. It defines the rules to orchestrate the collaboration in the crisis management processes. This package is inspired by the Business Process Model and Notation (BPMN) standard for process modeling.
    - E.g.: The orchestration process (*collaborative process*) can be composed of a list of actions (*task*) carried out by organizations (*partner pool/lane*), arranged in a specific order (*sequence flow*), and assisted by the flow of information (*message flow*).

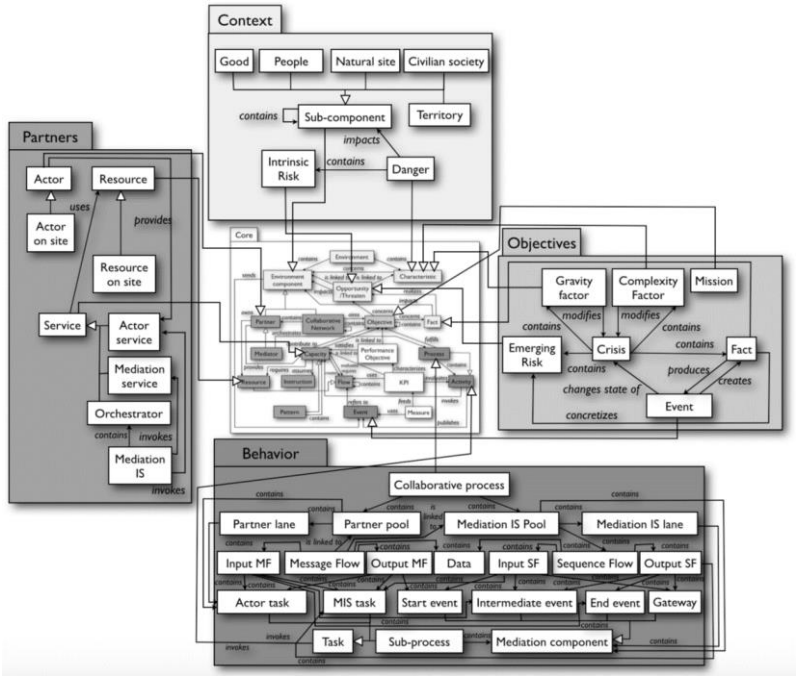

Figure 1. The RIO-Suite metamodel for knowledge management in crisis management (from Benaben et al. (2016))

Given all these inputs, the software is currently able to provide two outputs:

- A **Situational Model** with 1) a map of the stakeholders and the capabilities that they may need to mobilize, and 2) a cartographic vision of the issues at stake;
- A **Collaboration Process** to orchestrate the crisis, i.e. give advice to crisis managers regarding who should do what, at what time.

An overview of the input and output elements of the software are presented in Figure 2. To date, this model keeps being improved, so that it can be used for specific cases of crises, and to be sure it can embrace all types of collaborations in crisis management.

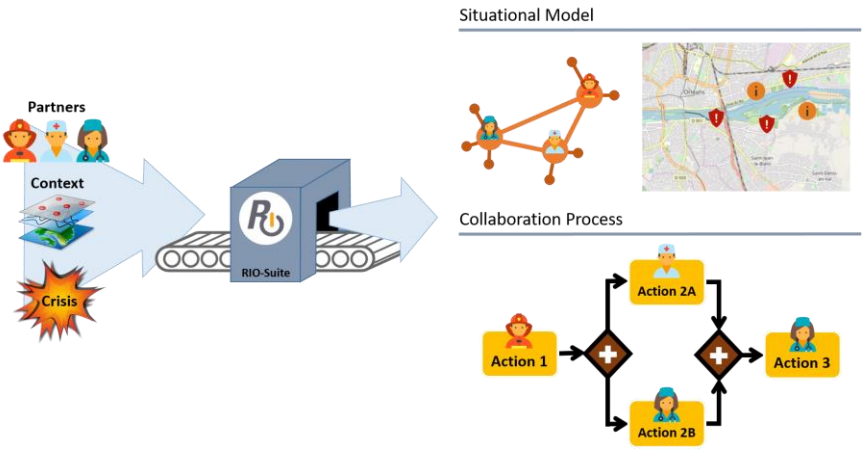

Figure 2. The current input data and output models of RIO-Suite

In the current state of development of the software, only official crisis responders, their skills and resources are taken into account as "Partners". To meet the definite need to integrate citizen initiatives into crisis management tools, the research is now focused on the volunteers, and seeks to make the most of their contribution.

PROPOSAL – INTEGRATING INITIATIVES TO SUPPORT CITIZEN-PROFESSIONAL COLLABORATION

Making the most of citizens' contribution: improve situational awareness and understand action

To capitalize on citizens' contribution in a crisis situation, the first need is to identify this contribution. In the literature, a large amount of research has been done to classify and categorize volunteers in crisis situations, but most of them were focused on the social structure of such initiatives. Distinguished between *Old* and *New structure* by Dynes (1970), *Individual* and *Organized* by Shaskolsky (1965), *Emergent* and *Organizational* by Wolensky (1979), *Formal* and *Informal* by Cnaan et al. (1996) and Whittaker et al. (2015), this social structure in which the volunteer initiative takes place tends to define its level of formalization, or its reliability from the officials' point of view.

Another strong distinction that appeared more recently between forms of volunteerism is related to the emergence of new initiatives fostered by the advent of ICT and social media in our society. Called *digital volunteers* by Whittaker et al. (2015), *virtual volunteers* by Reuter et al. (2013) as opposed to *real volunteers*, these emerging groups are identified by the communication channels they use rather than the initiatives they take.

However, among the diversity of citizen initiatives, from a group of people moving rubble in search of victims and an individual volunteer sharing a picture on Twitter, an important distinction that appears is that they don't provide all the same elements to the crisis response. While some volunteers perform or manage actions on the ground intending to help crisis responders or address personal needs, other ones share or organize information about the unfolding crisis, that might improve the situational awareness. In other words, when some volunteers are focused on the action, those focused on information help crisis responders to understand the first ones.

Thus, when looking at the RIO-Suite outputs, two ways of taking into account the citizen contribution appear:

- The *information-focused volunteers* will contribute to the situational model, by helping to instantiate new concepts of the metamodel. Thanks to the many information channels they use, from traditional ones to social media or other ICT, understanding the information shared by citizens can help to find new stakes, to identify a risk, or give insights on the progress of the crisis. This is in line with a profusion of work on the subject of social media data processing (Grace et al. 2019; Vieweg et al. 2010; Yin et al. 2015).
- The *action-focused volunteers* will contribute to the collaboration process, by carrying out actions thanks to their skills and their resources. Whether in a constructive or destructive way, these citizen initiatives will tend to change the situation on the ground, and might be detected by the *information-focused volunteers* or other stakeholders or tools (Ludwig et al. 2017; Neubauer et al. 2013).

By setting aside the method of identifying these *action-focused volunteers*, the next steps in this article will aim to discuss decision types regarding their potential integration into the crisis response process.

Towards integration of action-focused volunteers

From this objective, we can identify two main areas of research, that will be detailed below:

- What status should a volunteer initiative take?
- How to update the collaboration process with an identified initiative?

Status of the volunteer initiative: parameters influencing decision-making

Given a group of people moving rubble to find victims after an earthquake, what parameters can make the decision-makers change from wanting to stop them doing this action to wanting to provide them tools to improve their efficiency? Such a decision might rely on a list of implicit or explicit parameters. Here are some possible elements of influence on the decision:

- The **reliability** of the initiative can be a deterministic element for the decision making. This element includes the criteria of affiliation and skill level, which can be closely linked to each other in some cases. Indeed, it will be easier for professionals to cooperate with a volunteer registered with an official organization such as a volunteer firefighter whose skills are known, than cooperating with spontaneous unaffiliated volunteers with uncertain skills;
- The **ethical and social aspects** that integrating a volunteer initiative might represent, and the risk that this integration might represent for the volunteer him/herself;
- The **variety and volume of the needs to address**: depending on the size of the crisis and its intrinsic characteristics, professionals might estimate that they have enough resources to address all the needs or not;
- The **professionals' competences and resources**: whereas the former parameter defines the needs created by the events, the diversity and number of official responders and the scope of their skills will define their control of the situation;
- The **professionals' attraction and experience** with the use of social media and their openness to citizen contribution.

Such parameters might be deterministic for professionals to decide whether an initiative should be taken into account, ignored or stopped to improve the response. Moreover, all along the crisis response, the unfolding events might change the implicit value of these parameters, and consequently change the way professionals perceive a volunteer initiative.

Update the collaboration process from citizen action

Secondly, how can a citizen action influence the crisis management process? Indeed, as the software creates a process model describing collaborative behavior to respond to the crisis, if the goal is to have an agile management of this process, everything that happens during the crisis should be taken into account. In such a context, with the means and skills in their possession, citizen contribution for the response can be constructive, neutral or even destructive. For example, we can imagine that citizens can either start by themselves to fulfill a task that was assigned to other partners, or act in the opposite way and unintentionally create new tasks that will need to be accomplished by other partners. In both cases, crisis managers need to understand the way citizens behave, to be able to instantiate a new task or a new sub-process, or change the way tasks are assigned to stakeholders.

An overview of the prospective improvements that citizen integration can bring to RIO-Suite and its outputs is presented in Figure 3. Volunteers, whether they are known in advance or not, can be considered as additional partners. Thus, knowing their skills, resources and tasks in progress could improve the common operational picture (i.e. situational model) and update the collaboration process in several ways.

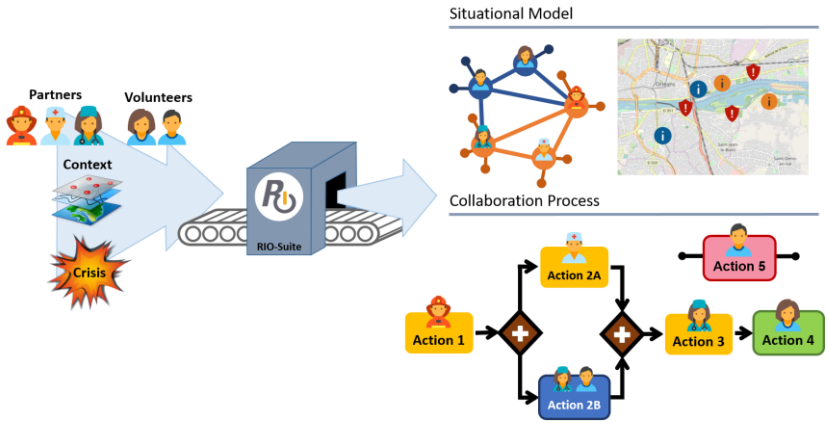

Figure 3. The target situation after taking into consideration the citizen initiatives into RIO-Suite

Different types of decision and their respective consequences

Given the different parameters that can influence the decision making regarding a citizen initiative, four types of decision have been identified, listed below with examples of crises during which such decisions were taken or should have been taken:

- Ignore
  - E.g.: During the 2015 migrant crisis in Europe, hundreds of refugees arrived daily by train at German and Austrian train stations. Spontaneous groups of volunteers mobilized to provide relief to refugees. Suffering from a lack of clear political directives, humanitarian organizations were bypassed by citizens, resulting in a chaotic situation and pointing out the lack of institutionalized cooperation (Zettl et al. 2017).
- Stop
  - E.g.: Following the 1999 Golcuk earthquake in Turkey, a traffic jam of 32 kilometers of spontaneous aid volunteers blocked professional aid workers and rescue vehicles to get to the disaster location (Helsloot and Ruitenberg 2004). Identifying and finding ways to stop this mass movement could have helped to save lifes.
- Consider
  - As it will be explained later, the fact of *considering* a citizen initiative will not have any consequence on the crisis response on the ground, but it will result in incorporating the initiative process into the global collaboration process. In other words, *ignoring* and *considering* a citizen action will both have no impact on the ground.
- Support
  - E.g.: Soon after the Swissair 111 crash into the Atlantic Ocean in 1998, fishermen near the crash location immediately headed out to sea to search for survivors. Upon arrival at the accident site, the Royal Canadian Navy ship asked them to line up and help them searching systemically the area (Scanlon et al. 2014).

These types of decision will have different consequences, both in the crisis response and on the collaboration process, as presented in Table 2.

Among these four decision types, the easiest one to put into practice will be to *ignore* the identified citizen behavior. Indeed, this means being conscious that this behavior is happening, but doing absolutely nothing regarding it, both on the ground and on the crisis management process. However, being the easiest decision to take does not mean this is the smartest one, because it may mean missing a relevant opportunity for the crisis response, as it has been the case during the migrant crisis in 2015 (Zettl et al. 2017). The fact of *considering* a citizen initiative aims at letting them act, without trying to change their action or supervise them.

Although the professionals' intention might be completely different, the difference between *stopping* and *supporting* a citizen initiative is slight. Indeed, these two decisions may result in new tasks for professionals (responders or mediators), resource mobilization, and may bring several updates to the collaboration process. Further research work needs to be done to understand citizens' motivations when acting during a crisis, to understand which impact *stopping* or *supporting* them could have on their behavior.

Table 2. The four decision types regarding citizen initiatives, and the changes it brings to the response and to the RIO-Suite collaboration process

Decision type	Potential change in the crisis response	Potential impact on the collaboration process
Ignore	None	None
Stop	• Mobilize official crisis responders, their resources and their skills • Volunteers switching to another task • Anxiety, distrust from the population • Increasing complexity of the crisis	• Adding professional tasks
Consider	None	• Adding the current volunteer tasks
Support	• Mobilize official crisis responders, their resources and their skills • Dedicate resources to the citizen action	• Adding the current volunteer tasks • Removing, Updating or Adding professional tasks

DISCUSSION AND CONCLUSION

Given the previous research on the subject, a fifth type of decision could be added: *crowd tasking*, as some tools presented in the literature review do. As this decision aims to pre-register volunteers and control citizens' behavior in the crisis response, it doesn't appear in the scope of objectives of RIO-Suite so far.

The four decision types presented in this article, and the parameters of influence on the decision-making might be closely correlated. For example, given a volunteer initiative, the gravity or complexity of the crisis might change the decision professionals will make.

Among the parameters of influence on volunteer integration, some tend to increase the relevance for professionals to do it: the reliability of the initiative, the needs generated by the crisis, and the ethical and social possibilities for integration. The remaining parameters, the professionals' competences and resources, and their attraction and experience with social media might be limiting to make an opportunity happen: the more professionals are overwhelmed, the less time they will be able to devote to the integration. These first hypotheses of correlation between the parameters and the decision types are presented in Figure 4 and will be discussed in future research work, based on case studies, interviews and observations.

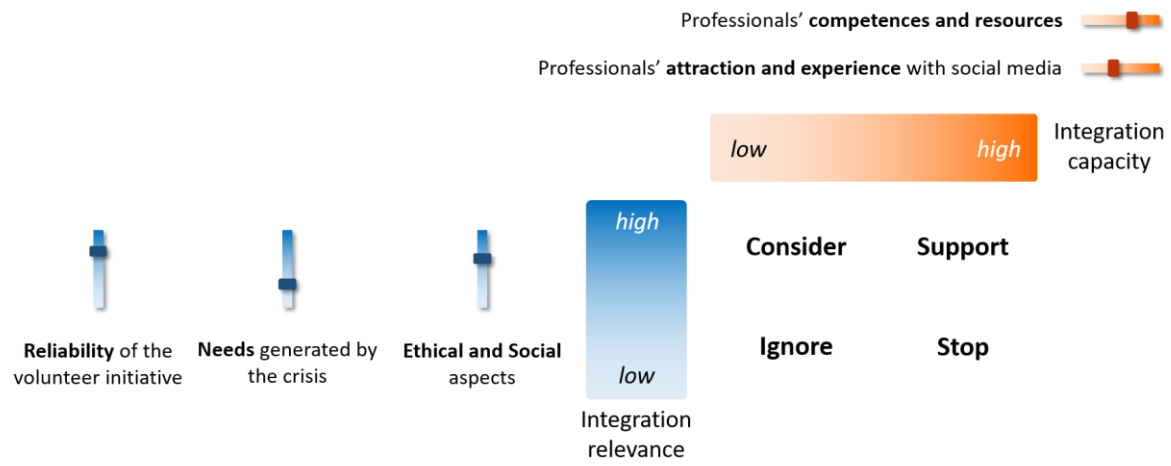

Figure 4. First attempt of framework for correlation between influence parameters and decision types

To summarize, this work in progress paper presents (i) the global parameters that can influence the crisis responders' decision making, and (ii) the four identified decision types regarding citizen initiatives. Future research work will focus on studying the correlations between (i) and (ii).

With the idea of integrating volunteers into RIO-Suite to foster multi-stakeholder collaboration, several works can be done for the future of this project:

- Test the robustness of the model by confronting it with specific case studies, interviews and observations;
- Find potential weaknesses of this model and suggest changes to make it more inclusive for all types of events;
- Propose possible additional layers to specialize it to the integration of citizens and their tools

Regarding the detection of the *action-focused volunteers*, social media are one of the few ways to detect such initiatives. Thus, when making decisions regarding volunteer integration for the crisis response, it should be kept in mind that the only volunteers that can be detected are those whose action can be shared through social media or other ICT. In addition, outside the crisis management unit, decisions taken by professionals on the ground must be taken into account in the crisis management process.

ABSTRACT

This paper presents the INSITU research project initiated to provide a systematic approach for effective sharing, integration and use of information from different sources, to establish a common operational picture (COP) and shared situational understanding among multiple actors in emergency response. The solution developed will provide an interactive map display, integrating harmonisation of terminology and collaboration support for information sharing and synthesis. The enhanced COP will also support evaluation and learning from exercises and incidents. The project involves close collaboration with emergency management stakeholders in Norway, for requirements analysis, participatory design, and validation of project deliverables. The research will improve information sharing and decision support in emergency operations centres, which will contribute to improve societal resilience through more effective response capability.

Keywords

Common operational picture, situational awareness, collaboration support, geographic information systems, terminology harmonisation.

INTRODUCTION

A recurring challenge in emergency response is to quickly be able to collect and integrate relevant information to form an initial shared understanding of a crisis situation, and to dynamically update a common situational picture of the evolving incident (Laakso and Palomäki, 2013). The core of this challenge is to be aware of the information needs of the collaborating partners, effectively share relevant and timely information to the right receivers, and similarly - to know what information is available to be requested (Petrenj et al., 2012). Evaluations from several incidents and large-scale exercises document challenges of ineffective information sharing between involved responders and lack of a common operational picture (COP) (e.g., Bunker et al., 2015; Steigenberger, 2016; Wolbers and Boersma, 2013).

While an increasing amount of digital information sources are available, the information landscape remains fragmented with lack of interfaces among the different sources and a varying data quality. Digital map services provide a key resource for developing a COP. However, the lack of standardisation of tools and symbols in use for crisis maps limits the possibility for integrated use for sharing incident and threat information across collaborating entities (JRCC, 2018). Further, as highlighted by the Norwegian Ministry of Justice and Public Defense (Stm. 10, 2016-2017), different terminology in use by the different responders for depicting the same concepts and events also represents a challenge for information sharing and shared situational understanding. Finally, there is currently limited support for visualising and sharing a COP as a basis for systematic learning from incidents and exercises.

On this basis, we have initiated a research project titled "Sharing Incident and Threat Information for Common Situational Understanding" (INSITU), funded by the Research Council of Norway. The goal of this project is to contribute to effective sharing, integration and use of available information from different sources, to establish a COP as a basis for shared situational understanding. Reaching this goal requires systematic analysis of current practices and needs for information sharing, developing suggested standards for map symbols and a common map-based interface, supporting harmonisation of crisis terminology, and developing methods and tool support for collaborative information synthesis. These research challenges are currently being addressed by an interdisciplinary team of experts in emergency management, information systems, geographic information science and systems (GIS), terminology harmonisation, and computer science. The project is led by the Centre for Integrated Emergency Management (CIEM) at University of Agder, Norway. Other academic partners are the Norwegian University of Science and Technology (NTNU), Department of Geography, the Center for Advanced Research in Emergency Response (CARER) at Linköping University, Sweden, and the Interoperability in Extreme Events Research Group, The University of Sydney Business School. The project consortium also includes two companies: Tingtun AS is a developer of methodology and software for terminology harmonisation, and One Voice AS is supplier of the leading crisis management system (CIM) in Norway. End user involvement is secured through the participation of the emergency preparedness office of the County Governor in Agder as a partner in the project, and there is a broad representation of core emergency management stakeholders in the project reference group.

To address the above-mentioned challenges, a core focus of this project is to strengthen the collaborative process in establishing a COP and shared situational understanding. This will include contributing to harmonisation and standardisation of crisis-related terminology and map support, and procedures for effective collection and sharing of relevant information. The INSITU project seeks to answer the following research questions:

- Which information elements are critical to share in scenarios involving collaboration between several emergency responders, and how and in what formats can this information be accessed?
- What are the perceived needs for harmonisation of terminology in use between the different responders, and how can such harmonisation be supported?
- How can geographic resources and interactive map-based interfaces be used more effectively to support collaboration and shared situational understanding, e.g. through standardisation of map symbols and functionality?
- Which method and tool support is required for effective synthesis and presentation of information from different sources, as a basis for common situational understanding and for evaluation and learning from incidents?

RELATED RESEARCH AND PRACTICE

While former research has provided important contributions in the form of concepts, architectures and tools for supporting situational awareness and COP (e.g., Cordeiro et al., 2015; Luokkala et al., 2017; Stiso et al., 2013; van Dijk, 2015), experience from practice shows that developing a shared situational understanding remains challenging. For example, the Norwegian National Forum for Exercises and Evaluation in 2018 hosted a seminar with Norwegian emergency responders for discussing current challenges in establishing a COP and shared situational understanding. Among the barriers discussed here were inefficient information sharing due to lack of knowledge on the information needs of the different response organisations, and problems with interoperability of existing support technologies being used by the different responders. The responders agreed that rather than aiming for developing a joint, national COP supporting different scenarios, what is needed is an information infrastructure supporting COPs for specific scenarios that can be adapted to the context of the local emergency responders.

Bunker et al. (2015) discuss how existing solutions for supporting a COP are not able to represent "the range of perspectives, options, facets and changes that often challenge responders" (p. 52). Further, there is currently no

universally agreed upon definition of a COP. The International Forum to Advance First Responder Innovation (IFAFRI, 2018) also lists as one of four capability gaps the first responders' ability to collect data from traditional (e.g., weather maps, sensor readings) and nontraditional (e.g., social media) information sources and integrate this data into a user-configurable COP.

As an illustration of the problem, according to the rescue services personnel working at command and control level during the extensive forest fires in Sweden in summer 2018 a major challenge inhibiting fast decision-making and response was the lack of digital maps and other digital tools, e.g. for information sharing and weather forecasts. Thus, the Swedish rescue services had to rely on whiteboards with information and forecasts that quickly became outdated.

The INSITU project focuses on three core elements in supporting a common situational understanding: 1) integrated map services; 2) harmonisation of terminology; and 3) collaboration support for information sharing. A brief status on knowledge in these three areas is presented here.

Integrated Map Services

As documented in the recently published Handbook for the Norwegian Rescue Services (JRCC, 2018), no common norm exists for map support among the different first responders and public emergency stakeholders. A range of different "platforms" for map services is currently in use (e.g., ArcGIS, Avinet, Basecamp, GIS-link, Locus TransMed, Locus TransFire, Terra and Vision). However, interviews with emergency responders show that none of these services are considered to fully cover their needs. Furthermore, the use of symbols and colours is not fully standardised, and good drawing functionality is not fully incorporated. There are also local variations in the services utilised within each sector. This limits the possibilities for effective information sharing based on a common map interface, and points to a need for more standardisation of map support that also allows for integrating data from different sources (JRCC, 2018).

While formalised map symbol standards for emergency contexts do exist, these have not been widely adopted by map providers (Robinson et al., 2013). A main goal for map displays is to design effective representations of spatial information using cartographic symbols. Ideally, all users should understand the symbols correctly, quickly, and identically, but this is not always the case. Further problems arise when map users are unable to spend time referring to a legend during the map reading process because the map is used in an emergency situation where response time is critical (Akella, 2009).

A change is needed to encourage the standardisation of symbols for emergency response, and future maps for emergency management must be better adapted to individual user groups. As agencies are obligated to collaborate in their operational practice and emergency scenarios during crisis incidents such as industrial hazards or flooding, an extensive understanding of common scenarios is required to equip a COP map display with adequate and efficient interactive functions. The functions, on the one hand, must efficiently support expert users in their operational tasks, and, on the other hand, cannot make users confused with their multiplicity and complexity. Thus, our research will focus on map usability in both map content and visual controls to make map use more intuitive.

Harmonisation of Crisis Management Terminology

The need for harmonisation of terminology among crisis responders has been recently highlighted (JRCC, 2018). As an example of this challenge, there are at least four different Norwegian terms for an incident site ("åsted", "fareområde", "skadested", "tiltaksområde"). In addition, we have sectorial abbreviations for locations related to an incident site.

This problem is not specific for Norway. Snaprud et al. (2016) have explored the availability of crisis vocabularies in several countries and found that if such resources exist they are generally scattered on different websites, represented in different formats and forms, and not harmonised across sectors.

Examples of resources on process and methodology for terminology harmonisation that we might build on in the INSITU project include: Terminology work - Harmonisation of concepts and terms (ISO 860:2007) and ISO 22300:2018 Security and Resilience – Vocabulary.

Collaboration Support for Shared Situational Understanding

Challenges of effectively sharing information across organisational boundaries for managing emergency situations have been documented in several studies (e.g., Laakso and Palomäki, 2013; Ley et al., 2014). An ethnographic study of disaster exercises in the Netherlands (Wolbers and Boersma, 2013) documents how the coordination process was distorted by the emergent management professionals attributing different meanings to

information. They thus conclude that "information management during emergency response operations is about interpreting information and negotiating its relevance for different professions" (p. 195). Barriers to effective cross-agency communication and information sharing have also been reported in disaster healthcare (Abbas et al., 2018). The related efforts of specifying minimum data sets of essential data elements to be exchanged among the agencies are clearly relevant for our project.

Existing procedures for situational reports provided by the Norwegian Directorate for Civil Protection specify the communication structures and actors involved. However, they do not provide detailed guidelines concerning what specific information elements to share, where to find them, and how to best synthesise and present this information. Research in the area of collaboration engineering focuses on how to develop detailed, easy to use 'scripts' for effectively conducting collaborative processes without a trained facilitator (de Vreede et al., 2009). These collaboration scripts also specify the use of relevant digital tools, and provide support for inter-disciplinary teams in effectively processing and making sense of available information (Lazareva and Munkvold, 2017). In the domain of emergency response, the use of collaboration scripts has been demonstrated to support situational awareness (Appelman and van Driel, 2005).

Finally, there is currently also a lack of shared resources for supporting systematic learning from exercises. Being able to use a COP and an integrated map-based interface also in the evaluation phase, would represent a major improvement in practice.

RESEARCH APPROACH

As depicted in Figure 1, the INSITU project will apply a combination of research methods for addressing the three focal areas in the project as presented in the previous section.

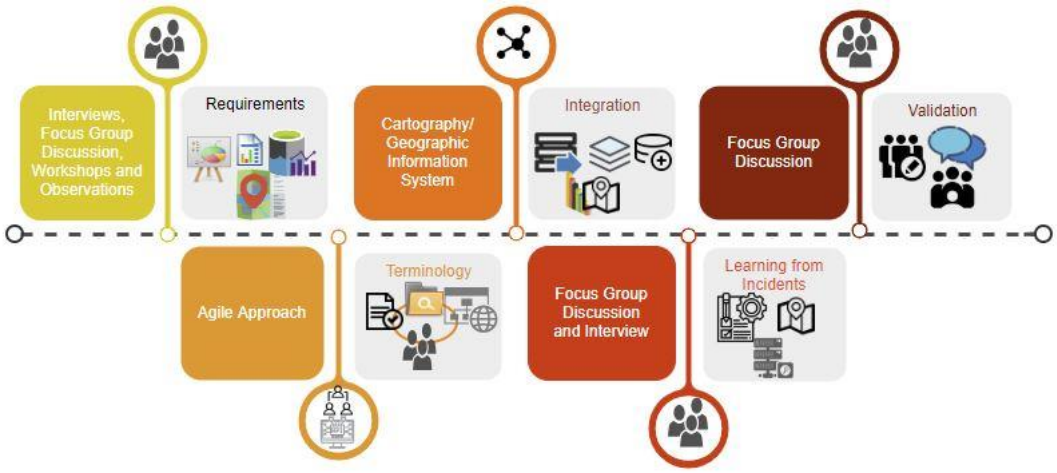

Figure 1. Combined Research Approach

The initial *requirements gathering* will be conducted through focus group discussion (FGD), literature review, document analysis, workshops for requirements elicitation and prioritisation, and observation of emergency exercises. This task will focus on identifying the critical information elements needed to be shared between the involved stakeholders, what information sources are currently being used, and the format of the relevant information. This analysis will explore different types of threats and incidents, as caused by both natural and man-made hazards. The analysis will also consider additional information sources that are not already used, such as sensor data and social media data. Processing such data will then require use of methods for real-time detection, filtering and classification, based on natural language processing, machine learning and visual analytics (Reuter et al., 2018). This task will also scrutinize possible security concerns involved in sharing information between different responders. This will form the basis for design recommendations for a harmonised terminology and standard map symbols and the integration of these in a common map interface. An agile approach will be used, working together with end users in a participatory design process (Sanders et al., 2010), and collecting their feedback throughout the development process.

The methodology for *harmonisation of terminology* will combine a participatory process with a quantifiable justification process as a basis for selecting terms to be included in a common vocabulary. The idea is to compute a justification score for each term as input to the harmonisation discussions. The justifications will include references to external definitions of a concept in a law, regulation, standard, guideline or other prominent

references. The sources of references and possible weights for them will be tested and agreed with the users in the participatory design process. The harmonisation will address both the form and the content of the terminologies. The form will cover how to represent the terminology from the metadata describing it, the terms and their properties including attributes and classifications.

Concerning *integration*, the aim is to integrate various interactive displays into one, consistent map-based interface facilitating shared situational understanding in the different phases of an incident. The resulting interactive tool support will provide users with a map display featuring switchable thematic layers showing standardised cartographic symbols representing critical information elements. The symbols will be retrieved from a shared data repository that is to be designed as a project deliverable. Of critical importance in this task is to avoid sharing irrelevant information that may lead to information overload. Literally, a map-based interface cannot be visually cluttered by a multiplicity of point, line, and area symbols, and at the same time it cannot be overloaded by too many interactive functions. Therefore, the interactive tool support will be developed through a sequence of proof of concept implementations accompanied by rapid prototype assessments with target users, in order to test combinations of various map symbols with particular interactive functions.

Complementing the integrated map support for COPs, the project will develop collaborative scripts detailing information management procedures for collecting, sharing and synthesising information from different sources. These collaborative scripts will specify required information elements, the sources for these elements and how to access them, the procedure for sharing information with other stakeholders (including formats and tools), and how to effectively combine the information elements to support situational understanding. The collaborative scripts will be presented through an interactive, easy-to-use, web interface.

For developing enhanced support for systematic *learning from incidents*, a combination of focus group discussions, review of incident report studies, and After Action Reviews will be conducted. This task will address the need for common information sources supporting systematic learning from exercises and incidents. The integrated terminology, map and collaboration support will be adapted for this purpose. In addition, the possibility of adding functionality for recording and playing back event handling in the common map-based interface will be analysed.

The process for *validation* of project deliverables will be conducted iteratively throughout the project, using process walk-throughs for all project outcomes in workshops, questionnaires, field trials in relevant exercises, and validation in a simulated, realistic environment provided by one of the project partners in the form of an experimental control room facility for crisis management training and tool testing.

PRACTITIONER INVOLVEMENT

As outlined in the previous section, the participatory design process applied in the INSITU project requires close interaction with emergency management practitioners from the initial requirements elicitation to the validation of project deliverables. This involves authorities and associations both at the national and regional level.

Examples of organizations that so far have confirmed their participation in the project reference group include:

- Norwegian Directorate for Civil Protection
- Norwegian Police Directorate
- Norwegian Communications Authority
- Norwegian Radiation and Nuclear Safety Authority
- Norwegian Water Resources and Energy Directorate
- Norwegian Mapping Authority
- Norwegian Public Roads Administration
- Norwegian Defence University College
- Norwegian Fire Protection Association
- Norwegian Fire Academy
- Norwegian Council for Search and Rescue
- The Joint Rescue Coordination Centre, Southern Norway
- Barentswatch (Centre for the Sharing of Sea and Coastal Information)
- The Society of Voluntary Search and Rescue Organisations
- The Language Council of Norway

This broad representation is required for being able to develop useful support for information sharing and collaboration that caters for the needs of the organisations involved. Also, the list demonstrates the shared view on the importance of the research questions addressed in the INSITU project, and provides a good basis for the uptake of the project deliverables among the practitioners.

CONCLUSION

The research presented in this paper will contribute to strengthen the overall resilience of society by providing methods and tool support for developing common situational understanding among different emergency management sectors and units. The INSITU project will develop knowledge that addresses critical shortcomings in today's practice, regarding harmonisation of terminologies in use and interoperability and standardisation of map resources. By this, the project will contribute to improved preparedness, response and learning from experience. Through broad involvement of key crisis management stakeholders in Norway, the project will facilitate knowledge development on practices in the different sectors and increased understanding of the information needs for the tasks and roles involved. The software tools developed and adapted in the project will provide easy access to a harmonised terminology and common map support, for being included in COPs, training material and procedures for inter-sectoral communication and collaboration.

The INSITU project is based on an interdisciplinary perspective, building on knowledge from multiple, related research areas including situational awareness and COP, collaboration engineering, terminology management, GIS and crisis mapping, and human-information interaction. The project will also contribute new knowledge in these domains, through combining harmonised terminology, standardised map support and collaboration scripts for information sharing and synthesis, in an integrated solution for enhanced situational understanding.

ACKNOWLEDGEMENTS

The INSITU project is funded by the Research Council of Norway. We thank the reviewers and Track Chairs for their constructive comments.

INTRODUCTION

The goal of this poster is to introduce the very first steps of a framework to support decision-making during the crisis response step of the crisis lifecycle. Indeed, crisis situations are unstable phenomena by nature and by the effects of the crisis response itself. So, the crisis response is challenged over time: new objectives, new risks, lack of resources, evolving weather conditions, etc. Reacting once events happened to adapt the response is not sufficient enough to provide the agility required by the decision-makers.

Based on the projected effects of the chosen crisis response on a real-time model and several anticipated models of the situation, the proposed framework aims to achieve the last step of the situation awareness approach: the projection of the current situation in the near future. This can enable a proactive on-the-fly agility of the crisis response. The presented idea relies on the main results of the previous research work of two research teams on the agility of the crisis response (Barthe-Delanoë et al. 2018) and the transformation of raw data into a Common Operational Picture (COP) in a context of Big Data (Fertier et al. 2018). The aim is to combine these results to achieve the highest level of situational awareness by supporting proactive agility of the crisis response instead of reactive agility.

METHODOLOGY AND PROPOSAL

Based on a model-driven and event-driven approach, two models of the crisis situation are designed, describing the current situation from two different points of view:

- The *expected model* M_E that depicts the planned and expected situation at time *t* (i.e. what it is expected with respect to the executed actions planned into the crisis response).
- The *field model* M_F that represents the real situation model of the collaboration at time *t*. It can be understood as the ground truth model.

The chosen crisis response is projected on M_E leading to one model with the expected outcomes, called the projected expected model M_{Ep} (as shown on Figure 1), into a reasonable time window until a projected time t_p. The same is done on M_F but with additional variability (regarding weather conditions, traffic, etc.), leading to several models of the envisioned crisis situation, called the projected field models M_{Fp}. To this end, the states of the elements composing the model of the current situation are projected in the near future: partners, services, environment, dangers, risks, etc.

Trends, forecasts and models are crucial to support the proactive agility in order to perform the projection of events and actions: the system can use the combination of weather forecasts, traffic flow models (Poole and Kotsialos 2016), atmospheric dispersion models (Wang et al. 2015), crowd movement models, etc. to feed the projected models. The choice of the relevant simulation models depends on the nature and the location of the crisis: road crisis, chemical plant accident, major flood, hazardous material release etc.

The idea of proactive agility relies on the calculation of the projected distance, named $\partial_p(t_p)$, between these models. The systemic difference between the projected expected and field models can be calculated, through an adapted tree-edit distance algorithm to detect and analyze significant changes. The difference ∂_p between the states depicted into M_{Ep} and one of the M_{Fp} is quantified as shown on Equation 1:

$$\partial_p(t_p) = \sum_{i=1}^{n}(\partial_i(t_p) * w_i) \quad \text{(Equation 1)}$$

Where:

- w_i is the edit distance cost (create, update, delete) of an element from the expected projected model M_{Ep} (compared to the studied projected field model M_{Fp}) regarding its nature (risk, partner, etc.); $w_i \in \mathbb{N}^*$.
- $\partial_i(t_p)$ is the weight of the element. It represents the importance rank between elements of a same nature, and it is a function of time; $\partial_i \in \mathbb{R}$ and $0 \leq \partial_i \leq 1$

∂_p evolves over time and can be represented as a function of time. The greater the distance, the less relevant the crisis response. In the case where ∂_p exceeds a given threshold ∂_t, it means that the crisis response should be adapted. Thus, the objective of the distance is to assess the stability of the proposed crisis response regarding the uncertainty and the changes of the context over time. This would support decision-makers in choosing the best response candidate.

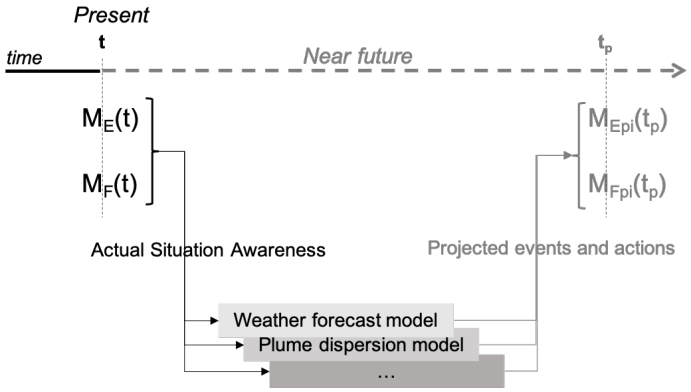

Figure 1. Using forecasts and simulation models to feed projected expected and field models.

CONCLUSIONS AND FURTHER WORK

In this poster, an improvement of the Agility Service for crisis response proposed in (Barthe-Delanoë et al. 2018) is presented. It is defined to provide a proactive agility and thus achieving the third step of the situational awareness: the projection of the future states and events. This improved framework will enable to detect future crisis evolutions based on the forecast of future events and the monitoring of the ongoing process activities.

The main idea is to assess if the ongoing crisis response is still relevant given the current situation and the current response process. To this purpose, anticipation is introduced through the detection of potential gaps using projected models, and the simulation of the effects of the proposed adaptation over time.

Further issues to address are: (i) dealing with the number of projected models (how to choose the set of crisis and environment variables and their combinatory); (ii) dealing with data integration to feed the models with a Complex Event Processing engine: raw data from the ground as well as data coming from simulation tools, forecast models, etc.; (iii) analyzing the performance of the whole solution.

The Search for Embeddedness: Leveraging Scientific Modeling in Disaster Response

Theresa Jefferson

jrharrlad@gmail.com

INTRODUCTION

Numerous studies concerning the response to extreme events demonstrate serious management, coordination, and problem-solving issues that diminished the ability to minimize human suffering. A plethora of scientific modeling technologies exist that can aid in both the panning and response to disasters. In fact, the availability of scientific models is accelerating – but the ability to adopt this technology has had a much slower growth pattern. This research focuses on determining methods for appropriating, integrating and using scientific modeling technologies to improve disaster response efforts in the area of mas care. This work will build on previous research concerning the modeling of technology embeddedness.

METHODOLOGY

This research investigates the reasons that emergency managers, in disaster response environments, under-utilize scientific modeling technologies. The goal is to provide guidance to increase the utilization of the technologies.

This research aims to address the question: *Can an embeddedness model (Figure 1) provide insight on why emergency managers under-utilize scientific modeling technologies for disaster response?*

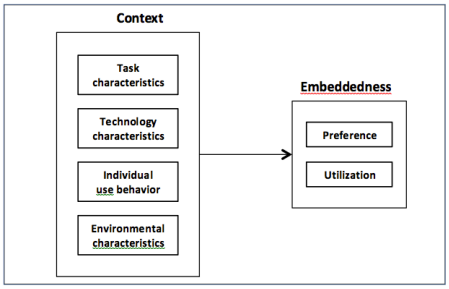

Figure 1. Model of Technology Embeddedness (Phillips-Wren and McKniff, 2015)

The proposed model portrays embeddedness of technology as a function of Preference and Utilization. In order for emergency managers to rely on scientific modeling technology it is necessary that they trust in the technology. This study conceptualizes trust and the interaction between the emergency manage and the technology (Dix et al. 2005) as preference. Preference portrays the emergency manager's desire to use the technology to undertake a task. In this research, preference describes the emergency managers feelings of trust and personal familiarity with the scientific modeling software. Utilization is the degree of use of the technology to accomplish a goal. In the proposed model the emergency manager and the scientific modeling technology work together to respond to the disaster.

The proposed model shows that Context is a pre-condition to embeddedness. By integrated the Extended Technology Acceptance Model (UTAUT) and the Task-Technology-Fit Model, Context can be characterized by four constructs: Task Characteristics, Technology Characteristics, Individual Use Behavior, and Environmental Characteristics (Phillips-Wren and McKniff). A goal of this research is to fully define these four constructs in terms of a disaster operations environment. Emergency managers are focused on making decisions to minimize the impacts of a disaster on the human and built environment. This research focuses particularly on decisions

regarding mass care. Therefore, the task characteristics involve the ability for the modeling technology to align with the decisions regarding mass care and to contribute in a meaningful way toward the accomplishment of response efforts. Technology characteristics concern the reliability of the software/hardware, availability and flexibility to accomplish the task, and ease of use. Individual use behavior concerns the individual's willingness to use the technology and their knowledge concerning appropriate usage. Environmental Characteristic refers to appropriate training, organization adoption, and culture, concerning the use of scientific modeling technologies.

The related, more detailed questions that can be extracted from exploration of the proposed embeddedness model include:

- *What causes individuals to reject the use of scientific modeling technologies?*
- *What are the impediments to emergency mangers using scientific modeling technologies for disaster response?*
- *What are the characteristics of the disaster context that influence the use of scientific modeling technologies for disaster response?*

The end objective is to provide insights that will allow emergency managers to harness the capability that scientific modeling technology provides to improve decision making in the complex and chaotic disaster response environment.

Results

The first phase of this research has involved the formulation of a methodology for studying the under-utilization of scientific modeling technologies in disaster response. This study will use an exploratory case study approach. This approach is beneficial when studying events occurring within a fairly structured environment and can be used to make inferences as to why certain occurrences happen (Yin 2003; Shanks and Bekmamedova 2012). This research is primary exploratory.

This research will use data collected through both semi-structured interviews and surveys of emergency managers. Specifically, information concerning individual use, along with task, technology, and environmental characteristics will be gathered regarding the use of scientific modeling tools identified by a federal interagency effort led by FEMA and the Modeling and Data Working Group (MDWG) (US Department of Homeland Security, 2016). Initial work has involved coordination with the Talbot County Department of Emergency Management (Maryland, USA).

Currently, this research is in Phase 1. We have begun developing the questionnaire that will be used in the interview process. In addition, we are in the process of identifying subjects.

CONCLUSION

The focus of this research is not developing new technology but instead determining methods for appropriating, integrating and using candidate technologies to respond to an extreme event. It involves the evaluation of scientific modeling technologies to enable the decision making necessary in this often-chaotic environment. Initial tasks have involved a survey of current scientific modeling available for emergency management, the development of research objectives and the development of a methodology. The goal of this study is to provide guidance to increase the use of modeling technologies.

INTRODUCTION

Risks for crowd in mass gathering events are so called "High Impact Low Probability" risks (e.g. terrorism, lone wolfs, domestic extremisms) and therefore managing them accordingly, i.e. without a sufficient statistics, means to "*seek a method that leads us to make the least egregious errors in decision-making across the range of possible scenarios that might develop in the future*" (Willis, et al., 2005). Thus, the LETSCROWD project proposes an innovative **Dynamic Risk Assessment** (**DRA**) methodology for Law Enforcement Agencies (LEAs) to assess risks for the crowd on the basis of dynamically collected information to minimise decision-making errors across the possible scenarios that might develop in the critical time frame from the event planning to the event execution.

METHODOLOGY

The proposed methodology is inspired by the network Intrusion Detection Systems (IDS) approaches as those proposed by (Chakir, et al., 2017) based on the analysis of Weak Signals (WS). A WS can be defined as (Schoemaker & Day, 2009) "*a disconnected piece of information that at first appears to be background noise but can be recognized as part of a significant pattern by connecting it with other pieces of information*".

WSs can be detected by different sensors detecting threat precursors: from humans as sensors (e.g. policemen in crowd or a citizen call to 112) to CCTV-based systems, from Cyber-Threat Intelligence systems to physical sensors (e.g. explosive detectors). Each received WS has a **Significance** (**S**) value assigned to it that is a linear weighted combination of the **Credibility** of the sensor in detecting the considered precursor, the **Reliability** of the detection and the **Time Distance** from the event (a speeding car can be considered differently if it is happening 3 days before the event or during the event), where S(WS)∈ [0, 1]. Moreover, each WS has metadata (geolocation, time, etc.) characterising it.

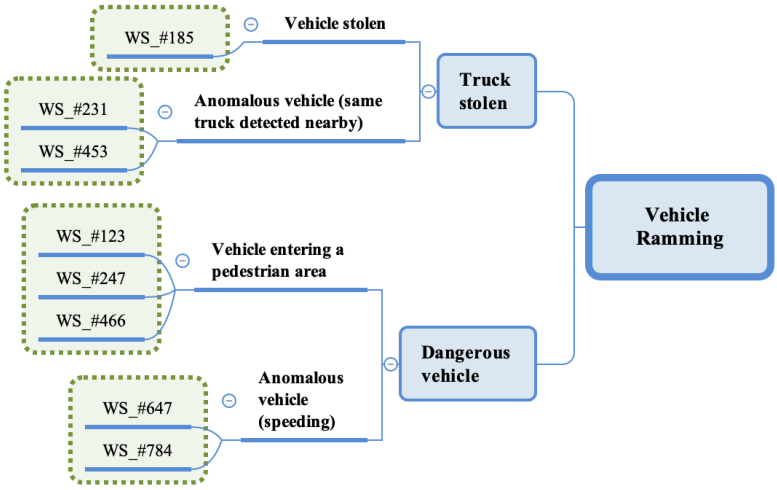

Figure 1 - An example of SP clustering

A WS alone could be insignificant, but when put in combination with other WS could become important. Thus, DRA uses the following mechanisms to group 2 or more WSs into a so-called **Suspicious Pattern** (**SP**) (see an example in Figure 1):

1. A priori, using the LEAs' knowledge through the application **rules** of type (IF conditions THEN grouping). Clearly rules are specific to each LEA and to the identified threats.
2. Dynamically, using an **automatic grouping** of WSs using logic similar to those currently used, for example, at some airport security checks: 3 or more credible WSs "**simultaneously**" happening in space or time from different sources of information can be grouped into a SPs.
3. Dynamically, using **data analytics** - applied on all received WS to generate suspicious pattern. Recently, researchers (Hasan, et al., 2016) started to publish deep learning techniques to automatically learn high-level representations, and then avoid the requirement of domain experts in designing features.

Each SP inherits significance from contributing WSs according to Certainty Factors theory (Lucas, 2001). In case of 2 WSs, with significance S_1 and S_2 respectively, significance of SP is derived using the following formula

$$S(S_1\ and\ S_2) = S_1 + (1 - S_1) * S_2$$

Having more than 2 WSs contributing to the same SP, it is possible to iteratively apply the proposed formula as follows (in case of 3 WSs with Significance S_1, S_2 and S_3, respectively):

$$S_{1\ and\ 2} = S(S_1\ and\ S_2) = S_1 + (1 - S_1) * S_2$$

$$S_{1\ and\ 2\ and\ 3} = S(S_{1\ and\ 2}\ and\ S_3) = S_{1\ and\ 2} + (1 - S_{1\ and\ 2}) * S_3$$

RESULTS

DRA has been integrated in the LETSCROWD Server (LS) developed by ETRA that incorporates also a policy making toolkit and crowd evacuation modelling tools. LS uses the trending Web technologies and receives info from external modules (web crawling, crowd info and multimedia suspicious behaviour detection) using REST technology. SPs above a selected Significance threshold are brought to the attention of the operator together with the attached multimedia information (e.g. a snapshot of the scene, a picture of the suspicious person) and related metadata to allow a risk-aware decision-making process.

CONCLUSIONS AND FURTHER WORK

The proposed approach is going to be tested and verified using data collected during mass gatherings events in Bilbao by Ertzaintza.

DRA methodology has the following advantages over more traditional approaches:

- It searches for **out-of-the-ordinary behaviours** and unseen threats;
- It allows **memory of hypotheses** and data rejected by security analysts and notices what **analysts are watching and asking**.

Finally, the proposed DRA approach is fully in line with the European Security Model (Council of the European Union, 2010) that prescribes, amongst other guidelines, *"… stronger focus on the **prevention of criminal acts** and terrorist attacks before they take place can help reduce the consequent human or psychological damage, which is often irreparable*" and "***Guidelines for hazard and risk-mapping methods, assessments and analyses** should be developed as well as an overview of the natural and man-made risks that the EU may face in the future.*"

ACKNOWLEDGMENTS

This work has received funding from the EU H2020 project LETSCROWD "Law Enforcement agencies human factor methods and Toolkit for the Security and protection of CROWDs in mass gatherings" (GA no. 740466).

Comparative Study of Feature Representations for Disaster Tweet Classification

Pallavi Jain, Bianca Schoen-Phelan, Robert Ross
School of Computer Science
Technological University Dublin, Kevin Street, Dublin, Ireland
{pallavi.jain, bianca.phelan, robert.ross}@dit.ie

INTRODUCTION

Twitter is a popular social media platform where users publicly broadcast short messages on a myriad of topics. In recent years it has enjoyed an increased usage around disaster events due to availability of information in near real time. Additionally, enhanced information representations to facilitate the classification of social media in terms of relevancy and type of information is currently a highly active research area **(**Ashktorab et al., 2014, Imran et al., 2014, Win et al., 2018). In this work we consider the usefulness and reliability of a range of representation models in the analysis of disaster related social media.

EXPERIMENT DESIGN

In order to assess the effectiveness of individual feature representations, we examine the performance of a classification task when applied to labelled tweets on two levels: first, on the basis of informativeness, and then on the basis of type of information. We used a total of 15 twitter datasets of different disasters where 6 datasets are taken from CrisisLex (Olteanu et al., 2014) and 9 datasets are taken from Crisis NLP (Imran et al., 2016). Each dataset consist of data labelled according to informativeness of the tweet on the particular event, and according to type of information of tweet. Pre-processing was applied to the dataset. Hashtags, URLs, punctuation, emoticons, special characters, and stop words, such as 'the' and 'a', were all stripped from the data. Also we used unigram, hybrid unigram and bigram features to add word to word relation features and part of speech (POS) tagging, which results in syntactic behavior of words (Schütze, 1995). We used the Gensim phrase model for bigrams, whereby all bigrams whose count is above three are considered and combined with tokenized unigrams of each tweet. For POS tagging CMU ARK Tweet NLP has been used. Furthermore, Spacy POS tagging removed location information as it contributes noise to a conversation. Additionally, the least 20 frequent words and words consisting of less than three characters were removed from the dataset before lemmatization was applied. Following this, duplicate tweets were removed using cosine similarity for those tweets having more than 90% similarity.

Feature representation that were investigated were BoW, TF-IDF, Word2Vec and Doc2Vec. The pre-trained Google word2vec model "GoogleNews-vectors-negative300.bin.gz" has been used for Word2Vec, for this POS tagging feature has not been considered as it is not supported by pre trained model. For Doc2Vec, each tweet is considered as a document and adds a Paragraph ID to each tweet with the tag of 'train' or 'test' for the respective data. The tagged data was then trained using the Genism Doc2Vec library (Rehurek et al., 2010) using both Distributed Bag of Words (DBOW) and Distributed Memory (DM) individually, in order to get 300 vector size document vectors from each model, which are then combined to get the document vector size of 600. Text categorization usually has high dimensionality. Thus, in order to reduce the dimensionality of data, Information Grain was used to limit features to the top 3,000 words features in the data.

RESULTS AND CONCLUSION

Our results are based on two types of data split; the first is leave one out (LOO), that is model tested on one dataset, and trains on the remaining 14 datasets. The second is cross-disaster training where a model is trained

on one type of disaster, and then tested on another type of disaster dataset. As the dataset has unbalanced classes, the F1 score has been used as the evaluation metric. The results presented in Table 1 indicate that word2vec outperforms all other types of representation in leave one out as well as cross-disaster training approach, while there is very minute difference between hybrid n-gram and unigram. This could be due to the use of a pre-trained model, which does not consist of words related to hashtags and bigrams. The result of cross-disaster training shows that disaster related tweets appear to be independent of the actual type of disaster. This could be due to similar vocabulary shared across the type of disaster in terms of donation, sympathy, needs, etc. The results strongly suggest that a pre-trained word2vec model gives better results than BoW, TF-IDF and Doc2Vec. This is due to the fact that a pre-trained model is trained on a comparatively large corpus, which creates a much improved context similarity representation. However, word2vec struggles with out of vocabulary words, which is more prevalent in text from a Twitter feed, as it contains human created hashtags and slang words.

INTRODUCTION

Emergency response drills, conducted mostly by means of simulations, are strategies used by various complex social-technical systems in order to prepare organizations and people to deal with foreseen or unforeseen risk situations. Collaborative work is part of these practitioners' work, which requires communication, cooperation, coordination, and awareness from them so they can properly do their job. Such collaborative work may be supported/aided by technological artifacts that ensure, for instance, a shorter response time, improved information sharing, and a better understanding of the local situation. Previous research in several types of firefighters' training (Huber et al., 2016) and observations of teams in Command and Control Centers (Carvalho et al., 2015) indicated the need of training approaches better suited to the reality of these practitioners, as well as better ways to analyze training results, enable an effective organizational learning. Immersed in this context, the purpose of this study was an analysis of an emergency response simulation exercise carried out by firefighters, to identify aspects of collaborative work to identify issues on the practitioners' communication, coordination, cooperation, and awareness.

METHODOLOGY

The research method is an empirical workplace study based on a systematic observation of training activities divided into several steps with different objectives which are highly interconnected. Even considered that is very difficult to list research activities in clear steps, due to the grounded nature of the research and its evolution over time, the main research phases were 1) Social construction, enabling the participation of the research team in the firefighters' activities; 2) Investigations of the standard operating procedures' (SOPs) norms, and work practices of firefighters; 3) Assist in the development and preparation of exercises; 4) Organization of the research team for observation and data collection; 5) Observation of the simulations including briefing, simulation, and debriefing phases; 6) Data analysis according to the 3C model (Fucks et al., 2005), discussion, and validation with firefighters' commanders.

RESULTS

Collaborative work issues appeared through communication, coordination, and cooperation as described in the 3C model of collaborative work (Fuks et al. 2005), and awareness (Dourish and Belloti,1992).

Communications: Communications between the participants and the command center relied solely on two-way radios. Radios are usually the tool used by the fire department in real work circumstances. In the simulation, each team was equipped with one radio, which was entrusted to a single member (the operator). That fact alone limited the access of all team members to the information exchanged with the command center and made it harder for them to understand all messages. Additionally, because all messages were heard by all groups, at different times during the simulation we noticed the groups had trouble understanding who was sending such messages or to whom they were being sent. The teams' ability to understand the content of the information was also compromised, and messages had to be repeated more than once so they could be understood by the main persons involved. Table 2 transcribes some excerpts from conversations showing these problems.

Coordination: The difficulty in assigning the roles of each team and plan future actions became even clearer when the Central Command radioed a new message of the exercise reporting on another event at the same site (vehicle fire). The Local Commander request a fire engine to the COCB, the Command center's deployment of the relevant team, and the team's doubt whether such vehicle was available engendered the messier part of the simulation, where everyone seemed to have trouble understanding what was going on, which response vehicles had been requested, and which ones were no longer at the site of the event. From then on, the teams were clearly unsure about what to do and tried to sort out which steps had been taken and which resources had been deployed. They had a hard time sharing the actual information and understanding the situation as a whole. That fact led the exercise facilitator to include an unplanned element, i.e. the media, to request information from the command post. Hence, information would have to be concentrated at that place, which encouraged the participants to share information and helped them understand the actual situation.

Cooperation: The actions to be carried out during the simulation had the common goal of handling the prescribed event: a collision between a train and car at a level crossing, with victims in different categories of risk. However, the fact the simulation did not actually feature victims at the site and lacked the physical number of response vehicles listed in the script, that is, the teams had one physical vehicle that stood in for up to four, seems to have compromised the exercise, especially regarding the aspect of cooperation. The teams kept being dispatched to the site, but as they got there they did not have common goals to be achieved. They focused on assessing the scene, deciding on whether they needed backup and on the "virtual" transport of victims, and filling out the forms supplied for the exercise.

Awareness: Understanding the messages sent, resources available, actions already carried out, and backup needed at the site and by fellow officers are examples of awareness-related aspects that permeate and provide support for coordination, cooperation, and communication. Different resources were included in the exercise to provide information and let individuals and teams to get a picture of the event: (i) two-way radios, the main resource for communications between the field and the command center; (ii) the flip chart, where the exercise's main messages were posted, and which was at the site; (iii) the command post, tasked with centralizing the information and allowing everyone to see the (iv) organization chart listing the information on the then-current level of the event and the persons in charge of each macro activity; and (v) as a resource included for the exercise, the very form which the teams were required to fill out with the information exchanged in the course of the simulation. However, despite the resources for accessing and sharing information, at several points during the exercise it was observed participants were unsure at which level the simulation was, who was at the site, what they were supposed to do, how the team was expected to behave, or who to turn to for information.

CONCLUSIONS AND FURTHER WORK

Scarcity and information overload have great impact on building understanding of the situation among team members and control and command, and consequently on decision making during crisis events. Under such constraints collaborative work supported by adequate tools is paramount for a better response. Workplace studies based on ethnographic methods have proved to be a good approach for analyzing the scenarios as explored in this study. It was possible to observe confusion in the transferring of information, extensive need to information repetition, and the high dependence of the command center on the flow of information coming in from the teams. The officers lacked the clarity of the information and thus spent more time soliciting radio confirmations and trying to understand what was actually happening, and in some cases misunderstanding what was communicated. The analysis of communication shown that radio communication was not enough, therefore future work on new a framework for the development of communications tolls is important.

INTRODUCTION

Global social media use during natural disasters has been well documented (Murthy et al., 2017). In the U.S., public social media platforms are often a primary venue for those affected by disasters. Some disaster victims believe first responders will see their public posts and that the 9-1-1 telephone system becomes overloaded during crises. Moreover, some feel that the accuracy and utility of information on social media is likely higher than traditional media sources. However, sifting through content during a disaster is often difficult due to the high volume of 'non-relevant' content. In addition, text is studied more than images posted on Twitter, leaving a potential gap in understanding disaster experiences. Images posted on social media during disasters have a high level of complexity (Murthy et al., 2016). Our study responds to O'Neal et al.'s (2017) call-to-action that social media images posted during disasters should be studied using machine learning.

METHODOLOGY

Our study develops/evaluates a transfer learning framework for classifying 17,843 images posted to Twitter. We use VGG-16, a Convolutional Neural Network (CNN) to categorize images shared on Twitter during Hurricane Harvey in 2017 by their urgency, relevance, time period, and the presence of damage and relief motifs.

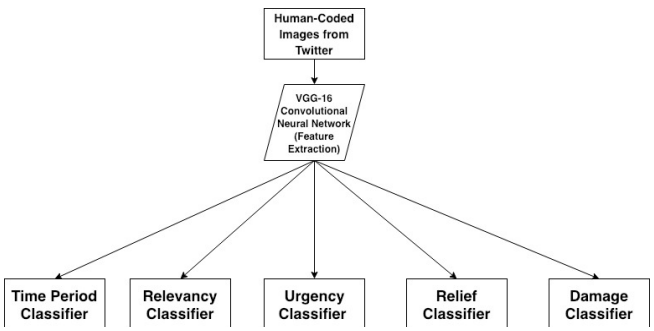

Figure 1: Deep Learning Framework

Human Annotation: To develop the 'training' dataset (i.e., data used to train an algorithm) for our study, we

randomly sampled 1,128 images (approximately 6.45% of all images collected) and human-coded these images using a rubric with categories drawn from established crisis literature.

Deep 'Transfer' Learning for Feature Extraction: Because most deep learning techniques require large datasets and computational resources, it is common to employ a pre-trained model and adapt it to a specific learning task. In this study, we treat output from the second-to-last layer of VGG-16 as low-dimensional 'feature vectors' representing each image. Using these feature vectors, we trained five multilayer perceptrons to classify images by time period, relevancy, urgency and the presence of 'damage' and 'relief' themes. We used nearly identical model architectures for the classifiers, and we evaluate each classifier's accuracy, categorical cross-entropy loss, and F1(-macro/-micro) scores.

RESULTS

Existing crisis-related image filtering approaches using deep learning indicate state of the art baselines with F1 scores ranging from 0.60-0.70 (Nguyen et al., 2017). Our results, particularly with the relevancy, urgency, and damage classifiers (see Table 1), provide evidence that we can obtain high-performance, robust classifiers even with just 1,128 human-annotated images.

Classifier	Time Period	Urgency	Relevancy	Damage	Relief
Training Loss	0.6398	0.9514	0.3313	0.1441	0.128
Training Accuracy	0.7705	0.6098	0.9035	0.9957	0.9484
Validation Loss	0.7515	1.0841	0.5222	0.253	0.2335
Validation Accuracy	0.677	0.6195	0.8186	0.9023	0.9336
F1 Macro Score	0.3735	0.5847	0.752	0.6973	0.824
F1 Micro	0.5012	0.6157	0.811	0.4375	0.7568

Table 1: Classifier Results for Accuracy, Loss, and F1

CONCLUSIONS AND FURTHER WORK

Our framework reliably classifies images based on relevancy, urgency, and damage. Stakeholders such as emergency response organizations do not have to create custom models. Our transfer learning models can be used real-time to filter images by urgency, relevancy, and damage. During future hurricane events, this will not only save time, but help target limited resources to look at relevant images posted on social media

INTRODUCTION

A disaster seriously disrupts the functioning of a society and generates human, material and economic losses. Unfortunately, some are weakly predictable such as the terrorist. But even the predictable ones, like the cyclones whose intensity remains difficult to assess are not always easy to forecast in terms of damage. Over the past 10 years, disasters have killed more than 700,000 people worldwide, 1.4 million injured and total economic losses of more than 1,100 billion euros. For example, on Friday, the 23rd of August 2013, Tripoli, north of Lebanon, was hit by terrorists. Two Sunni mosques were struck by two car bombs, leaving at least 42 dead and 500 others injured. Likewise, on January 12, 2010, an earthquake measuring 7.3 on the Richter scale (between 0 and 12) rocked Haiti for 35 seconds. More than 220,000 people were killed, more than 330,000 were wounded and about 1.3 million were homeless. Due to the sudden occurrence of disasters, the reaction must be quick and efficient as much as possible in order to minimize the human loss by providing help and rescue to the injured people. The main objective is to assist and take them as fast as possible to the nearest treatment center that can treat their cases. The presented work concerns the definition of a new decentralized model combining proactive-reactive approaches and Multi-agent systems (M.A.S) for solving the planning problem of a terrorist attack scenario. It is dedicated to present a PhD research work involving both The Production Engineering Laboratory in France and the research laboratory of the Lebanese-French University of Tripoli in Lebanon.

METHODOLOGY

Bidot et al. [1] presented four different approaches for planning under uncertainty distinguishing: reactive, proactive, progressive or continuous, and mixed techniques, and associated with both design and execution phases. The first one aims at creating a plan, while the second one is to its deployment on the real situation. The question is how and when it can be created or modified according to the technique used. To value uncertainties two theories mainly apply respectively related to: fuzzy logic or probability theory. The fuzzy logic approach works with variables or imprecise events while the probability theory uses precise but random events. In our case, planning and execution are shared among distinct professionals in charge of deciding or performing the tasks. Multi-Agent Systems (MAS) [2] are a natural approach to cope with that, and may also appear more effective to deal with uncertainty tan centralized systems. One of the most famous definitions of agent, set by Russell [3], is to consider an agent like an entity perceiving its environment through sensors and acting on this environment via autonomous triggers. Thus, MAS is an organized corpus of agents in which a certain number of phenomena comes out as the result of interaction between these aforesaid agents.

RESULTS

We present a scenario of terrorist attack discussed in centralized and decentralized models. We then analyzed both models by adding few assumptions to the scenario, unknown number of victims, blocked or impassable road to access the crisis site or the nearest hospital. The main concern of our problem is to intervene as quickly as possible to evacuate the greatest number of wounded and to transfer them to the nearest and the most appropriate health centers.

With this in mind, the proactive-reactive approach is used. We suppose that each resource is an agent:

- **First case**: EMAS (Emergency Medical Assistance Services), two MERS (Mobile Emergency and Resuscitation Services) and two hospitals.
- **Second case**: EMAS, two MERS, two hospitals and a Transport system.

We assume that the number of resources is enough, there is no communication problem and the capacity of the hospitals is sufficient for the number of victims. Also, we suppose that every new condition or parameter that will be added in the next steps is not predictive, so the reactive technique will be used. We should note that the solution developed in the first case model when the number of victims is unknown, can be applicable in the second case model too.

Unlike the centralized model when only one agent has the responsibility of making a decision, a decentralized model gives each agent a degree of autonomy. So in some cases, he can decide what to do. For example, in centralized models, $MERS_1$ and $MERS_2$ should always communicate with the EMAS. They ask the EMAS, which hospital to send the wounded, which wounded should be served first and which hospital to send each injured person. When the road is blocked, they wait until the EMAS find a solution after the transport agent proposes the possible roads to EMAS. While in the decentralized models, $MERS_1$ and $MERS_2$ can communicate with each other directly and take some decisions without the intervention of EMAS. The transport agent chooses the best road and send it to $MERS_1$ and $MERS_2$. Thus, we notice that the communication between the agents is high in the centralized models.

Moreover, we should mention that the transport agent in the decentralized model, will give the MERS the best and the shortest road in real-time so it will never be blocked. A more interesting problem that we propose to analyze is when the situation is not completely observable by the transport agent and the MERS will only discover a blocked road when it reaches it.

CONCLUSIONS AND FURTHER WORK

We have presented a proactive-reactive approach to multiple centralized and decentralized models for terrorist attack crisis aiming at minimizing human losses. We compared the models and highlighted their difference. In addition, we presented the different techniques to generate a plan. Then, we aim to construct a distributed decision support model for the construction and execution of coordinated multi-agent intervention plans. The next issues to be addressed are related to dynamic environment planning and tasks distribution between agents. If possible more autonomy will be given to the agents to be able to make decisions. Furthermore, we will make a formal analysis of cost and quality. Thus, we will focus on minimizing the cost and increasing the quality. We will study the classic planning techniques in multi-agent systems based on the generalization of the Markov decision process. Then, we will compare them and choose an algorithm that will allow us to represent our scenario. We will simulate and test all the models and propose others to indicate which one will be the best to solve addressed issues. For example, we will test the models by comparing a makespan to save the wounded. Thus, we will optimize the transport operation by minimizing the transport's duration between the crisis zone and the treatment center.

Finally, and after having designed the multi-agent system, the next step will be to select the platform for the implementation of the model. We will choose the JADE platform because of its simplicity and its aptitude to make prototypes using native JAVA programming language.

INTRODUCTION

The high and continuously rising number of passengers using public transportation in Germany is leading to an expansion of the services offered by public transport operators. The existing transportation infrastructures, especially the railway stations, can only partly cope with this rapid growth in passenger volume. Overcrowding on platforms and access routes is already occurring, especially in the event of operational disruptions by natural disasters or major public events. This crowding may lead to passenger injuries or to a standstill of operations for safety reasons. The collaborative research project "Crowd-Management in Transportation Infrastructures – CroMa" aims at improving the robustness, safety and performance of railway stations during peak loads. For this purpose, improved building regulations, suitable crowd management as well as guidelines for risk management, resilience and inter-organizational information management will be developed.

Within CroMa, the Institute of Public Safety and Emergency Management conducts research on the identification and modelling of information flows between the various stakeholders. An analysis of existing information management concepts and domain specific crisis scenarios will help to develop an information flow process model and guidelines for effective inter-organizational information management.

The poster "CroMa - Crowd Management in Transportation Infrastructures" describes the collaborative research project of the same name. The poster contribution highlights the research questions addressed within the framework of the project as well as the underlying methodological approach. The expected results, including guidelines for end users, are also presented.

METHODOLOGY

Within this project, the Institute for Public Safety and Emergency Management is focusing on the design of a holistic crisis and risk management system across organizational and system boundaries. This includes the development of inter-organizational crisis management guidelines for operators of interconnected transportation infrastructures. In addition, the research project will concentrate on maintaining the performance of transportation infrastructures – especially railway stations – even under difficult and critical operating conditions.

During the initial phase of CroMa, information flows will be recorded and translated into a generic UML model. A user-oriented approach is used to identify these information flows. Field and practical observations (e.g. crisis management teams and incident command teams at major events) will be performed to investigate information flows and decision-making processes in real environments. These are then analyzed and used to develop the model. In this way, they represent the as-is situation.

Besides analyzing existing concepts for cross-organizational information exchange and decision making, the project CroMa develops application scenarios with a special emphasis on information management. Past incidents related to rail transportation have been collected and will be analyzed and clustered according to different characteristics (e.g. predictability, duration, impact). The results of this analysis are reflected, validated and refined in guided expert interviews. Linking the analysis of past events and expert interviews, conclusions will be drawn on the subsequent development of a causal model for possible future scenarios. A suitable approach for the development of this causal model is provided by the functional resonance analysis method.

Based on the model of the as-is state and the past and possible future scenarios, a desired state of the communication model and a set of recommendations and guidelines for effective inter-organizational cooperation will be developed. These guidelines will be validated within the framework of an expert panel or workshop. Subsequently, a publication and broad communication of the guidelines is planned.

The involvement of end users includes the participation in qualitative expert interviews, field studies in Germany, Austria and Switzerland as well as the coherent scenario and guideline development. In addition to an impact assessment for various scenarios on the transportation system's performance, a major focus will be on the development of an information flow process model. This model will serve as a basis for the above mentioned end-user guidelines.

RESULTS

Expected results of the research project are the UML process model with the identified interfaces and information flows as well as the scenarios and the impact assessment on the performance of the transport system. They provide the basis for new concepts for effective cross-organizational cooperation between the participating organizations and the development of a uniform terminology. The guidelines for the inter-organizational exchange of information to be developed within the framework of the project are intended as a future basis for the creation or optimization of information management systems.

CONCLUSION AND FURTHER WORK

In the course of the carnival events in the Rhineland, Germany, it was already possible to observe incident command teams deployed in a real situation. Additionally at this occasion, initial orienting field observations were conducted. A number of preliminary interviews with experts has been carried out. These are currently undergoing evaluation.

The analysis of past events and the development of a causal model are subject of the current research in the project. First results of the work already carried out are expected in autumn 2019.

INTRODUCTION

In humanitarian practice, high-quality and context-specific geodata is crucial to come to informed decisions and to efficiently coordinate and conduct humanitarian activities. While humanitarian actors also make use of internal resources to collect various kinds of geodata, they mostly rely on external geodata providers. This is mainly due to a lack of own resources, appropriate expertise, and the complexity of humanitarian contexts. However, both research and practice show an imbalance between the geodata provided and humanitarian actors' needs and requirements (cf. Gralla et al. 2015; Van den Homberg et al. 2018), which leads to less efficient use of geodata in humanitarian activities.
The main aim of the work is to close this gap through a methodological approach that enables structured communication of these needs and requirements of humanitarian actors - to enable better understanding and in consequence, to facilitate geodata creation and sharing with a better fit for humanitarian purposes.

METHODOLOGY

The communication and identification of humanitarian geodata needs are addressed through a multi-tiered approach that was developed in the scope of the first research phase. This methodological approach begins with a comprehensive literature review and includes theoretical and practical activities as well as empirical analyses. As part of the literature review, on the one hand, conceptual spaces and perception, as well as insight and survey methods were elicited to acquire a thorough understanding of the current state of the art around knowledge extraction, which can consequently be put to use to gain an understanding of humanitarian actors' mindsets and perceptions. On the other hand, the literature review also focused on geodata quality as well as geodata use in humanitarian contexts. This part was extended with a review of reports from own projects of the authors with humanitarian actors, which further illustrate current geodata usage and related humanitarian practice.
Based on these efforts, an introductory survey was developed through which participants can provide insights about their background, previous experiences, and lessons learned as well as perceived limitations related to geodata usage in their current tasks. Building on this introductory survey, two additional approaches were developed to get a deeper understanding of the participants' needs and requirements as well as current hindrances in geodata use: the first approach is based on the concept of the Analytic Hierarchy Process (AHP) (cf. Saaty 1980, 2013), the second one is based on Design Thinking (cf. Plattner 2013).
The AHP is a Multi-Criteria Decision Making (MCDM) method that was included in the methodology to enable prioritization of geodata characteristics by humanitarian geodata users. In this survey-structured approach, participants are asked to conduct pairwise comparisons of geodata characteristics, based on their insights provided in the introductory survey, to learn about their main needs and requirements around humanitarian geodata use. Likewise to the AHP, the Design Thinking tools enable information gathering, but furthermore allow sympathizing and empathizing with participants. These tools are utilized to receive deeper insights about the humanitarian geodata users' perception and to assess, why they address their tasks the way they do. For this

second approach, small groups of participants join Remote Design Thinking Workshops, in which they discuss their previously provided insights, again building on results from the introductory survey.
As both methods can be applied in remote scenarios, they consequently allow for involving humanitarian actors in their oftentimes remote work locations. However, both approaches are yet to be assessed regarding their suitability for the communication and consequently the identification of the main needs and requirements of humanitarian geodata users.

RESULTS

Humanitarian actors and representatives of national and international humanitarian organizations, as well as scientific institutes, already supported the presented work through their active contribution in the introductory surveys, Remote Design Thinking Workshops, and AHPs. They hereby provided insights about their current approaches and challenges all around humanitarian geodata use. The AHP provided insights about more and less important geodata characteristics and related reasoning, the Remote Design Thinking Workshop furthermore allowed participants to discuss their perspectives, and to develop ideas towards related improvements.
Initial results indicate that, on the hand, accessibility, availability, and accuracy of geodata seem to be of greater importance compared to usability, completeness and the geodata being up-to-date. On the other hand, participants also reported about the current limitations in geodata use. These include lack of standardization and metadata, which both seem to pose a major challenge for efficient geodata use. Additionally, limited geodata sharing, which is partially also related to these previous factors, was discussed to hinder geodata use and to moreover affect geodata availability and accessibility. Trustworthiness was furthermore mentioned as being of great importance and at the same time, lack of trustworthiness as being a great hindrance in current geodata use.

CONCLUSIONS AND FURTHER WORK

The main aim of the presented research is to enable structured communication of the needs and requirements of humanitarian actors to close the gap between demand and supply in humanitarian geodata use. First results of the methodology already showed the potential for the communication of needs and requirements as well as current limitations and thus for knowledge gathering around humanitarian geodata use.

Further workshops, as well as AHPs, are already planned to get a more comprehensive sample and to evaluate findings gathered from the initial participants. Results will furthermore be assessed to evaluate the suitability of the two approaches in comparison to each other.

ACKNOWLEDGMENTS

The content of the poster was developed by Melanie Eckle as part of her Master Thesis. The topic draws on related work of the Heidelberg Institute for Geoinformation Technology/ GIScience Research Group at Heidelberg University which is core funded by the Klaus Tschira Foundation.
The research idea was developed in collaborative projects within the Missing Maps project and in collaboration with the named co-authors as well as Dr. Franz-Benjamin Mocnik.
We want to thank all participants of the research study for their valuable contributions.

Geographic and Content-Based Prioritization of Tweets for Emergency Response: The Case of Weather-Related Disaster Events

A. Marcela Suarez

amsuarez@ucsb.edu

Keith C. Clarke
University of California, Santa Barbara
kcclarke@ucsb.edu

INTRODUCTION

Content shared on Twitter usually represents timely, updated, and sometimes on-site reports. Because of this, and the speed and ease with which information is shared through this micro-blogging platform, forecasters and emergency managers have tried to leverage tweets as an on-the-ground reference for both confirming the occurrence of weather-related disaster events and for tracking their local impacts and damage. However, since Twitter data is massive, semantically varied, noisy and spatio-temporally uncertain (Steiger et al. 2015), little of this information is made useful and when it is, it usually requires exhaustive manual filtering - searching individually for tweets related to a specific event. This raises the questions of how can we both identify and prioritize tweets on weather-related disaster events based on their reliability in a timeframe that is useful for emergency response, and ultimately, which factors define their reliability.

This study presents an approach for prioritizing tweets so that they can be used by emergency managers and decision makers to assess local effects and damage caused by weather-related disaster events. Using Hurricane Harvey as a case study, we demonstrate how authoritative data, such as on-the-ground reports provided by weather spotters trained by National Weather Service (NWS), as well as the National Flood Hazard[1] information and damage maps created by the Federal Emergency Management Agency (FEMA) can be used to prioritize tweets based on their geographical location, and so allow them to assist in weather impact assessments.

DATA

This research relies on two type of datasets: a dataset of tweets, and datasets containing authoritative information. The Twitter dataset consists of 4,486 geotagged tweets sent within the US State of Texas selected from a sample of 7,041,866 tweets that were randomly collected from August 18 to September 22, 2017. The data was collected by the University of North Texas (UNT) and the original dataset is publicly available in the digital repository hosted by the UNT libraries[2].

Authoritative datasets consist of information of three different types: a flood hazard assessment, citizen reports sent during the emergency and a damage assessment carried out after the disaster. The first two were used as a reference to prioritize the tweets, and the last one was used for validating the prioritization. Authoritative citizen reports were contributed by Weather Spotters who are volunteers trained by the NWS as part of a program called SKYWARN. Spotters' reports were extracted from NOAA's historic Storm Event Database[3]. Geographic information related to hazards and the damage and impact caused by Harvey is provided by FEMA.

METHODOLOGY AND RESULTS

1 https://www.fema.gov/national-flood-hazard-layer-nfhl

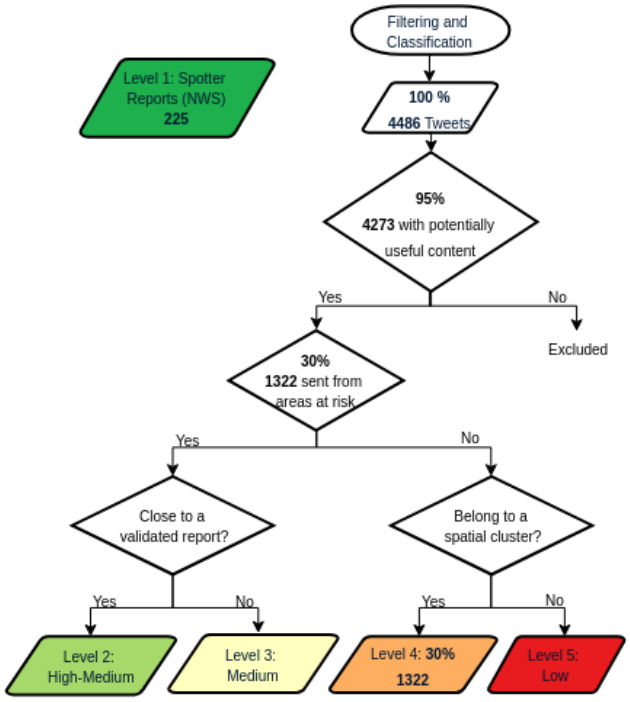

Figure 1. Flow Chart explaining process to filter and classify tweets

Five stages characterize this study: Data preparation, content analysis, spatial clustering, proximity analysis, and filtering and classification.

Data Preparation. During this stage the Twitter dataset was filtered in order to be used to address the objectives of this study and it was also preprocessed in order to reduce noise and any redundancy among the tweets.

Content Analysis. We used topic modeling to discover topics of tweets and filtered out those with no informative for the emergency response, such as those expressing sympathy and emotional support.

Spatial Analysis. We estimated if a tweet was sent from a flooded area by intersecting the two map layers that represent each dataset.

Spatial Clustering Analysis. It was used to identify areas with high densities of tweets. We used the hierarchical DBSCAN algorithm to identify and label spatial clusters.

Proximity Analysis. It allowed us to evaluate if around the area where a tweet was sent there was also a validated report. A hexagonal grid was used to represent "spatial vicinity." Each tweet and spotter report was assigned to a unique hexagon or unit area. Using this grid we evaluated whether any spotter report was sent from a hexagon that also contains tweets.

Filtering and classification. Figure 1 illustrates this stage which consists of the prioritization process and uses the results from the previous stages. The percentage of tweets retained in each stage is also included in this figure.

CONCLUSIONS AND FURTHER WORK

This research provides a framework that leverages geographic information to assess tweets reliability. Geographic information related to hazards as well as citizen reports validated by the NWS serve as an excellent reference to assess tweets reliability.

Although only a small portion of tweets actually provide useful information for emergency responders, they are still a good data source to complement official information.

Next steps include: i) Estimation of the optimal hexagon size in the proximity analysis. Grids of hexagons at a range of sizes will be evaluated by comparing the overall coefficient of variation–the hexagon size with the highest coefficient of variation will be considered optimal. ii) FEMA Modeled Building Damage Assessment data will be used to validate results from the filtering process.

INTRODUCTION

A series of R&D initiatives – recently completed and on-going projects – carried out within an interdisciplinary (cognitive sciences, ergonomics, software engineering) and international (Canada and Sweden) partnership that is comprised of universities (U Laval, Linkoping U) and college (Campus Notre-Dame-De-Foy, Canada) researchers, developers and engineers from the industry (OVA, Thales) and subject-matter experts from emergency response teams (Quebec security department) is presented. Some of the work is still in progress and part of PhD research work. The main researcher – Prof S. Tremblay is based at Laval University, Quebec City, Canada.

The aim of our R&D program is to develop and validate innovative adaptive systems and tools for the training of non-technical (cognitive) skills in crisis management and emergency response. Crisis situations are generally characterized by severe threats, uncertainty, and time pressure, which all pose challenges for first responders under demanding circumstances. We present two on-going projects related to the training of interoperability in joint operations as well as other key cognitive skills: A first project is focused on the use of serious gaming and the other project with the use of VR within collaborative environments. In both cases the scenarios are designed to require teamwork, coordination of decisions and actions, communication and collaborative sensemaking and also provide a set of behavioral indicators and biometrics in order to monitor skill acquisition and the cognitive-affective state of the trainees.

METHODOLOGY

Serious Gaming. Serious games are widely recognized for their potential to foster learning and the acquisition of non-technical skills. We used C3Fire – a gamified microworld that can be used by either an individual or a group of people collaborating with the goal to extinguish a forest fire (Granlund 2002) in order to train interoperability. It is a very flexible and tractable platform that allows researchers to simulate characteristics of real-world crisis management environments (complex, dynamic, and opaque). The collaboration can be supported by different means of communication and it is possible to configure the simulation so that inter-dependencies are created between the different members. Twenty-four teams of four participants completed four scenarios, each lasting 10 minutes. A set of cognitive and teamwork metrics was developed to assess team effectiveness. These included measures of performance, coordination effectiveness, monitoring effectiveness, adaptability, pattern of communications, and shared mental models.

VR training. By invoking a combination of realistic unforeseen events, taskload variations and time pressure, virtual reality (VR) can serve to train responders to perform under the acute stress and complexity of real-life crisis situations, and facilitate learning of non-technical (cognitive) skills. The first objective of this project was to develop a realistic simulation that placed four supervisors from different services (e.g., police, fire, paramedic, civil security) in a crisis situation in which they must communicate and coordinate for an efficient emergency response. This was done, in concert with subject matter experts, by defining the learning objectives and the team

and individual behaviors that could indicate the acquisition of non-technical skills. The second objective was to develop and integrate the automatic calculation of behavioral metrics within the VR platform allowing the assessment of interoperability and learning rate. Ten teams of four real life responders tested the simulation in which a criminal act resulted in an ammonia leak threatening citizens in an arena.

RESULTS

Results from the C3Fire project revealed that team members achieved better coordination as they progressed through the scenarios. This learning effect suggests that it could be beneficial to train team members to coordinate their actions efficiently. Preliminary results from the VR training project showed that the perceived amount of workload reflected the taskload associated with each service. The testing of metrics of interoperability and of non-technical skills provided valuable lessons learned regarding technical challenges.

CONCLUSIONS AND FURTHER WORK

Both serious gaming and VR provide a cost-effective means to train non-technical skills using simulated scenarios that are realistic in terms of time course, nature of critical events, and ensuing emotional states. These training methods could complement traditional training means by optimizing trainee potential while reducing logistical inconvenience, monetary costs and potential risks of field training exercises.

A comparison of two methodologies to assess shallow landslide risk

Erica Akemi Goto
University of California, Santa Barbara
ericagoto@gmail.com

Keith Clarke
University of California, Santa Barbara
kcclarke@ucsb.edu

INTRODUCTION

Landslides are natural processes that can be hazardous events when they threaten human lives and assets (Keller, 2011), and their incidence can be increased by improper land use, such as irregular urbanization and the construction of dams and roads without good engineering planning. Landslide disasters and catastrophes are not new, and the loss of human life to them is common in developing countries. Many people live in risk prone-areas in the Southeastern part of Brazil (IBGE, 2018). Major cities such as Sao Paulo and Belo Horizonte have 6% and 16% of their population living in at-risk areas, respectively (IBGE, 2018). Moreover, mapping these risk areas are critical for managing and mitigating the risk. Municipalities can use the mappings to monitor the risk areas and to allocate resources or prioritize to relocate residents living in high and very high risk levels sectors.

The Brazilian government through its Ministry of Cities and the Institute for Technological Research (Instituto de Pesquisas Tecnológicas – IPT) developed a landslide risk mapping methodology that we are calling the Brazilian Government Methodology (BGM) to map landslides and river-bank erosion risk (Carvalho, Macedo, & Ogura, 2007). Within the BGM, two technicians do field inventory, observing local geo-environmental variables, and based on their previous experience and personal observation, they decide on the level of risk. This mapping is biased since it does not involve any objective mathematical computation and is influenced by each technician's personal experience.

The purpose of this study is to discuss and compare the performance of two methodologies that quantifies the BGM and automatically classify the risk level of shallow landslide prone-areas. The first methodology is based on the Analytical Hierarchical Process (AHP) and it is heuristic/expert based. The second is statistically-based and uses Ordinal Logistic Regression (OLR). We compared how similar their risk level classifications are and how similar they are with the BGM. Additionally, we are using a user-friendly application (app) developed by the authors, that computes the level of risk and it can be used on a tablet, smartphone, or computer with internet access or with RStudio software installed. Both methodologies can use the app since the classifiers are both based on the BGM.

METHODOLOGY

DATASET

The dataset is part of the 2010 Sao Paulo landslide and river bank erosion risk mapping done by the Instituto de Pesquisa Tecnologico (IPT) and Sao Paulo Municipality employing the BGM. We reduced the original 11,789 to 754 sectors based, in which just shallow landslides were considered. After, we random divided the dataset as training (70%) and test (30%) sets.

ORDINAL LOGISTIC REGRESSION

Ordinal Logistic Regression is commonly used in medical, epidemiologic, educational, and psychological studies, in which the y variable (response variable) represents levels, such as low, moderate, and high and the x variables (predictor variable) can be categorical (ordinal or not), discrete, and continuous. In the BGM, there are four risk levels: low, moderate, high, and very high. Figure 1 illustrates the steps of the OLR methodology.

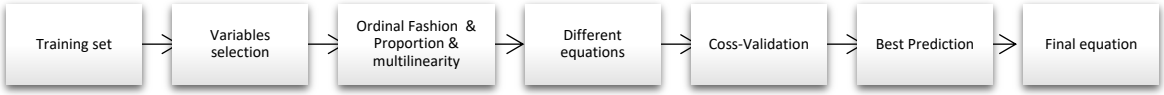

Figure 1 – Ordinal Logistic Regression flowchart

ANALYTICAL HIERARCHICAL PROCESS (AHP)

AHP has been commonly used as a decision support tool and relies on experts' knowledge and their pairwise comparison of the contributing variables to compute classifier weights (Saaty, 2008; Kousalya et al., 2012). Computing the classifier weights is a process that involves selecting the classifiers and building a hierarchical structure with them, designing a questionnaire with pairwise comparisons, selecting and delivering them to experts in the field, and checking the responses for consistency.

RESULTS

ORDINAL LOGISTIC REGRESSION

The test set was best predicted by Equation 3 (79.2%), followed by Equation 5 (76.8%), Equation 1 (76.0%), Equation 4 (75.2%), and Equation 2 (74.4%). However, the prediction of the five equations were not so significant different (*Mean = 76.32, SD=1.84, Range = 4.8*). Better performance of Equation 3 can be partially explained by the number of predictors. Threshold values from R1 to R2 (-0.74), R2 to R3 (4.20), and R3 to R4 are ordinal. The very high threshold between R3 and R4 is expected. Very high risk level (R4) is observed in risk sectors with signs of instability, like features that indicate movement in the terrain. Cracks in the wall or in the terrain, poles and trees tilted, or leaning walls are some examples. Also, these sectors can have landslide scars; which means past landslide occurred in these sectors.

ANALYTICAL HIERARCHICAL PROCESS (AHP)

The total of experts involved were 23 but for each classifier weight value, we used 7 to 13 experts do to the CR (*AVERAGE=9.77, SD=2.17*). The weight value of classifiers is higher for instability category when compared with anthropogenic and natural. In this analysis, we consider classifiers with weight values higher than 7.5 high value, a weight value between 3 and 7.5 moderate value, and weight values lower than 3 low value. The downward floor has the highest weight value (16.87), followed by landslide scars (12.64); both classifiers are in the instability category. Moreover, other instability classifiers have a higher weight value than classifiers from anthropogenic and natural categories. Instability category includes classifiers that indicate landslide initiation (i.e. downward floor) or past landslide (landslide scars), which are expected to be observed at a very high-risk level. Some of the slope angle classifiers are the ones with the highest weight values, like $\alpha = 90$ (5.85) and $60 \leq \alpha < 90$ (5.69). However, $\alpha = 90$ is not found in natural slope for shallow landslides. In the natural category, slopes with geology or soil favorable that contributes to unstable slopes have a moderate weight value, 4.65 and 4.72, respectively. Classifiers from anthropogenic category have lower specific weight, but some classifier, like garbage (3.88) and houses made of mix material (3.60) and wood (3.15) have a moderate specific weight. Thresholds between one risk level and another were computed using training set with a total of 530 shallow landslide risk sectors of Sao Paulo. For each sector, we use input data collected in the field and we computed a risk value. We plot a density histogram and used kernel density estimation to display normal distribution, and each normal distribution represents one risk level ($R1 < 31$, $31 \leq R2 < 49$, $49 \leq R3 < 69$, $R4 > 69$).

CONFUSION MATRIX

Based on three confusion matrix, OLR quantifies the level of the risk more similar to the BGM when compared with AHP. Experts based methodology is less conservative than OLR and BGM, classifying the level of risk lower than both methodologies.

CONCLUSIONS AND FURTHER WORK

Classifying quantitatively and qualitatively the landslides risk areas in urban area in Brazil is not an easy task, due to specificity of each sector. There are some aspects that are similar, like overall precarious and self-engineering dwellings. However, each dwelling and sector have their one particularity and are constantly changing. The developed application can help map these risk sectors and diminish the bias during the mapping. For future, being able to take photos using the application and manual drawing the risk sectors boundaries using a map would improve data collection.

INTRODUCTION

Prompt and accurate collection/distribution of information is important to minimize damage due to a large-scale disaster. The utilization of social media, particularly Twitter, during a disaster has attracted worldwide attention (Imran et al., 2015). The number of tweets increases explosively during a large-scale disaster. For example, on the day of the Great East Japan Earthquake, approximately 33 million tweets were posted. In the 10 minutes after the Northern Osaka Earthquake hit Japan on June 2, 2018, more than 270,000 tweets that contained the word "地震" (earthquake, in Japanese) were posted (Yamada et al., 2018). Therefore, to effectively utilize Twitter during a disaster, it is important to analyze the characteristics of tweets. In this study, we analyze Japanese tweets posted when 2018 Typhoon Jebi, one of the strongest typhoons that landed in Japan in the past, was approaching and striking Japan. Specifically, we create co-occurrence networks to visualize what kind of tweets have been posted a lot. We also develop an application that displays the position of the typhoon, precipitation, and the co-occurrence network simultaneously.

METHODOLOGY

Tweet Dataset

2018 Typhoon Jebi (Typhoon No. 21) caused extensive damage, particularly in the Kansai region such as Osaka, Japan. In this study, we analyze Japanese tweets about 2018 Typhoon Jebi that were posted between Sept. 3rd and 5th, 2018 and contained the word "台風" (typhoon, in Japanese). These tweets were collected by using the Twitter Search API by ourselves (6,096,493 tweets).

Co-occurrence Network Diagram

We make co-occurrence network diagrams of words used in the tweets for a better understanding of target tweet contents. This paper focuses on the word "上陸" (landing), which is a word not commonly used under normal circumstances (Japan Meteorological Agency defines "landing" when the center of a typhoon reaches the coastline of the main territory of Japan).

Application to display the position of the typhoon and the co-occurrence network

We develop an application that simultaneously displays the position of the typhoon, the precipitation distribution, and the co-occurrence network of the tweet at the analysis target time to facilitate understanding the relationship between inclement weather, the extent of damage, and tweets. In this study, we obtain the location of the typhoon from Digital Typhoon (http://agora.ex.nii.ac.jp/digital-typhoon/) and the amount of precipitation at each location from the Japan Meteorological Agency, respectively.

RESULTS

Figure 1 shows the co-occurrence network obtained from the original tweets (tweets that are not retweets) that contain "上陸" posted between 12:00 JST and 13:00 JST on Sept. 4th (3,237 tweets). In Fig. 1, the size of the circles indicates the word frequency. The direction of the arrows indicates that words are connected in that direction. Thicker arrows indicate more tweets and stronger arrow colors indicate a stronger relationship. As can

be seen from Fig. 1, many tweets referred to "Typhoon Jebi (Typhoon No. 21) landed on the southern part of Tokushima Prefecture." Moreover, we can find the important content that "a man repairing a roof in Itano town was injured," although the number of tweets mentioning is small.

Next, we developed an application that simultaneously displays the position of the typhoon, precipitation distribution, and co-occurrence network of the tweets. Figure 2 shows examples of the developed application screen. By changing the options on the top of the screen, the application can also display the results for a particular time one wishes to analyze. By using this function, the transition of tweet content can be identified interactively. Moreover, as well as the time, we can change the words to focus on.

CONCLUSIONS AND FURTHER WORK

We created co-occurrence networks of Japanese tweets about 2018 Typhoon Jebi to analyze and visualize what kind of tweets have been posted a lot. We also develop an application that displays the position of the typhoon, precipitation, and the co-occurrence network simultaneously. We collected tweets about the 2018 Typhoon Trami which also caused huge damage to Japan; therefore, we plan to compare the content of those tweets and tendencies in emoji usage in the future. Note that while the application developed for this study visualizes analysis results of already collected tweet data, we would like to build a system that displays analysis result in real time during a disaster in the future.

Standardization for an enhanced crisis management

René Lindner
DIN e. V.
rene.lindner@din.de

INTRODUCTION

The poster "Standardization for an enhanced Crisis Management" is describing the standardization activities within the research project DRIVER+ (Driving Innovation in Crisis Management for European Resilience). The integration of standardization in research and innovation projects is increasing and a well-established path and approved methodology that supports the integration of standardization in the projects is needed. This will address the need of the projects to exploit and disseminate the project findings with a suitable tool. DIN as standardization body is part of this project in which more than 30 partners work jointly to demonstrate and test crisis management solutions. Therefore the poster provides information on the project itself, the standardization methodology used within the frame of the project, the proposals for new standards as well as the possibility to join the standardization activities, the project related crisis management network CMINE and the future usage of the standardization work conducted in the project.

METHODOLOGY

The standardization activities within the DRIVER+ project have been led by DIN, the German Institute for Standardization. The main reason for the involvement of DIN is the possibility to exploit the standardization potentials out of the DRIVER+ results and to transfer these directly into new standardization activities. Therefore an integrative approach was used, with analyzing existing standards and assessing the standardization needs and potentials of the project by evaluating 1) the needs of the market and end-users in crisis management *(Demand side) a*nd 2) the DRIVER+ results being able to be transferred into a standard (considering various selection criteria) and any other relevant existing standard *(Supply side)*. The outcome of this assessment with the support of a dedicated workshop to support the identification of standardization ideas were several proposals for new standards (e.g. CEN Workshop Agreements).

RESULTS

Out of the first phase of the development of standards within the DRIVER+ project, three different CEN Workshops have been initiated: 1) Requirements on information exchange across borders and organizations; 2) Trial Guidance Methodology; 3) Building a Common Simulation Environment. For the upcoming standards development phase the concept of integrating several different stakeholders and especially end-users is of high importance. In this regard the *Community of Practice* network CMINE (Crisis Management Innovation Network Europe) is supporting the interaction with and integration of project internal and external organizations in the standardization activities.

CONCLUSIONS AND FURTHER WORK

The integration of standardization activities in research and innovation projects such as DRIVER+ supports the dissemination and exploitation of project findings, raises awareness on existing relevant standards and fosters the initiation of new standardization activities to which project externals are highly invited to contribute to. The approval of the methodology to integrate standardization in DRIVER+ and other research projects via survey and lessons learned assessment is planned. For the standards currently being developed, every organization interested to join one of the three above mentioned standardization activities are invited to contact the project.

ACKNOWLEDGMENTS

The DRIVER+ project has received funding from the European Union's Seventh Framework Programme for research, technological development and demonstration under grant agreement n° 607798.

Constructing Trust in Disaster Communications

Yuko Murayama
Tsuda University
murayama@tsuda.ac.jp

INTRODUCTION

The Great East Japan Earthquake on March 11th, 2011 caused severe damage to the northern coast of the main island in Japan. Since then we have been working to help out the affected area in terms of IT support such as internetworking and providing PCs. Through our support activities we came across an interesting issue concerning collaboration with people from heterogeneous backgrounds. Those people who worked on the disaster response came from different backgrounds and most of them were doing quite different tasks from what they usually did before the disaster. Disagreements and distrust happened quite easily. We call this problem disaster communications in this paper. We found that trust plays an important role in such communications.as well as how possibly we could construct trust based on the Salient Value Similarity (SVS) Model. In this paper we report our experiences during our support activities and our findings in terms of trust.

METHODOLOGY

We received a request from people in Tokyo indicating that some companies located in the Tokyo area would like to know where they could possibly send PCs and printers for use in disaster support. A group of engineers from academia and industry also offered to help set up data networking in the affected area. They needed to know where they could provide the equipment and network services. We contacted the emergency response headquarter of Iwate prefecture for information and suggestions about providing the coast area with network services and PCs. Moreover, we came to know the people in the large volunteer center (VC) in Tohno City located next to the affected coastal cities. Tohno City did not suffer as much from the Tsunami and was useful to support the disaster locations. In the end, we organized a loosely coupled federation of projects, organizations and people.

According to National Research Council (National Research Council,1989) risk communications is "an interactive process of exchange of information and opinion among individuals, groups, and institutions." Risk communications have been studied to a great extent (Reynolds, B. and Seeger, M.W., 2005), but focused mainly on the future risks. On the other hand, disaster communications are more immediate in dealing with real incidents; they are considered as a part of emergency management (Hilz, S. R. et al., 2009).

Disaster communications include many different entities such as sufferers, volunteers, administrative offices and supporters from organizations or by individual. All of them have different viewpoints and different background. For disaster support, they need to discuss the issues on the same table. They would have the same purpose but it might be hard to cooperate with each other. From our experiences, disaster communications have the following nature:

1. Heterogeneity of people
2. Most of us are novices
3. Communications with unknown people
4. Need for decision-making in changing circumstances
5. None knows the true needs
6. Don't expect appreciation

To better understand the implications of operating in this space we look to the Elaboration Likelihood Model (ELM) from psychology (Petty, R. E. and Cacioppo, J. T., 1981). According to the model, when we receive Persuasive Communication, such as a commercial message for a car, if we are interested in knowing more about the car in question (Motivated to Process) and knows much about cars (Ability to Process), we could decide to

accept the initial message or not by ourselves (Process with Central route). However, if one is not interested in the car, or does not know much about cars, then one would not look back at the initial message content, but would decide to accept the message or not according to environmental issues such as who sent this message or the way in which it is presented (Process with Peripheral Route).

For disaster communications we often need to process with the peripheral route and so need to be able to assess our trust in the source.

RESULTS

In the beginning of our support activities, most of us working in the information science and engineering area assumed that information and communication technology would be required desperately, however, the truth was that it was not so. We presumed the providers' viewpoint. What was really needed in the first place was support personnel and cars with drivers; moreover, a person who could listen to the people in the suffered area, as well.

According to the Salient Value Similarity (SVS) (Earle, T. C. and Cvetkovich, G., 1995). If one shared a salient value with someone else, we could trust someone. The question is how exactly we could share such a value at disaster. Eight years ago in a shelter, firstly we were asked to provide cars and helpers and we provided a helper. Next, they asked for a copier and we provide the one. Whatever was requested, when we showed our intention to provide what was needed. Gradually the managers of the shelter thought that they shared a salient value with us. Sharing the salient value might have been possible based on such transactions with requests and positive replies. We did not provide a hundred percent of what we were asked for, yet we succeeded in constructing trust. Our hypothesis is that transactions with requests and positive replies are important for the counterparts to presume they share a salient value with us so that they construct trust in us.

CONCLUSIONS AND FURTHER WORK

In this paper, we reported our experiences from our support activities just after the Tohoku earthquake and tsunami on March 11th, 2011 and our initial work on disaster communications derived from our experiences. Quite often officers in local governments as well as some in the prefectural emergency response headquarters office, regard that fairness is most important in the management of support. On the other hand, from our experience, what we needed for disaster communications included speed, rhythm and trust. We needed speed, because everyone expects a prompt reply. The best that we could do is to start creating whatever was requested and inform the requestor that we were working on it, so that the requester would feel the request was being addressed. We need rhythm in our activity so that even when we receive almost impossible request, we would have some way to deal with it.

From our experiences what we required was speed, rhythm and trust in disaster communications. In our previous work, we lead that the trust is required in disaster communications based on ELM. Moreover, using the SVS model, we came up with the hypothesis that speed and rhythm in disaster communications could lead to construct trust. We could possibly show the hypothesis in a heuristics way in future by try and use such communications at disaster response.

ACKNOWLEDGMENTS

I appreciate the cooperation with the people throughout the emergency response eight years ago in Iwate. In particular, I thank Yushi Oyama, Shuzo Koshino, Shinji Akitomi and Shuichi Takamatsu.

Gathering Local Knowledge for Disaster Risk Reduction: The Use of Sketch Maps in Group Discussions

Carolin Klonner
Institute of Geography, Heidelberg, Germany
c.klonner@uni-heidelberg.de

Luca Blessing
Institute of Geography, Heidelberg, Germany
luca.blessing@stud.uni-heidelberg.de

INTRODUCTION

Participatory approaches can be applied to investigate the geospatial knowledge and risk perception of citizens in disaster-affected regions. Knowledge gained this way can improve, for example, the precision of official risk maps for specific locations. A dialogue between researchers, citizens, and centers of expertise can be established, which enables exchange around recommendations for measures of disaster risk reduction on a local level. The presented approach is based on previous studies about the use of sketch maps for disaster risk reduction (Klonner et al. 2016; Klonner et al. 2018). These previous studies and related methods are further developed so that they can be used for group discussions. In this way, citizens can be involved in the whole disaster reduction process, which can help to motivate them to take own mitigation measures. In addition to Bustillos Ardaya et al. (2019), who also applied large maps in a similar way, our approach offers automatic georeferencing and color detection. This enables a fast processing of the data and efficient use for disaster management. Moreover, the approach is paper-based in order to include marginalized groups, which do not have knowledge of specific technologies or access to the internet.

METHODOLOGY

We apply a participatory approach to capture geospatial local knowledge. This method is based on a cartographic map in which inhabitants of flood-affected regions mark their flood risk perception with colored pens or stickers. Additionally, they can mark elements at risk as well as flood levels of historic flood events, which they experienced. If stickers are used, other groups can even reuse the base maps. These sketch maps are used in a DIN A0 format in order to allow their utilization in group discussions. In this way, people can share their knowledge, mark it on the common map, and thus, gather and combine their local knowledge. The discussions during the elaborations are valuable additional insights into the priorities of the participants who were already affected by disasters and are likely to be affected again. Furthermore, the communication can unveil information that a participant might not have mentioned in an individual interview. The evaluation can lead to more adequate disaster risk reduction measures for this specific region, and makes it possible to develop risk perception maps and to identify areas at risk, especially in areas, where no other risk maps are available.

We aim at providing a sustainable approach for the use by local governments, and thus, only little technical knowledge and equipment is required for the application. The DIN A0 maps consist of DIN A4 pages that are glued together. Furthermore, we use open source software to allow for availability of the tools also for communities with limited resources. We apply OpenStreetMap Field Papers as the base map of the sketch maps, and for the color detection we use the Open Source Computer Vision Library (OpenCV). The analysis of the geospatial information captured via the sketch maps is performed with the geo-information system QGIS. The easy-to-use paper-based method can be applied in the field, during workshops, in schools or community centers, and does not require battery or internet connection. Pictures of the sketch maps can be uploaded to the Field Paper homepage at a later date, where they are automatically georeferenced, and the resulting GeoTIFFs can be downloaded to QGIS. We use an automatic color detection, which saves a lot of time and avoids errors in comparison to manual digitizing of the participants' marking. The marking is stored in a separate vector file for further analyses in a GIS.

RESULTS

We applied the sketch maps for group discussions in Eberbach, Germany, which is regularly flooded by the Neckar river. Citizens were asked to mark the maximum water level they experienced (orange), the normal overflow (red) and elements at risk (blue). The participants discussed and exchanged their experiences and as soon as they agreed on the specific area, one of them marked it on the map (Figure 1). After the automatic georeferencing of the sketch maps and the download to QGIS, the marking of the sketch maps was automatically detected via the newly developed approach and saved in a separate vector shape file.

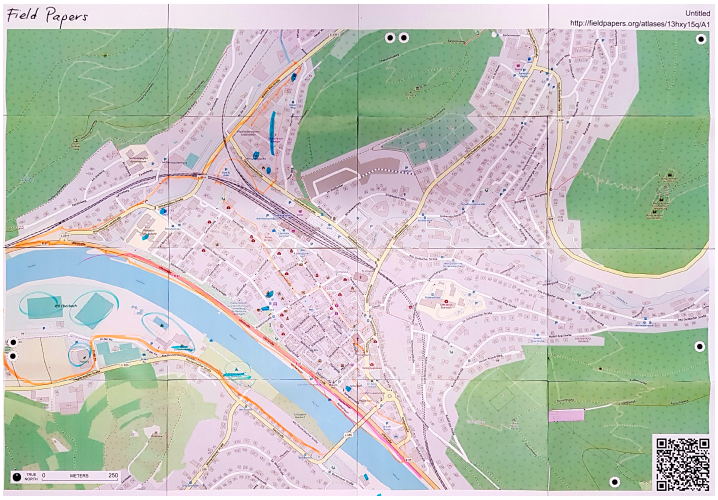

Figure 1: Sketch map of a group of four people who marked the maximum water level they experienced (orange), the normal overflow (red), and elements at risk (blue).

CONCLUSIONS AND FURTHER WORK

The results of the pilot study show that our approach of group sketch maps is an easy-to-use method, which works well for both capturing detailed local knowledge and visualizing this knowledge automatically. The information exchange during the group discussions led to very detailed markings. We will use this approach for further research in different flood-affected study areas in Brazil.

In addition to capturing local knowledge about floods, the presented approach can be adapted to different natural and anthropogenic hazard types. Moreover, beyond the use in research, the method is also applicable by practitioners. The use of sketch maps in group discussions offers to capture and visualize local information, for example, about elements at risk, flood risk perception as well as flood level estimation based on the experiences of the citizens. This local information can be combined with data provided by centers of expertise or local authorities such as historical data, models, and risk maps.

ACKNOWLEDGEMENTS

The research project is funded by the Belmont Forum and NORFACE joint programme Transformations to Sustainability (T2S) and by the Federal Ministry of Education and Research in the field of social-ecological research. We thank the city council and the citizens of Eberbach for their support of and participation in the project.

INTRODUCTION

Crisis situations require specific information to organize and respond to the events. The need of information is important and emergency management cells aim at gathering them as much as possible to build a common operational picture (COP) of the field. Also, citizens are using more and more social media to share what is happening around them during exceptional events. As (Justine I. Blanford et al. 2014) shows, citizens tend to send more messages during crisis situations. Social media, such as Twitter, Facebook or Instagram therefore participate in the exchange of information related to the crisis. Consequently, it is important to be able to take advantage of this by integrating citizens' social media data into the decision-making process.

Up to this day, many tools exist in the literature. However, information systems integrating social media data into the COP are rarely used in the facts because they are still resource-consuming. This leads to a paradoxical situation where decision-makers are looking for information to organize their resources while victims and witnesses' willing to share information is not taken into account by rescue organizations. Also, (Imran et al. 2018) points out some possible necessary improvements. Among them, "*how the added-value information extracted thanks to such social media-oriented system should be integrated in the decision-making process?"* echoes to this context.

Consequently, **how to fully integrate the information provided by social media data, in times of crisis, to improve the common understanding and thus the collaborative response of the responders?**

METHODOLOGY

The proposed approach relies on an understanding of the rescue organization by the algorithms. In (Kropczynski et al. 2018) authors highlight that in the American 911 call centers, staff are asking questions in order to answer the "6Ws" (What, When, Weapon, Why, Where and Who). Any answer related to one of these questions is then forwarded to the emergency teams. Assuming that they are taking decisions according to a specific set of concepts environment, resources, people involved, possible additional threats etc. It may be possible to map these concepts within the stream of social media data and, make the algorithm "understand" the corresponding extracted information.

Many people proposed metamodels or ontologies that cover concepts involved during an emergency. (Bénaben et al. 2016) introduces a metamodel focused on supporting the collaboration between crisis stakeholders. Its purpose is to describe the activities they carry out with each other in order to respond to the better way to the crisis.

Based on the metamodel, the approach proposed here is to couple a classifier that will help mining the information within the social media data stream and a metamodel to make sense of them thanks to well-known concepts. Doing so, it would be easier to monitor the operations and feed the COP. The classifier role would be to capture the data relative to the metamodel's classes and then, instantiate the them. This study is proposed for Tweets data flows as they remain the most accessible thanks to the use of the Twitter Application Programming Interface[1].

[1] https://developer.twitter.com/en/docs/api-reference-index

RESULTS

Hence, the proposed solution to our research question is composed of a classifier alongside a metamodel. While this solution allows the classifier to identify data which contains the concepts the responders are interested in, several challenges are ahead. The classifier needs to "reconcile" the data it receives, with the metamodel classes, in order to instantiate the classes. To do so, the classifier requires a text representation that keeps enough context to decide if this tweet, or this set of words (i.e. parts of tweets), relates to a class of the metamodel. This 'contextual' word representation should be handled first by a word embedding. Word embeddings represent word tokens through vectors according to the surrounding context of each word. Word embeddings are relevant if their vocabulary is sufficiently extensive, otherwise they encounter too many out-of-vocabulary words. Moreover, domain-specific embeddings face the lack of relevant training data too obtain large enough volume. (Karisani et Agichtein 2018) proposes as a solution to use a general-purpose word embedding with adjustments. Their solution is based on emphasizing the terms most related to their domain.

Then, having contextualized all textual tokens, the classifier must properly aggregate them and label the corresponding extracted information according to the metamodel. To do so, the system will use a clustering algorithm that still has to be chosen depending on a benchmark, that will be applied to the n-dimensional results of the word embedding. That way, clusters of words will be mapped to the concepts of the metamodel. The distance formula for the clustering algorithm will have to take several elements into account such as: a predefined relevant time window, a semantic proximity or a geographical source of data proximity.

CONCLUSIONS AND FURTHER WORK

This paper presents a novel social media analysis system which aims to integrate further the information collected on social media during a crisis into the decision-making process. The problematic raised at the beginning is: how to fully integrate the information provided by social media data, in times of crisis, to improve the common understanding and thus the collaborative response of the responders?

Future work will consist in both experimentation and implementation. Moreover, further work may lead to try to merge the data coming from social media and data coming from sensors available on the field (water level, CCTV…). Also, this work is not dedicated only to crisis cells and results may be reused in humanitarian supply chain management, to extract the different stakeholders thanks to previous records.

INTRODUCTION

For emergency management agencies information retrieval is of particular importance since it is crucial for decision-making and the gain of situational awareness during a crisis. Many different data sources are available for the usage in the context of crisis management like for example weather forecasts, sensor data, historical context information or social media messages. By including all these different information sources vast amounts of data can be generated in short times. If not handled appropriately this can lead to informational overflow for human analysts. To prevent this an automated analysis, efficient visualization and appropriate filtering methods for the multi-modal data are required. A combined visualization of the different data sources will also help in this regard. It will improve the ability of analysts to get a better overview of the current situation as well as their ability to validate and verify single events.

In order not to be limited to some specific data sources a generic approach to a combined visualization of the data is desired. This will increase on the one hand the applicability of such a tool for different emergency management agencies and on the other hand its adaptability to changes of crisis management systems it is used in. A trade-off that often comes along with these generic approaches is that the data will be broken down to common features between the different data sources, which often results in a loss of information. This work presents an approach to the realization of a visualization tool that tries to accomplish both: the ability to include many different data sources as well as being configurable to each single data source to prevent a loss of information. The presented approach was developed in the frame of the beAWARE project (Karakostas et al. 2018), which aims for the creation of a holistic approach, that supports decision makers through all phases of a natural disaster related crisis, i.e. preparedness, response and recovery.

DESIGN CONSIDERATIONS

From the motivation stated in the introduction two requirements for the workbench can directly be derived. These are the ability to visualize combined data from different information sources and the ability to include these data sources in a generic way that allows for a high configurability. To reduce the threat of informational overflow a further requirement is a powerful filter system. Since time is a crucial constraint in crisis management, it is important that the visualization tool enables analysts to get the information they need in a relatively short time. The last requirement therefore was a quick access to the important functionalities.

For the visualization of data from different data sources one needs an attribute that is shared by the data and can therefore be used as a base for the visualization. Since a lot of the data used in crisis management will be location based a map was chosen for its visualization.

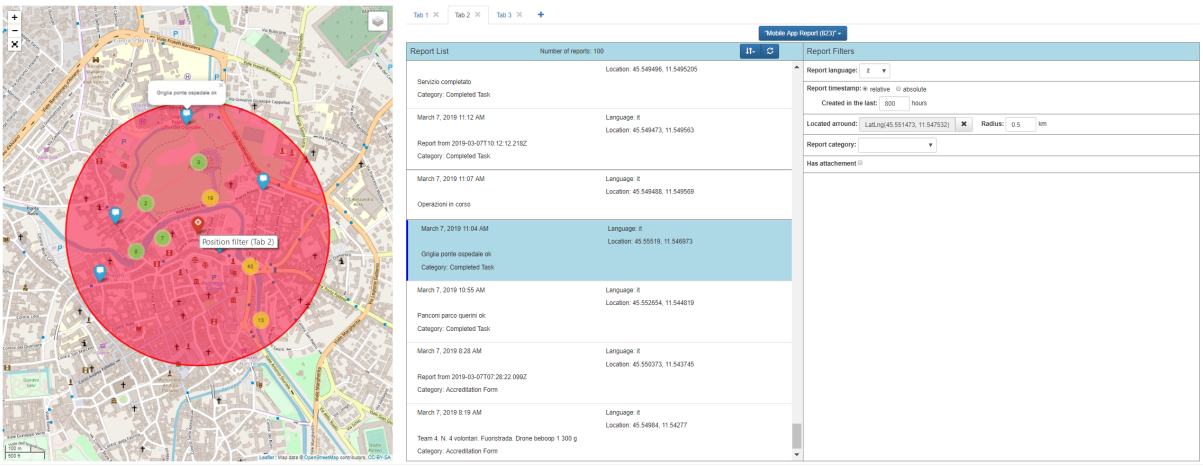

Figure 1. Overview of the Message workbench.

THE MESSAGE WORKBENCH

The message workbench was implemented as a web application, in order to be usable without a specific installation on multiple devices. Besides the map, a sortable list is used as a structured representation of the data. The graphical user interface of the tool consists therefore out of three main parts, which are the list, the filters and the map (see fig. 1). The list and the filters are placed inside tabs, which can be created and closed within the application. For each tab one data source needs to be selected. Due to the tab system a parallel analysis of different data sources is possible within the map.

In especially the filters and the list are implemented in a way, which allows for a high configurability to different data sources. On the one hand this allows analysts to filter and sort the list after each attribute available in the data. On the other hand, this enables an adaptable display of the data for each data source in the list.

The map will display all available origin locations of the messages in each tab that fits the chosen filters. The entries in the map and the lists are linked with each other so that a click on an entry in one of the two visualizations will highlight the entry in the other visualization as well. Further the map offers a second possibility to include data into the workbench by providing interfaces for the retrieval of data from several common spatial databases. For data that is integrated by one of these interfaces a map layer will be create, that can be toggled on and off. By this also non-message-based data can be integrated.

CONCLUSION AND FURTHER WORK

This work presents a design approach for a generic visualization workbench that is able to display data from different data sources in a common user interface. It includes a highly configurable filter engine, that shall allow analysts to gain knowledge from large amounts of data.

The workbench is still under developement. The inclusion of other visualization formats might be an interesting step in the future like for exp. a time-line as a time-based visualization of the data. Up to now a prototype of the workbench has been developed and was integrated into the crisis management system of the beAWARE project. A deeper evaluation of the system is currently ongoing.

INTRODUCTION

One of the recently revealed approaches to social media fake news detection is the propagation-based approach. the assumption is that information trustworthiness evidence could be unveiled by investigating different opinions and contradictions. In propagation-based methods, credibility networks are built to employ optimization techniques over different pieces of news giving the underlying point of view. Mining different viewpoints and reactions to news are referred to as stance detection tasks. Hence, stance detection attempts are required first to accomplish fake news detection. However, stance detection models are not either robust enough nor generalized on different datasets, since they are highly dependent on the specific training data feature space. That introduces the first challenge to propagation-based fake news detection. Another challenging and maybe avoided issue is the problem of biased opinions or accounts. That is because propagation-based techniques assume that trusted opinions would be a majority compared to fake ones. However, it is a bit naive hypothesis since biased and misleading viewpoints would be the majority in many cases. A biased piece of news could fall into three categories: *Biased purposely false*, *biased unintentionally false*, and *biased correct*. We consider only the first type as an obstacle to propagation-based fake news detection models since the other varieties do not have a considerable impact. The aim of our study is to develop a robust propagation-based fake news detection model that remains accurate regardless of the above-mentioned challenges. For that, we will simulate different use cases with biased and misleading stances. Our method does not require ground truth information for news credibility since we propose a non-sequential reinforcement learning instead of supervised learning. In the following sections, we will present the current solution and empirical results.

METHODOLOGY

We propose a distributed learning automata (DLA) method as a graph optimization framework to the problem of propagation-based fake news detection. DLA is a network of individual learning automata (LA). LA is a model of intelligent computation where learning is accomplished by exploring and its consequences, in an iterative and reinforcement manner. The objective is to decide the optimal action to select between all the possible actions. LA usually deals with randomness when there is no supervision of learning. Hence, LA learns by interacting with an

environment, sometimes is called a teacher. The environment sends regular feedbacks for when the LA explores a particular action. The LA refines its action selection in future explorations with regard to the environment recent response. Our DLA is constructed on top of a social graph where social media messages and their provided stance information are representing the graph vertices and edges weights respectively. Each automaton will be associated with a node in the graph. At each step in time, a randomly generated set of automata pairs is formed. In each pair, one automaton is active and the other is passive. For each pair, the active automaton is the one that will explore a possible action and the other one is considered the environment of the first automaton and will remain passive until next round. The DLA network is uninformed where all automata share the same structure with two possible actions: *Fake* and *Trust*. Each underlying node in the DLA is initialized with a weight that should guide its associated automaton to approximate its finally chosen action probability for the associated message. The initial weight is a probabilistic value which estimates a percentage of the non-biased contradicted opinions with the message. Then, and randomly, each pair elements interact together, and each active automaton tries to estimate its fake/ trust probability distribution vector according to the interaction feedback while nodes weights are adjusted as well. The below formula demonstrates how LA actions probabilities would change.

$$\pi_{[fake,\ t+1]} = \begin{cases} \pi_{[fake,\ t]} + \boldsymbol{\Delta} & penalize\ fake = \mathbf{0} \\ \pi_{[fake,\ t]} - \boldsymbol{\Delta}, & penalize\ fake = \mathbf{1} \end{cases}$$

$$\pi_{[trust,\ t+1]} = 1 - \pi_{[fake,\ t+1]}$$

$$\text{Where } \boldsymbol{\pi}_t = \begin{bmatrix} \pi_{[fake,\ t]} \\ \mathbf{1} - \pi_{[fake,\ t]} \end{bmatrix} \text{ or } \boldsymbol{\pi}_t = \begin{bmatrix} \pi_{[fake,\ t]} \\ \pi_{[trust,\ t]} \end{bmatrix}$$

and **Δ** is the amount to increase the probability of an action when rewarded or decrease it when penalized after evaluating some conditions at time step **t**. Then, the automaton probability vector $\boldsymbol{\pi}$ is updated. Our experiments used both artificial data to simulate different scenarios and real-world data collected by the PHEME project [1]. The latter was post-processed by us in order to structure the stances and credibility ground truth in an easy format. The PHEME dataset was originally collected and annotated from tweets talking about Charlie Hebdo shooting. In the following section, we demonstrate our empirical results on both types of data.

RESULTS

According to the below empirical results, it was inferred how a high biased data, providing less stance information, and difference in the percentage of fake samples would affect the performance of DLA. However, our proposed DLA still perform above average in some of these challenging situations.

Dataset	Number of Samples	Fake Perc	Stance Perc	Biased Perc	Accuracy	Precision	Recall	F1 Score	Convergence Time Avg (Iterations)
Exp1	**100**	**.50**	**.38**	**.34**	**.73**	**.64**	**1**	**.78**	**2500**
Exp2	**100**	**.50**	**.64**	**.40**	**.75**	**.66**	**1**	**.80**	**2500**
Exp3	**100**	**.50**	**.34**	**.64**	**.27**	**.36**	**.51**	**.42**	**2500**
Exp4	**100**	**.50**	**.67**	**.45**	**.73**	**.65**	**.98**	**.78**	**2500**
Exp5	**100**	**.10**	**.62**	**.08**	**.35**	**.13**	**1**	**.24**	**2500**
Exp6	**100**	**.90**	**.47**	**.87**	**.65**	**.87**	**.72**	**.79**	**2500**
Charlie Hebdo	**213**	**.34**	**.09**	**.35**	**.54**	**.52**	**.50**	**.51**	**2500**

CONCLUSIONS AND FURTHER WORK

We proposed an under-development method to propagation-based fake news detection which is more robust in biased scenarios. The empirical results show how the DLA performance varied with different percentages of existed fake samples. Moreover, the percentages of biased and provided stances affected how DLA performed. Further work would be the investigation of these obstacles with a complete formalization of both problem and solution, we also suggest developing a different LA structure and compare it with the current LA structure.

INTRODUCTION

Large-scale natural disasters are a frequent occurrence in Japan. During and after the disasters, numerous messages (i.e., tweets) related to the disaster are posted on Twitter. At the times of recent disasters, such as the 2017 Northern Kyushu Floods in Japan and the 2018 Japan Floods (the July 2018 Heavy Rain Disaster in Japan), victims who needed to be rescued used the hashtag #救助 (meaning #Rescue) in the tweets they posted to request a rescue. Usually, if a victim needs to be rescued, an emergency phone call with a rescue request can be made (to the numbers 110 or 119 in Japanese phone networks). In the 2018 Japan Floods, a record-breaking heavy rain poured down in western Japan in July 2018, killing 222 people and causing severe damage. Media reports have noted that the fire department could not receive and respond to all of the rescue request calls because of their vast number. However, many victims did post tweets requesting a rescue on Twitter as an alternative to making emergency calls. Because only a few studies have investigated the effectiveness of such hashtags, an investigation into the circumstances of the posted tweets with rescue request hashtags needs to be conducted to enable better rescue and supporting activities. In this study, we collect and analyze tweets with rescue request hashtags that were posted during the 2018 Japan Floods.

ANALYSIS OF TWEETS WITH RESCUE REQUEST HASHTAGS

The tweets posted during the 2018 Japan Floods that included the word 救助 (rescue) were collected using the Twitter Standard search application programing interface (API) provided by Twitter Developers. We investigated the tweets that were posted between 12:00 on July 6 and 23:59 on July 8, focusing on the 224,976 tweets with a rescue request hashtag. The rescue request hashtags we considered in this study include #救助 (meaning #Rescue) and combinations of the type #救助 xxxx (a combination of #救助 and another word), the number of original tweets (OTs) was 3,395 and the number of reposted tweets, or retweets, was 221,581. We classified the OTs into one of the categories listed below. If the tweets included images, videos, or hyperlinks that were still available, we referred to them to improve the classification.

- R1: Tweets that are requesting the rescue of a contributor, an individual, or a group. Tweets in this category include a detailed address (such as the house number, street number, and name of the location) or a description of a landmark at the location where the rescue is requested. These tweets should use the hashtag #救助, as instructed by the @TwitterLifeline account (@TwitterLifeline, 2018).
- R2: Tweets that are requesting a rescue, but which do not satisfy the conditions for category R1, e.g., detailed information on the location in which the rescue is requested.
- X: Tweets that describe the process of posting and/or sharing rescue request posts or the use of hashtags on Twitter or another social networking service (SNS).
- Y: Tweets not classified as an R1-X tweet, but talking about the disaster.
- Z: Tweets not classified as an R1-Y tweet.

Figure 1 shows the distribution of the OTs in the five defined tweet categories for 3,395 tweets. Even though the

number of tweets with rescue requests was small during the 2017 Northern Kyushu Floods (Sato and Imamura, 2018; Nishikawa et al., 2018), the number of such tweets during the 2018 Japan Floods experienced a marked increase. One reason for this may be the larger scale of the disaster than that which occurred in 2017. Conversely, 74.6% of the tweets (2,534 of 3,395) did not contain a rescue request and was classified into the categories X, Y, or Z. This behavior is similar to that observed in the case of the 2017 Northern Kyushu Floods (Sato and Imamura, 2018; Nishikawa et al., 2018).

Figure 2 shows a histogram of the number of posted OTs per hour. The total number of tweets began to increase from around 4:00 on July 7. The number of tweets began to increase about five hours after the special heavy rain warning was issued at 22:40 on July 6 at Kurashiki City in the Okayama Prefecture, where the most serious damage occurred. In Japan, such a special warning is issued by the Meteorological Agency when a weather phenomenon is observed that far exceeds the criteria for a general weather warning. The total number of tweets approached the first peak around 9:00, after which it slightly decreased, only to reach the second, higher peak around 13:00. The number of posted OTs then decreased, reaching comparatively small values after 23:00. The number of tweets may have decreased after 23:00 because of the late hours of the night or because the special heavy rain warning was called off (at 6:00 on July 8). On the next day, the number of OTs per hour began to increase again, up to the value of tens of tweets per hour.

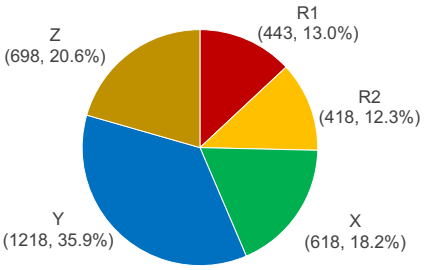

Figure 1. Distribution of tweet categories for 3,395 original tweets (OTs).

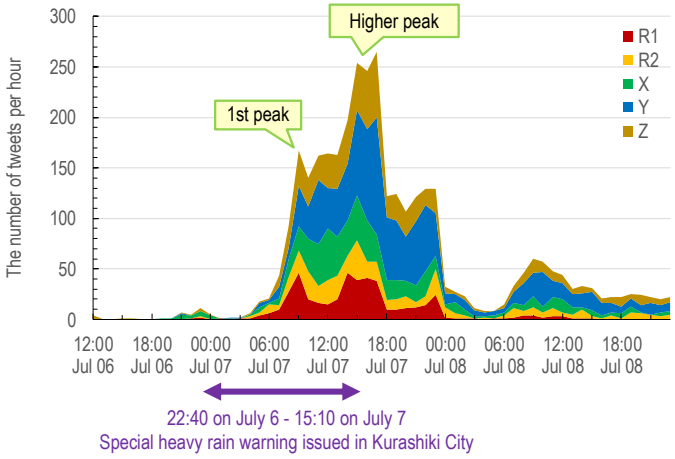

Figure 2. Histogram showing the number of original tweets (OTs) (stacked graph).

CONCLUSIONS

We analyzed the contents and trends of the tweets with rescue request hashtags that were posted during the 2018 Japan Floods. To efficiently and quickly utilize the rescue request tweets and respond with actual rescue activities, it would be useful to have a system, which can display the rescue requests on an online map based on the provided location information. We plan on developing this system in the future.

INTRODUCTION

The purpose of this paper is to examine the role of social media in the underserved communities to manage disasters. We draw on the *Uses and Gratification Theory, Situational Theory of Problem Solving,* and the research on *Communication Behavior* to develop a comprehensive model that will help identify people's behavior in the underserved communities when faced with an imminent disaster and their choice of social media for communication purpose during disaster. Our conceptual model and the propositions are given below. This paper is still work in progress. In the methodology section, we provide the method used to develop the conceptual model and the propositions. In the results section, we provide our conceptual model and the propositions. This paper finally concludes by proposing the further work that needs to be undertaken for completing this project.

METHODOLOGY

In order to understand the use of social media in disaster management, we conduct an extant literature review pertaining to social media and disaster management. We then identify the theories that can help us answer our question regarding the use of social media. Based on the theories, we develop our research model and state our propositions.

Prior studies have indicated that there is an increase in the use of social media for managing disasters. Social media enables open online discussions through interactions and conversations (Ngamassi et al., 2016). They facilitate the formation of new communities and have the potential to re-energize old ones (Omilion-Hodges and McClain, 2016). They also have the ability to establish widespread communication and flexibility to the changing needs of disaster responders and at the same time reinforcing information flow (Ngamassi et al., 2016). Despite social media being a powerful communication tool with great potential to aid in disaster management, past studies have indicated that it has not been used effectively in managing disasters (Ngamassi et al., 2016). This is specifically true in case of underserved communities (Nakahara and Ichikawa, 2013). In this study, we examine Uses and Gratification (U&G) theory, Situational Theory of Problem Solving (STOPS), and research on Communicative Actions in Problem Solving (CAPS) to understand how social media can be used effectively in the underserved communities for disaster management.

RESULTS

As mentioned in the previous section, we use U&G theory, STOPS, and literature on CAPS to develop our research model. We then state our propositions based on our research model.

Figure 1 shows our research model.

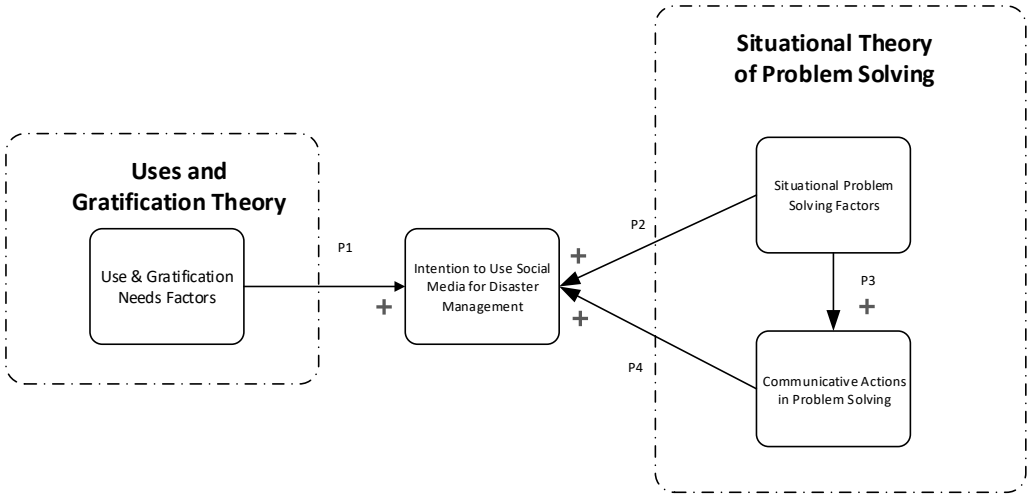

Figure 1: Research Model

Based on the above model, we make the following four propositions:

P1: There exists a positive relationship between social media use in gratifying needs factors and the intention to use social media for disaster management

P2: There exists a positive relationship between individuals' situational problem solving factors regarding disaster and the intention to use social media for disaster management

P3: There exists a positive relationship between individuals' situational problem solving factors regarding disaster and the communicative actions of problem solving for managing disasters

P4: There exists a positive relationship between communicative actions of problem solving and the intention to use social media for disaster management

CONCLUSIONS AND FURTHER WORK

In conclusion, this study focuses on providing a conceptual model to understand the use of social media for disaster management. Four propositions provide a theoretical foundation for future empirical studies. This study also contributes to the literature focused on the use of social media for managing disasters and has practical implications as well.

Further work is required in operationalizing these constructs and collecting the data. Once data is collected, the next step involves testing the data for reliability and validity issues. The final step is to test the model to see how well the data fits our model.

INTRODUCTION

The Europe population experiences yearly about 2 million to 2.5 million fires with 20 to 25 thousand deaths and 250 to 500 thousand reported injuries [1]. Moreover, EUFireAcademy states European countries suffered 558 fatalities per million inhabitants due to fire hazards during the year 2010.

Even though satellite-based positioning technology allows rescue workers to already operate efficiently, GPS availability, reliability, and accuracy are often poor during fire operations, for example due to thick smoke, dense forests, rough terrain and inside buildings. In this context, the objective of AIOSAT (Autonomous Indoor & Outdoor Safety Tracking System) [2] is to progress beyond the state of the art by defining the AIOSAT concept that aims to overcome aforementioned limitations of GNSS usage in rescue interventions. For this purpose, GNSS positions are enhanced with EGNOS and fused with position information inferred from IMU and RF.

METHODOLOGY

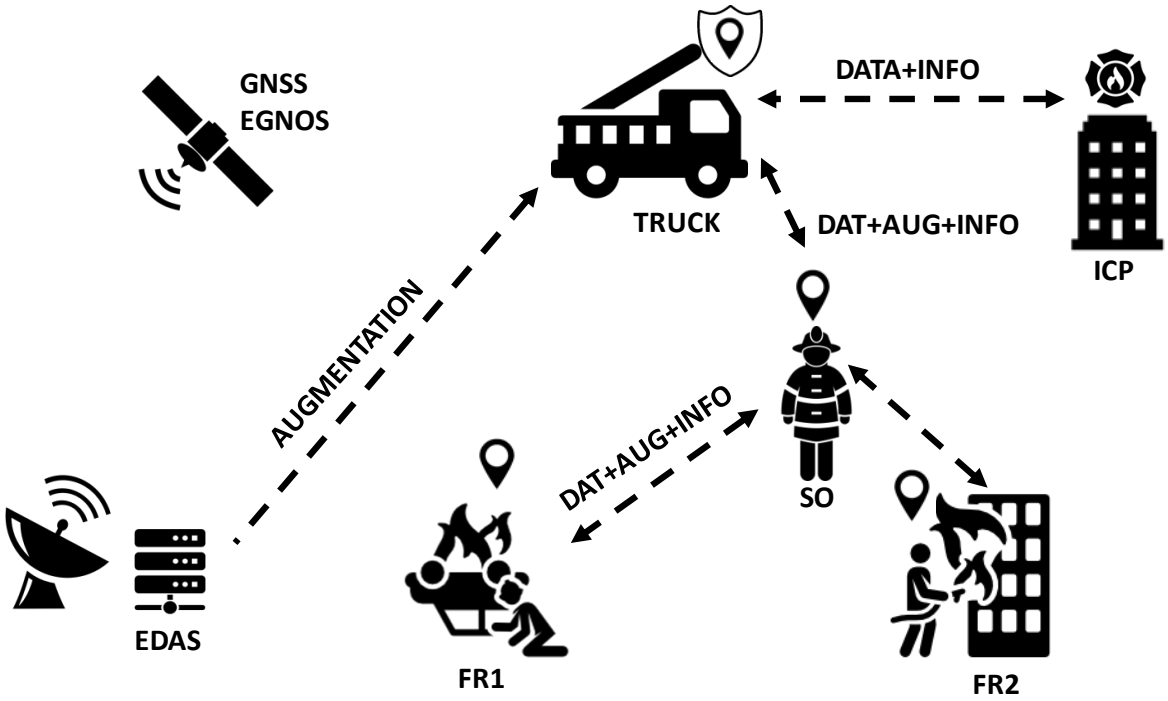
The main paths to the goal will be to define 1) the end-user requirements for the AIOSAT system, 2) the Advanced Positioning Subsystem 3) the Communications Subsystem 4) the tracking and alerting (TA) application and, 5) build an integrated prototype system validated during field tests.

The overarching objective of AIOSAT system is to advance beyond the state of the art in tracking rescue workers by creating a high availability and high integrity team positioning and tracking system. On the system level approach, this goal is achieved by fusing the GNSS with RTK approach [3], EGNOS, pedestrian dead reckoning (PDR) and ultra-wide band (UWB) ranging information, possibly augmented with map data. The system should be able to work both inside buildings and rural areas, which are the test cases defined by the final users involved in the consortium and the advisory board panel of the project.

The AIOSAT system will allow the team/brigade commander to track the location, including a confidence margin on the location, answering a necessity of the emergency services, and therefore the team commander will handle the information required for the success of the operation and to avoid any fatalities.

RESULTS

The AIOSAT system architecture is based on the components shown in the following figure:



CONCLUSIONS AND FURTHER WORK

The AIOSAT project aims at providing high-reliability location information during rescue operations for a safer operation. Its design focuses on modularity and ensuring data availability by integrating multiple sensors such as GNSS, IMU and UWB ranging subsystem, from which information, a fusing algorithm obtains the localization data. In the coming months, the partners will work towards the integration of all the sub-components for subsystem validation and full system validation in the 3 scenarios defined with the international end users.

ACKNOWLEDGMENTS

Results incorporated in this project received funding from the European GNSS Agency under the European Union's Horizon 2020 research and innovation programme under grant agreement No 776425.

INTRODUCTION

Intelligent Systems in Smart Cities capture and exchange a large variety of information, for example, environmental data, localisation, biometric and personal data, health records, among others, in order to improve the quality of services.

On one hand, such systems could represent an important, lifesaving resource for public services aimed at addressing emergency situations (e.g. firefighters, police), by providing access to a large amount of diverse information. On the other hand, they are also a threat with respect to data protection and privacy when disclosing all sort of personal and sensitive information.

Since not all the information available can be used or helpful for handling the emergency we have the challenge of ensuring that the least possible amount of sensitive information is exchanged, therefore reducing the risk of unwanted disclosure and misuse. Thus, being aware and include a privacy-by-design approach when managing personal and sensitive data is essential in the context of emergency systems.

This work aims to analyse the privacy issues that Intelligent Systems face when sharing information with public services to attend emergency situations. By characterising these issues, we aim of informing the knowledge requirements for designing an Intelligent System that only allows valuable and helpful information to be exchanged, minimising personal and sensitive data disclosure.

BACKGROUND AND RELATED WORK

Smart Cities have put in place a set of different Intelligent Systems (IS) that are constantly monitoring, sharing and storing a heterogeneous range of information with the aim to help at improving and planning public services (e.g. transportation, energy and water consumption, environment, education, health, social), for the benefit of their citizens (van Zoonen, 2016). It is clear that the information collected by such systems is diverse and ranges from public data to private and sensitive data, according to its objective (Wang et al., 2015). For instance, systems that assist daily activities for elderly people by monitoring biometric data of the patient (Aleksandar Rodić et al. 2016), or applications that aim to help citizens with respiratory problems by monitoring air pollution and its location to suggest safe routes (Mateo Pla et al. 2016), video surveillance systems capturing and recording images/videos of citizens (Dufaux and Ebrahimi 2005), are some examples of IS that manage sensitive information. In addition, the information generated by Intelligent Systems is becoming essential for the development and function of Emergency Systems which rely on the detailed information given by the Smart Cities to improve citizen's safety and attend emergency situations (Garcia et al. 2018; Palmieri et al. 2016; Patsakis et al. 2015). However, data privacy breaches appear in the context of Smart Cities Systems, as mention before, mainly because these systems gather an exceptional volume of information that can compromise citizen's privacy (Martinez-Balleste et al. 2013). Therefore, in the context of emergency systems, providing access to this information represents an important resource (Chehade et al., 2018), but in the same way, this massive disclosure of information constitutes a threat with respect to data protection and privacy when this information contains personal and sensitive data.

APPROACH

As not all information available is important or helpful for emergency services, we have the challenge to assure the minimal possible amount of personal and sensitive information is shared. Thus, protecting people's privacy and preventing disclosure and misuse (Ding et al. 2016). However, since this information is heterogeneous and comes from many different sources, the need for one intelligent layer that can govern this diversity is imperative. In this context, semantic technologies can play a crucial role (d'Aquin et al. 2015), for example, in governing the multiplicity of data, processes, and policies involved (Daga et al. 2015, 2016). Our approach consists of developing an ontology for discriminating between sensitive and not sensitive information. Giving a person in danger the ontology should be able to automatically evaluate what is the information necessary to help this person and, at the same time, assuring that the minimal and sufficient information is disclosed, hence avoiding data privacy issues and providing emergency services/systems with helpful information.

RESULTS

To illustrate how privacy issues arise when Intelligent Systems share information with emergency systems, we selected a use case scenario (Srinivasan et al. 2016) to exemplify the case of a fire event. Next, with the purpose to learn how privacy issues are handled in a given emergency event (a fire event), we conducted an extensive survey in a large organisation: The Open University. The University and its Health & Safety Department provide a great amount and well structure documentation that is not limited only to fire events (for instance covers topics as First Aid, Accident, Incident and near-miss information and Display Screen Equipment (DSE)). Furthermore, it complies with Statutory Instruments and British Standards. Therefore, it constitutes a good, paradigmatic and concrete case study. At first, we analysed the relevant information and the procedures in case of fire events stated in the University's documentation, then we familiarised ourselves with the organisation's fire safety guidelines and regulations. Next, we identified the data privacy issues to later extract the requirements that a privacy-aware Intelligent System has to consider. Finally, we analysed the findings in the light of an Intelligent System solution. The list of competency questions in Table 1 is our first output of this work in progress poster that we want to present and discuss with the audience.

Number	Competency Questions
CQ1.	Is the IS able to differentiate between public and private information?
CQ2.	What information can be considered as public, private or sensitive information?
CQ3.	Is the IS able to understand the impact of sharing sensitive and non-sensitive information?
CQ4.	Is it possible for the IS to identify trusted services or systems?
CQ5.	Is the intelligent system able to discriminate what information could be necessary in order to attend the emergency?
CQ6.	What is the level of detail of information required to attend a specific emergency event?
CQ7.	Is the intelligent system able to discriminate what information could be sufficient in order to attend the emergency?
CQ8.	Is the intelligent system capable of assuring the minimality of the data shared in order to attend the emergency?
CQ9.	How to preserve data security of information stored after it was used by an emergency system?

Table 1 Competency questions

CONCLUSIONS AND FURTHER WORK

Undoubtedly, data privacy concerns are present in Intelligent Systems that collect, store and share any type of information. In emergency situations, the IS deal with a large amount of personal information, that once shared with emergency systems might derive in privacy disclosure. This work in progress poster aims at presenting the initial results towards a proposed approach of building an ontology capable of (i) discriminating between sensitive and not sensitive information, (ii) disclosing as minimal information as possible and equally important (iii) serving necessary and sufficient data to help the emergency.

INTRODUCTION

Organizations are facing threats which can cause great damage and jeopardize its viability. Hence, they must be prepared beforehand to respond effectively by elaborating action plans to limit damage propagation. Nevertheless, this emergency response plans are presented in different formats, such as documents or data sheets that show little effectiveness at an emergency situation by making it impossible to respond in an effective manner.

For that reason, they should be prepared to respond to their materialization, stopping further damage through:

- Security plans.
- Self-protection plans.
- Crisis-management plans.
- Site emergency plans.
- Environmental emergency plans.
- Business continuity plans.

Plans are usually displayed in a little functioning format in a real emergency situation, making an effective response more difficult:

- Alert: misinformation on what to communicate, to whom, and how.
- Classification: lack of information on the type of the event, magnitude, and exact position. f
- Activation: difficulty to identify and locate team members of intervention in every step, or to its substitutes.
- Response: difficulty to locate the suitable action sheet in each case for every team.
- Coordination: difficulty to identify the location of each team at any time, and to follow the degree of advancement of actions.

Mission Track is a system aimed at helping operational deployment, monitoring and controlling mission critical systems. Mission Track is a very suitable tool to use it for planning, developing and training Emergency teams.

METHODOLOGY

During the Demo Session we will present several functions of Mission Track, as well complete interactive emergency scenario with different roles (Figure 1):

- The system provides the notification of an incident detected by any observer through an application (app) by reporting the magnitude of the incident, the number of possible victims and its geolocation.
- The coordinator, who receives a notification of the alert in the app, takes the decision to activate

the planned response program based on the information and location of the incident.

- In case of activation, the system sends an alert to all members of the emergency response teams, who must confirm their availability.
- The system sends to each member of the response team the instructions of the planned response program and the location of the incident.
- The system allows the emergency control to monitor the location of the intervention teams' members, as well as tracking the progress of the response.
- The head of the intervention team informs the emergency control of each of the steps completed in the action plan through the app.
- The system automatically records not only the progress time of each intervention status (arrival at the location, start, control and end of the intervention), but also each step of the action plan by facilitating the subsequent evaluation of the emergency.

Figure 1: Mission Track

With this demo we will show how Mission Track:

- Improves the identification and notification of incidents
- Improves training and emergency training
- Improves the deployment and control of response plans and equipment
